PITTSBURGH, PA.
A

DICTIONARY

OF

PRACTICAL MEDICINE:

COMPRISSING

GENERAL PATHOLOGY,

THE NATURE AND TREATMENT OF DISEASES, MORBID STRUCTURES, AND THE DISORDERS ESPECIALLY INCIDENTAL TO CLIMATES, TO THE SEX, AND TO THE DIFFERENT EPOCHS OF LIFE;

WITH

NUMEROUS PRESCRIPTIONS FOR THE MEDICINES RECOMMENDED

A CLASSIFICATION OF DISEASES ACCORDING TO PATHOLOGICAL PRINCIPLES, A COPIOUS BIBLIOGRAPHY, WITH REFERENCES;

AND AN

APPENDIX OF APPROPRIED FORMULAE:

THE WHOLE FORMING A LIBRARY OF PATHOLOGY AND PRACTICAL MEDICINE, AND A DIGEST OF MEDICAL LITERATURE.

BY JAMES COPLAND, M.D.

Consulting Physician to Queen Charlotte's Lying-in Hospital; Senior Physician to the Royal Infirmary for Diseases of Children; Member of the Royal College of Physicians, London; Member of the Medical and Chirurgical Societies of London and Berlin, etc.

EDITED, WITH ADDITIONS,

BY CHARLES A. LEE, M.D.

VOL. V.

NEW-YORK:

HARPER & BROTHERS, PUBLISHERS,

82 CLIFF STREET.

1847.
Entered, according to Act of Congress, in the year 1846, by

HARPER & BROTHERS,

In the Clerk's Office of the Southern District of New York.

APPENDIX OF FORMULAE.

In order to prevent repetitions, and to facilitate references, the following collection of Formulæ is here appended and arranged in alphabetical order, in addition to those which it was necessary to give in the body of the work. The author has not added any of the formulæ prescribed by the three British Colleges of Physicians, as they are already in the hands of every practitioner. The preparation of these, and recipies he has given, both here and at other places, consist of a careful selection of those which are most approved, contained in the Pharmacopoeias of various hospitals and foreign countries, and from the writings of a number of eminent practical physicians, as well as of those which he has been led chiefly to confide in during a practice of upward of twenty years. He has followed the Nomenclature adopted by the London College in the latest edition of their Pharmacopoeia; and to avoid circumlocution, he has retained the short and characteristic names usually employed, although many of them are by no means classical.

Form. 1. ACETUM ANTIHYSTERICUM. (Disp. Fulld.)

Form. 2. ACETUM CAMPHORATUM.

R Camphora Pulver. cum Alcoholis paulliul solve, Æs.; Sacchari Albi, 3ij.; Aceti Vini, 7ij. Solve. (Æs. contamnae, &c. camphor.)

Form. 3. ACETUM CAMPHORÆ ET AMMONIÆ.

Form. 4. ACIDUM NITRO-HYDROCHLORICUM.

Form. 5. ACIDUM NITRO-HYDROCHLORICUM DILUTUM.

R Acidi Nitri, Acidi Hydrochlorici, Acquis Distillatis, Æs., 6i. Mag. (The nitro-hydrochloric acid bath may consist of three ounces of this diluted acid to every gallon of water.)

Form. 6. ETHER PHOSPHORATUS.

Form. 7.

R Phosphori Purî, gr. iij.; æther. Sulphur., Æs.; Olei Vamentæ, 3ij. M. (In doses of 1j. to 3j. drops on sugar.)

Form. 8. AQUA COSMETICA.

Form. 9. AQUA STYTICA.

R Ferrî Sulphate, Alumini Sulphate, Æs., 5ij.; Æs.; Aquæ, 3ij. Solute et cola; dein adde Acidi Sulphureti, 3j.

Form. 10. AQUA STYTICA CUPRI ET ZINCI.

Form. 11. AQUA STYTICA ZINCI.

Form. 12. AQUA TRAUMATICA THEDENII.

R Acidi Acetici, Bucii, Alcoholicis, 8ij.; Acidi Sulphur., 8ij.; Mollii Despantium, 8ij. Maccæ.

Form. 13. AQUA VANILLE.

Form. 14. BALSAMUM IODURETUM. (Lugo).

Form. 15. BALSAMUM SULPHURETUM.

Form. 16. BALSAMUM POTASSII SULPHURETI.

R Potassii Sulphuræ, 5j. ad 5ij.; Aquæ Communis, Æs. ad 5j. Solvæ. (Nearly the same as the sulphurous baths of Barcæ.)

Form. 17. BALSAMUM POTASSII SULPHURETI ET GELATINÆ.

R Potassii Sulphuræ, 5ij. ad 5iv.; Aquæ Communis, Æs. ad 5ij. Solvæ. et ade lecthvoiles, 8ij. ad 8ij., in Aquæ ballonis solutione, 3x. (Düpplæren.)

Form. 18. BALSAMUM ASTRINGENS.

R Olei Terebinthæne part., iij.; ade guttae Acidi Sulphuri, part. iiij.; in viso vino, opæ balneoarenara calcæfacta. Lucto refrigerato, adde graduatam Alcoh., part., viij.; Maccæ per diem septr. (Dosis 33s.-7j. vehiculo quoibus, idoneæ, in Moribus Hernorrhagica.)

Form. 19. BALSAMUM ASTRINGENS.

Form. 20. BALSAMUM SUCINATUM.

R Balsami Coquæ, Terebinthæne Veneti, Olei Sœcinæ, 3ij.; 3ij. Mag. (Dosis max. ter quotidie in quoibus vehiculo idoneæ.)

Form. 21. BALSAMUM SULPHURIS, vel OLEUM SUL-

R Florum Sulphuræ, partem j.; Olei Amygdali, Dolæ., part. 1ij.; Olei Amni, part. ij.; Maccæ per diem sept. in balneo arenaro.

Form. 22. BALSAMUM SULPHURIS TEREBINHTHATIM.

(R. Balsamum Vite Raudici.)

R Florum Sulphuræ, part. ij.; Olei Lini, 8ij.; Olei Amni, part. v.; Solute in balneo arenaro, et ade Olei Terebinthi, part. 5j. Maccæ (Excatum, duareticæ, expectorant, &c.)

Form. 23. BALSAMUM TEREBINHTHATIM.

(R. Balsamum Vite Raudici.)

R Olei Lini, 3j.; Terebinthi, 5ij.; Ceræ Flave, 3j.; Bals. Peruvian, 3ij.; Camphoræ tarm., 7ij. Solute Oulem, Terebinth., et Ceram, et ade alle. (Nearly the same as the Balsam of Chiron, a long-celebrated medicin.)
APPENDIX OF FORMULE—BOLUS—Decoctum.

Form. 24. BOLUS ANODYNUS.

Form. 25. BOLUS ANTE SPASMOS.

Form. 26. BOLUS ARNICE.

Form. 27. BOLUS BISMUTII COMPOSITUS.
R Moschi, gr. x.; Bismuthii Tincturatis, gr. iiij.-vij.; Opii Puri, gr. ss.-vij.; Conservae Rosar. q. s., ut fiat Bolus, pro re matutina.

Form. 28. BOLUS CAMBOGIE.

Form. 29. BOLUS CAMPHORE.

Form. 30. BOLUS CATECHEI THEBAICAE.

Form. 31. BOLUS FERRI.

Form. 32. BOLUS GUAICI AMMONIATI.

Form. 33. BOLUS GUAICI COMPOSITUS.

Form. 34. BOLUS KINO THEBAICUS.

Form. 35. BOLUS MOSCHI COMPOSITUS.

Form. 36. BOLUS NITRO-CAMPHORATUS CUM OPIO.
R Camphora rasa, gr. iij.-vij.; Potassae Nitrit. gr. x.-xx.; Opii Puri, gr. ss.-vij.; Conservae Rosar. q. s., ut fiat Bolus, horâ sumendus.

Form. 37. BOLUS RHEI COMPOSITUS.

Form. 38. BOLUS SEDATIVUS.
R Acidis Benzoei, 2jij.-ss.; Conservae Rosar. et Sirupi, q. s., ut fiat Bolus, pro re matutina.

Form. 29. BOLUS SUDOREM CIENS.

Form. 40. BOLUS VETERANAE CUM FERRO.

Form. 41. CATAPLASMA IODURETUM.

Form. 42. CATAPLASMA SINAPEEOS FORTIUS.
R Pulv. Sinapess, 8ss.; Pulv. Capaciti Aurii, Pulv. Zin-
APPENDIX OF FORMULÆ—Decoctum Eucalyptium.

Form. 89. Eucharistia Deorsum.

Form. 90. Eucharistia Ferrugineum.

Form. 91. Eucharistia Ferrugineum Hoffmanni.

Form. 92. Eucharistia Ferrugineum Thullerii.

Form. 93. Eucharistia Ferri Ammonio-Chloridi Compositum.

Form. 94. Eucharistia Ferri Potassio-Tartratis.

Form. 95. Eucharistia Nitrif Camphoratum.

Form. 96. Eucharistia Purgans.

Form. 97. Eucharistia Scillle Compositum.

Form. 98. Eucharistia Senne Compositum.

Form. 99. Eucharistia Terebinthinum.

Form. 100. Eucharistia Terebinthinumat.

Form. 101. Eucharistia Valerianae Compositum.

Form. 102. Eucharistia Vernoformum.

APPENDIX OF FORMULÆ.—Emulsion—Extr讯tum.

Form. 121. EMULSIO AMYGDALO-CAMPHORATA.
R Amygdal. Dulc, decorat. 5 ss.; Amygdal. Amar. Nat., 13 ss.; Acidi Hydrocyanici, mixt.; Spiritus Camphorae, 8 ss.; Decocti Opii, mill. 5 ss.; Spiritus Camphorae, 6 ss.; Misc. pro Emuls. 122. EMULSIO ANTISTARRHALIS.
R Sem. Phelland. Aquat. coa, 5 ss.; Gum. Acaciae, 5 ss.; Aq. Ferv. 5 ss.; M. Gum. Acaciae, 5 ss.; Aq. Ferv. 5 ss.; Misc. pro Emuls. 123. EMULSIO CAMPHORATA.

Form. 124. EMULSIO CAMPHORATA ANODYNS.

Form. 125. EMULSIO NITRO-CAMPHORATA.
R Camphor Subactae, Potassee Nitratis, m., 2 ss.; Polv. Gum. Acaciae, 2 ss.; Infusi Pectoralia vel Aq. Fluor. Auranti, 3 ss.; Sirupi Altheae, 3 ss. M.

Form. 126. EMULSIO PRO TUSI.
R Olei Amygdal. Dulc., 2 ss.; Vetillum Ovi unius; Aq. Fluor. Auranti, 3 ss.; Misc. pro Emuls. 127. EMULSIO SEDATIVA.

Form. 128. EMULSIO PRO TUSI.
R Olei Amygdal. Dulc., 10 ss.; Vetillum Ovi unius; Aq. Fluor. Auranti, 3 ss.; Misc. pro Emuls. 129. EMULSIO TINCTORIA.

Form. 130. EMULSIA ACIS ET ASAFETIDAE COMPITE.
R Extr. Alces, 8 ss.; Asafetidae, 5 ss.; Camphorae rasae, gr. xj.; Oliei Olearum, 2 ss.; Decoci Avene, 3 ss. Misc. (In Fluitant Colic, Aescaridic, &c.)

Form. 131. EMULSIA ANTHYSTERICUM.

Form. 132. EMULSIA ANTYSPASMODICUM. (1.)
R Tinct. Opii, 3 ss.; Infusi Valeri, 3 ss.; Mucilag. Acaciae, 4 m.

Form. 133. EMULSIA ANTYSPASMODICUM. (2.)

Form. 134. EMULSIA ASAFETIDEA, VEL ETIQUITUM.
R Asafetidae Gummi Resinae, 5 ss.; Decoci Malve Compotes, 5 ss.; Spiritus Ammoniaco Compotes, 3 ss.; Tinctura Opii, 3 ss. Misc. pro Emuls.

Form. 135. EMULSIA ASAFETIDEA ET TEREBINTHINE.
R Asafetidae, 3 ss—j.; Camphorae rasae, gr. xj.; tere cum Decocito Altheo, 2 ss.; dein adde Oliei Terebenthinis, 3 ss. ad 5 ss. Misc. et 4 das Enema.

Form. 136. EMULSIA ASAFETIDEA ET TEREBINTHINE.
R Asafetidae, 2 ss—j.; Camphorae rasae, gr. x.; Decoci Avenae, 3 ss. Misc. pro Emuls. Interum adde Oliei Terebenthinis, 2 ss—j.; Misc. pro Emuls. (In Fluitant Colic, Wurmic, &c.)

Form. 137. EMULSIA BELLADONNE.
R Fol. Belladonnae exists, gr. xj.; vel Extr. Belladonnae, gr. 2 ss. ad gr. j.; Aq. Fervidi, 3 ss. (For Retention of the Urine from the Spasm of the Spinal Vertebrae, or Spasm of the Rectum.)

Form. 138. EMULSIO CAMPHORAE COMP.

Form. 139. EMULSIO CAMPHORATE.
R Acidi (compositi Camphorae, (F. 2), 3 ss.—j.; Infusi Valerianae, 3 xj. M. (Augustin.)

Form. 140. EMULSIO CATHARTICUM.
R Decoci Malve Compotes, 3 xj.; M. Saccharis Sulphatis, 3 ss.; Oliei Olearum, 5 ss. Misc. pro Emuls.

Form. 141. EMULSIO COLOHYDROSCYSIS.

Form. 142. EMULSIO CONTRA SPASMOS.
R Camphorae rasae, gr. x—x.; Potassee Nitratis, 3 ss.; Oliei Olearum, 3 ss.; tere simul, et adde Infusi Valerianae, Decoci Malve Compotes, 6 ss. 3 xj. M.

Form. 143. EMULSIO CROMENSIS.

Form. 144. EMULSIO CROMENSIS.
R Semini Lini contus., 3 ss.; Aq. Fervidi, 3 xj.; M. erra et cola; dein adde Opii, gr. j—q.—xj. Misc. pro Emuls.

Form. 145. EMULSIO OPHTALMICA.
R Tincturae Opii, 2 ss.; Mucilag. Amyli, 3 ss.; Decoci Herbae, 2 ss. Misc. pro Emuls. Tepidum injunctum.

Form. 146. EMULSIO SOAPIS.
R Saponis Nollis, 3 ss.; Aq. Ferventissim., 3 ss. Solve, et tepidum exhita.

Form. 147. EMULSIO SEDATIVUM.
R Semini Lini contus., 3 ss.; Aq. Ferventissim., 3 ss.; M. erra et cola; dein adde Opii, gr. j—q.—xj. Misc. pro Emuls.

Form. 148. EMULSIO SEDATIVUM.
R Infusi Lini Comp., 3 xj.; Tincture Opii, 3 ss.; Bi-boratis Sodi, 3 ss.; Camphorae rasae, gr. x. M. Fiat Enema, his terve in die injunctum.

Form. 149. EMULSIO TEREBINTHINATE.
R Camphorae rasae, 3 ss.; Oliei Terebenthinis, 3 ss—j.; Oliei Olearum, 3 ss.; Misc. pro Emuls.

Form. 150. EMULSIO TEREBINTHINE.
R Terebinthini Vulgaris, 3 ss. (vel Oliei Terebenthinis, 3 ss. ad 5 ss.); Oliei unius Vitellum. Tere simul, et gradum adde Decoci Avenae tepali, 3 ss. Injuctor pro Enemate semel in die, pro re nata. (When it is requisite to evacuate the lower bowels, Ol. Riciuni, 3 ss., will be found a useful addition.)

Form. 151. EMULSIO TEREBINTHINO-CAMPHORATE.
R Oliei Terebenthinis, 3 ss.; Oliei Olearum, 3 ss.; Camphorae rasae, gr. x.; Decoci Avenae, 3 ss. Fiat Enema.

Form. 152. EMULSIO THERAECAUM.
R Opii Puri, gr. j—q.—xj.; Mucilag. Acaciae, 2 ss.; Lactis Tepactae, 3 ss. Misc. pro Emuls.

Form. 153. EMULSIO VERMIFUGUM.

Form. 154. EXTRACTUM ALOES ALKALINUM COMP.
R Aloeis Scirpticis Extr. contrati, 3 ss.; Zingiberis Radices cosc., 3 ss.; Myrrhae Pulvis, Coqu. Stigmatum, 5 ss., 3 ss.; Potassii Chloridi, vel Sodi Carbonatus, 5 ss. et M. erra per trudam leni cum calore, dein cola. Liquorem dextatcam consumere, domo idoneam habeat crassitudinem. (Dose gr. x. ad x.)

Form. 155. EXTRACTUM DULCAREM.
R Stipit. Dulcarem, part. j.; Aq. Bullient, part. vij. (Sp статьum dulce ac dulce) et adde Lactamor longo, et adsan et macere in the water for twelve hours; boil for a quarter of an hour; and express the fluid. Afterward boil the residue with four parts of water, and finally
express. Mix the two liquors, and evaporate with a gentle heat to a proper consistence.)

Form. 156. **Extrac tum Hellebori Nigri Backeri.**

R. Radix Hellebori Nit. exsic. 6ij.; Potassa Carbon., fss.; Alcohol. (22. præpar.), ½ij. (Hacker directs the above to be digested in a sand-bath for twelve hours, shaking it frequently, and afterward to be expressed and strained. Eight pounds of white wine are to be poured upon the residue, and digested with it for twenty-four hours in a sand-bath, and afterward to be expressed and strained. After a few hours both these tinctures are to be mixed together, and evaporated with a gentle heat to the consistence of an extract. This is the best preparation of Helleborum. Dose from 3. to 10 gramine.)

**Form. 157. Fomentum Camphoratum.**

Form. 158. **Gargarisma Acidii Hydrochlorici.**

Form. 159. **Gargarisma Acidii Hydrochlorici Compositum.**

Form. 160. **Gargarisma Antiseppticum.**

Form. 161. **Gargarisma Astringens.**

Form. 162. **Gargarisma Astringens Zobelli.**

Form. 163. **Boratosis Soda.**

Form. 164. **Gargarisma Tinctura Threni.**

Form. 165. **Gargarisma Comune.**

Form. 166. **Gargarisma Potasse Nitritae. I.**

Form. 167. **Gargarisma Potasse Nitritae. II.**

Form. 168. **Gargarisma Comp.**

**Form. 169. Guatte Acetatis Morphi.**

**Form. 170. Guttur Antimonii.**

**Form. 171. Guttur Anthriscis.**

**Form. 172. Guttur contra Spasmos.**

**Form. 173. Guttur contra Spasmos. (Stoll).**

**Form. 174. Guttur Nervine.**

**Form. 175. Acidi Nitrii Et Opil.**

**Form. 176. Acidi Nitrii Et Opil.**

**Form. 177. Haustus Acidii Nitrii Et Opil.**

**Form. 178. Haustus Acidii Nitrii Et Opil.**

**Form. 179. Haustus Acidii Nitrii Et Opil.**

**Form. 180. Haustus Anodynus.**

**Form. 181. Haustus contra Emesis.**

**Form. 182. Haustus anti-emetici.**

**Form. 183. Haustus Aperien.**

**Form. 184. Haustus Aperien ex Jalapa et Aloe.**

**Form. 185. Haustus Aperien ex Scammony.**

**Form. 186. Haustus Aperien ex Scammony.**

**Form. 187. Haustus Calamine et Ferro.**

**Form. 188. Haustus Colchici.**

**Form. 189. Haustus Colchici.**
Form. 189. Haustus cum Colchico.

Form. 204. Haustus cum Iodini.

Form. 205. Haustus Laxans.

Form. 206. Haustus cum Plumbi Acetate.

Max. Fiat Haustus, quarti vel sexitas horarum succedas.

Form. 207. Haustus Quinæ et Zinci.

Form. 208. Haustus Sedativus.

Form. 210. Haustus contra Sphæmos. (1.)

Form. 211. Haustus contra Sphæmos. (2.)

Form. 212. Haustus contra Sphæmos cum Puliæ Compos.

Form. 213. Haustus Stimulantis.

Form. 214. Haustus Stomachicus.

Form. 216. Haustus Teredinithinis Apertus.

Form. 217. Haustus cum Uva Ursi.

Form. 218. Infusum Aurantium.

R. Summi. Absinthii Artem, 3ij.; Cortici Auranti, 3ij.;
Appendix of formulæ.—Infusum—Injectio.
APPENDIX OF FORMULAE.—INJECTO.—LINIMENTUM.

Form. 275. In ejcto Boracica.

Form. 276. In ejcto Zinci Acetatis Composita.
R. Zinci Sulphatis, Plumbi Acet., 4a., 3ss.; Camphora, 3ss.; Opis, 3ij. Solve in Aq. Bulbis, 0ij.; collo, et fiat injecto, ter quaterque in die monda; phiaia agitata.

Form. 277. Iodum Hydragry.
Internally, in doses of from one grain to three, and externally in ointments.—(Vide Unguent, Iod. Hyd.) For the pretty clear account of the preparations and uses of iodine, consult Dr. O'Shaughnessy's translation of Lugol on Scurfula.

Form. 278. Iodum Plumbi.
Internally, in doses of from half a grain to five grains; and externally.—(Vide Ung. Iod. Plumb.)

Form. 279. Juleps Sedatives.

Form. 280. Linctus Acidii Hydrargyri.

Form. 281. Linctus Boracicis.
R. Cetacei, 3ij.; Pulv. Tragacanthi Comp., 3ij.; Sirupi Toluini, 3xv.; Bi-boratis Solis, 3ss.; Extrait. Rose, 5xv.; Sirupi Altheae, 3xv.; Fiat Linctus, de qua lambat paiuum supe. (Sure Throat, Equinácia, &c.)

Form. 282. Linctus Camphoracei.
R. Camphora, jij.; Pulv. Gum. Arceae, 3; Sirupi Altheae, 3xv. M. Sirupi Sinece. (Niemans.)

Form. 283. Linctus Chloroverti Calcis.
R. Chloróreti Calcis, gr. xij.; solve in Aq. Destill., 5ij.; et addie Melis, 5ss. M. Caput infus Cochracea mmoomnum ramalde. (In Softening of the Digestive Mucous Surface.)

Form. 284. Linctus Demulcens. (1.)

Form. 285. Linctus Demulcens. (2.)
R. Cetacei, 3ij.; Pulv. Tragacanthi Comp., 3ss.; Sirupi Papaveris et Sirupi Toluini, 3xv.; 3ss.; Potassae Nitratis, 3ss.; Sirupi Rham., 3ij.; Sirupi Sique, 5xv., ut fiat Linctus, de qua lambat paiuum pro re neato.

Form. 286. Linctus Demulcens et Aperiens.

APPENDIX OF FORMULE.—POTUS—PULVIS.

Form. 590. Potus Diureticus. (1.)

Form. 591. Potus Diureticus. (2.)

Form. 592. Potus Ferruginosus. (1.)

R Potassæ Nitratis, 3 j.; Seri Lactis, Oij.; Sacchi Luminos, 5 j.; Sumat pro Pot. ordinariæ.

Form. 593. Potus Ferruginosus. (Stoll.) (2.)

Form. 594. Potus Amino-Sulphatis CUM ZINCO.

XXV

Pulvis
Olei
Pulv.
Nitratis
Hydrarg.

Form. 657. PULVIS DIURETICUS. (1.)

Form. 658. PULVIS DIURETICUS. (2.)

Form. 659. PULVIS ECCOYCIOTICUS.

Form. 660. PULVIS EUPHORICUS. (1.)

Form. 661. PULVIS EUPHORICUS. (2.)

Form. 662. PULVIS EXCITANS.

Form. 663. PULVIS INFANTILIS.

Form. 664. PULVIS IPECACUANHE CUM CALOMELANE.

Form. 665. PULVIS JALAPICA COMPOSITUS.
R Jalapa Radices Pulveris, 3j.; Potassse Bitartaris, 3j.; Capiat Baearum Pulv. 3j.; Omina, securum terræ, pro dose, &c.; 3j. &c.; ad 3j. &c.; manco.

Form. 666. PULVIS JALAPICA ET CALOMELANGS.

Form. 667. PULVIS KERMIS MINERALIS.
( Hydro-Subsolidum of Antimony. Bruzelsis.)
R Acque Pluvial., part. 280.; Carbon. Soda, part. 128.; Sesquiospuidullum Antimonii pulver., part. 6. Dissolve the Soda in the water while boiling; and hold the Sulphuret in the solution for half an hour, stirring it frequently. Filter the boiling liquor in a vessel containing warm water which had been previously boiled. De- caust the water after it is cooled. Wash the precipitate which is formed, et first with cold water, afterward with warm water, until it passes off quite inspissated. Lastly, press it, and dry it in the shade.8 (Stimulans, Emeticus, Diaphoretic, Alleviator, Bocchic, Expectorant.)

Form. 668. PULVIS KERMIS MINERALIS ET CAMPHOR.
R Kermis Mineral., gr. x.; Camph., subact. in Pulv. gr. xii.; Potassium Nit., gr. vi.-xj. M.

Form. 669. PULVIS KERMIS MINERALIS CAMPHORATUS.

Form. 670. PULVIS LESTIVUS HYPOCHONDRIACUS. (Klein.)

Form. 671. PULVIS LIESTERICUS.

Form. 672. PULVIS NITRO-VITAESE IPECACUANHE, etc.
R Ipecac. Radices conu., 3j.; &c.; Oleum Crudeli comitati, gr. xlv.; Potassse Nitratus, 3xj., et gr. xv. Tere manco, et fuit Pulvis. (A Bure in of this powder contains one grain and a half of opium, two grains of sectional, and sixteen grains and a half of nitrates of potassa.)

Form. 673. PULVIS PENGANS.

Form. 674. PULVIS RUPHERSIS. (1.)

Form. 675. PULVIS RUPHERSIS. (2.)
R Potassse Bitartarizatus pulverizatus usius duas; Nitratus drachmata tres. Masse et divide in partes xii. aequales.

Form. 676. PULVIS RESOLUTIONS, etc. DEOBSTREUS.

Form. 677. PULVIS RHEI COMPOSITUS.

Form. 678. PULVIS RHEI ET MAGNESIA.

Form. 679. PULVIS RHEI ET SULPH. POTASS.

Form. 680. PULVIS SCAMMONIE CUM CALOMEL.

Form. 681. PULVIS SCAMMONIE CUM CALOMEL. (2.)

Form. 682. PULVIS SCAMMONIE ET JALAPE.

Form. 683. PULVIS SEDETIVUS.

Form. 684. PULVIS SEENEL ET CAMPHOR.

Form. 685. PULVIS SODA COMPOSITUS.

Form. 686. PULVIS SODA COMPOSITUS.

Form. 687. PULVIS SPESIFICUS STOMACHICUS. (Po- terii.)
R Freri Sequentes, Assimoni Crudii, &c.; partes aequales vel unus; Potassse Nitr., part. vi.; Decina seu defa- gra, et lavo.

---

8 I have given the directions for this preparation, and a few others, as Vigilios, to prevent any mistake occurring in the use of them.

Form. 669. Sapo Terebinthinae. R Potassae Hydratis, ½j.; Liquefac lento igne, et adfive Olei Terebinthinae, ½j. Miscæ bene donec reflexerit. (Used both externally and internally.)

Form. 670. Sapo Terebinthinata. R Saponis Castell., ½j.; Olei Terebinth., 3j.; adde Solutione Potassae Carbon., ½j.; Camph. eg. der. 3j.; Miscæ bene. (Used both externally and internally.)

Form. 671. Solutio Iodini. (Lugol). No. 1. No. 2. No. 3.

R Iodini . . . . . . . . gr. ij.; gr. ij.; gr. ij.;
Potassi iodidi . . . . . . . . gr. iv.; gr. iv.; gr. iv.;
Aquæ Destillatæ, 10 j.; 10 j.; 10 j.;
Solve. (Chiefly for external use; for injections in Scrofulous Fistule, &c.)

Form. 674. Solutio Morphiæ Hydrochlorat. R Morphæ Hydrochlorat., gr. x.; Aquæ Destillatæ, Calid., ⅓j.; 1000. Solve. (Done twenty-five minims—equal to 4 gr. of the Hydrochlorate.)

Form. 675. Solutio Morphiæ Sulphatis. R Sulphatis Morphiæ Ver., gr. iv.; Aquæ Destillatæ, ½j.; Solve. (Of the same strength as Laudanum.)

Form. 676. Solutio Aetherei Hydrochlorici. (Olum. Spiritus Ferri Flavidi Oletae.) R Acidum Sulphuret. ij.; ½j. (per pond.); Acidi Hydrochlorici, ½j. (per pond.); Spiritus Rectificati cong., Distillat locuplet, secundum artem.

Form. 679. Solutio Castrii Composita. R Castorei contr., ½j.; Croci Stigm. ij.; Herba Artemisia, ½j.; Spiritum Teuariou, ½j.; Mercurii per dies xj, et colia. (Externally as a Liniment; and internally in Colics and Nephritic Complaints, in doses of from 10 to 20 drops, and in Dropso.)

Form. 685. Sirupus Morphiæ Acetatis. R Morphiæ Acetatis, gr. iv.; Sirupii Clarificati, 3j.; Misce ut fiat Sirupus. (In doses of from two to four spoonsfuls to a tablespoonful every three hours, or only at bedtime.)

Form. 686. Sirupus Morphiæ Sulphatis. R Morphiæ Sulphatis, gr. iv.; Sirupii Clarificati, ½j.; Miscæ. (In the same doses as the Acetate. May be given alternately with the Acetate.)

Form. 689. Sirupus Quinque. R Sirupi Simplicis, ½j.; Quinque Sulphatis, gr. xxxiij.; Carthami, ½j.; aquæ destillate, ½j.

Form. 692. Sirupus Sulphureti Solidi. R Sode Pure (cum Alboh prep.), ½j.; Aquæ Destillatae, ½j.;
Liquet. leni igne, et ade Sulphuris Puri quantum solvi polet.

R Liquor, 3 j.; Sirupi Comunis, 5 j.; Mace bené in vasa incensuri. (Doses of 25–35 j. for infants, 5–35 j. for adults.)

Form. 693. TINCTURA ACETATI FERRI COMP.

Form. 694. TINCTURA MORPHIACEI COMPOSITA.

R Morphacei, gr. xvi.; solvi. in Aqu. destillat. 3 gi.; Aceti Aether. 1 ml.; Tinct. Lavandula, Co. 5 gi.; Spiriti. Myrrhae, vel Tinct. Canthar. comp. 3 gi. M. Dosis, 5 ml. xvi.

Form. 695. TINCTURA ETHEREA VALERIÆ.

R Radix Valerian, pulv., 5 j.; Aetheris Sulphuresi aereetriculis, 5 j.; Alcoholi. Recti, 5 j.; Macea per duas et cola.

Form. 696. TINCT. ALGERICA ALKALINA. (Saxon Ph.)

Form. 697. TINCTURA ALKALINA POTASSICÆ.

R Pastas Hydratis, 8 ss.; Alcoholis Conveat, 5 j.; Macea per dies septem in balneo urearno.

Form. 698. TINCTURA ALKALINA STIPITATA.

R Antimonii Crudis, 5 gi.; Pastulis Carbon., 2 gi.; Melt in a crucible, and reduce them to yellowish scoria; then powder them immediately in a hot iron mortar, and pour upon them rectified Alcohol, 5 j.; Mace rate for three days, and filter.

Form. 699. TINCTURA AMARA.

Form. 700. TINCTURA AMMONICI ALKALINA.

Form. 701. TINCTURA BALSAMICA. (1.)

R Olei Trecenth, 5 gi.; Tinct. Myrrhae, 3 gi.; Tinct. Benzoini, 5 gi.; Compota. in loco calidum. (Internally, and to Indolent Sores, &c.)

Form. 702. TINCTURA BALSAMICA. (2.)

R Balsami Tolutiani, 8 ss.; Balsmi Peruvianii, Styraici Balsami, Aceti Benzoe, Myrrhae, 3 gi.; Croci Stigmatis, 5 j.; Spirit. Vini Recti, 5 j.; Macea per dies tres et cola. (Wurtzburg Ph. nearly.)

Form. 703. TINCTURA BALSAMI TOLLATANI.

Form. 704. TINCTURA BELLADONNE.

Form. 705. TINCTURA BENOZIAE ANODYNA.

Form. 706. TINCTURA BRÜCHE.

R Brucie Porz., gra. xvi.; Alcoholis (s. g. 857), 5 j.; Solvi. (S) contag. gr. j. of Brucie. Dose 5–8 j.

Form. 707. TINCTURA CALAMI.

Form. 708. TINCTURA CAMELLOPHAREAE.

Form. 709. TINCTURA CARYOPHYLLIUM.

Form. 710. TINCTURA CASGARILIAE ALKALINA.

Form. 711. TINCTURA CASTOREI ALKALINA.

Form. 712. TINCTURA CENTAURI CAECIUM.

Form. 713. TINCTURA CINCHONIAE SULFATIS.

R Cinchonii Sulphatis, gr. xxvi.; Alcoholis Recti, 5 j.; Solve. (Dose 3–5 j.)

Form. 714. TINCTURA CONI.

Form. 715. TINCTURA DIGITALIS ETHEREA.

R Fol. Digitalis excus. et pulv., 1 j.; O. Ethe., Sulphur., part. iv.; Macea per tria duodecim, et cola. (Dossis, max. 10 j., ter dio. Several Continental Pharmacopoeias.)

Form. 716. TINCTURA DIGSME CRENATE.

Form. 717. TINCTURA DIVERGETICA.

Form. 718. TINCTURA FERRI ETHEREA.

R Acidi Hydrochlorici, 5 gi.; Acidi Nitrii Diuti, 5 j.; Ferri Luminæ, q. s. Dissolve the iron in the acids; evaporate to dryness; afterward dissolve the residue by exposure to the air, and mix the desiccated liquor with double its weight of Sulphuret. Ether, agitating the mixture frequently until it assumes a golden yellow color; decant, and add double the quantity of rectified Alcohol. This Tincture may be used previously to the addition of the Alcohol, or subsequently. In the state of Ether the dose is from 15 to 20 drops; in that of Ethereal Tincture, from 20 to 30 drops. It is useful in Diseases of Debility, and in Spasmodic Affections.

Form. 719. TINCTURA FRUCTUS VANILLIE.

R Fructus Vanilloe concis. et contus. part. j.; Alcoholi., part. vj.; Macea leni cum calore per dies octo, et cola. (Nervine, Amaleptice, Excentum, &c.)

Form. 720. TINCTURA GALBANI COMPOSITA.

Form. 721. TINCTURA GALLAE.

Form. 722. TINCTURA IDEONI FERTIOR.

Form. 723. TINCTURA IDEONII MITIOR.

Form. 724. TINCTURA LABELLE INFLATAS.

Balsamum-Bolus.

recovery of the patients. It is difficult, and even not very requisite, were it easy, to state the classifications and arrangements which may be adopted in various circumstances. In these matters, as well as in the organization and management of these institutions, medical knowledge, and an acquaintance with mental disorders, under the guidance of common sense, will generally enable the physician to arrive at judicious conclusions. But in all arrangements and modes of organization, a due separation of the different classes of cases, and of convalescents, who are otherwise public or private, should be allowed or licensed that is not placed under the constant superintendence of a regularly educated and qualified medical practitioner, who should reside in it, and be in constant communication with its inmates. On this particular topic, much information will be obtained in many of the recent publications referred to in the Bibliography attached to this article. I can furnish only a brief abstract of what has been stated regarding it by Pinel, Esquirol, and Georgean.

519. a. The classification of lunatics is requisite, not merely for the purpose of separating such as are liable to injure themselves or others, but also with the view of permitting those to associate together who may contribute to each other's cure. A lunatic asylum should be composed of several parts, more or less insulated. There ought to be a quarter for each sex; a division for the violent; a special ward for those who are in the prime of life. It is absolutely requisite to have the management of the patients. It is absolutely requisite that a judicious arrangement of authority and subordination be established in all asylums, and that the power of the physician should be superior to all, in respect of everything that concerns the patients.

IX. Insanity, Connect; and Puerile Imbecility.—Syn. Idioty, Natural Idiotism, Congenital Premonition of Intellect, Puerile Imbecility, Weakness of Mind, Stupidity, Stupidity, Connect Fatuity, Primary Fatuity, Idiotism, Mental Deficiency, Original Deficiency of Understanding: Stupolitas, Vecordia, Amentia, Imbecillitas Ingenii; Fatuitas; Amentia Congenita, Sauvages, Sagar, Vogel; Demence Vance, Fodere; Idiotisme, Pinel; Die Sprachgelenheit, Blindheit, Germ.; Idiotismo, ital.

522. Defic.—Deficiency or entire premonition of intellect, appearing during infancy and childhood, depending either upon an original defect, or upon an arrest of the development of the mental faculties.

523. Puerile imbecility and idiocy may be considered as representing two grades of primary mental deficiency. The former is that state or degree in which there is an original impairment, but not an entire want of intellect. The latter is a more complete grade of deficiency, sometimes amounting to an absence not only of the moral and intellectual manifestations, but also of the instincts necessary to self-preservation. Between these, however, this is the highest degree of idiocy, and the slightest state of intellectual deficiency, there is every intermediate grade. Original defect of intellect should not be confounded with the imbecility, or incoherency, or fatuity consequent upon other forms of insanity, or upon cerebral diseases—the Amentia acquista of authors; nor with senile fatuity, im-
becility, or dotage—the Amentia senilis. The distinction has been very properly made by Erique and Richard; and most succinctly and correctly stated by Dr. Klein Grant, in his edition of Hooper's Medical Dictionary. Original deficiency and entire want of intellect may appear unconnected with any bodily disease; may be simple and uncomplicated, or they may be associated with other maladies, or complicated. Complete idiocy, especially, may be farther associated with congenital deficiency of some organ or part, or connected with malformation, or arrest of development of some portion of the brain, or organ of sense.

524. i. Deficiency of intellect appears in every grade and form until it amounts to complete idiocy. The slighter degrees of deficiency are manifested chiefly by weakness of character and capacity, or by stupidity or deficiency of the powers of perception, or of the understanding. These grades of defect are generally not sufficient to render an individual incompetent to the management of his affairs, or to conduct himself with propriety, and are hence not considered sufficient to constitute unsoundness of mind, in its legal acceptation. But as the original defect may present every grade, from the slightest of those just mentioned to complete idiotic apathy, the drawing of a line of demarcation between what may be considered soundness or unsoundness of mind. This line must still remain unfixed, or at best be only conventional, for no standard or criterion can possibly be established. As in consecutive impairment or disorder of mind, so in original deficiency of intellect, there are every shade and degree of mental manifestation, descending from the highest state of perfection of the human understanding down to the lowest state of privation of intellect and of instinct; there being no break in the scale, or in the continuity of declension.

525. Deficiency of intellect begins to appear from the first to the eighth or ninth year of age. When it is congenital, it may manifest itself even somewhat earlier than the former period. When it arises from an arrest of the development of the mental faculties, owing to injury or physical disease, it may not be evinced until a later period than that assigned. In this latter case, the deficiency is seldom so great as when it occurs at earlier stages, or depends upon changes that have taken place in the encephalon either previous to or soon after birth.

526. From what has been already stated, it is obvious that all the grades and forms of original imbecility cannot be described within moderate limits. Nor is minute description at all requisite: the works of George and Esquiror will furnish it, and numerous illustrations of it. I may, however, briefly observe, that imbecile persons have a great deal of inconstancy of character or situations or employments, and acquire but some degree of facility in performing these. They generally execute in a tolerable manner, while they are quite incapable of any other modes of exertion or occupation. Habits have a great influence on all their proceedings, and gives to many of them an appearance of regularity which may be mistaken for the result of steadiness and of higher powers. All are, however, deficient in the powers of attention and thought. They are generally timidious, often decile, weak and inconstant in purpose, and frequently irascible. The senses of some give rise to feeble and dull impressions; of others, to more lively perceptions. Memory is strong in some; while in others it is weak, confined in its range to the most ordinary objects and frequently repeated ideas, or it hardly exists. They display some indications of mind, of intellectual faculties and of feeling and affections; and they have the use of speech and of language generally in a degree proportionate to the grade of perfection of their several senses and mental powers. They show the same varieties of character, inclination, and moral propensity, as persons of stronger understanding. Left to themselves, they are careless, lazy, and filthy. At the age of puberty, they evince the animal instincts by the most offensive gestures, habits, and solitary vices. Some become subject to paroxysms of capricious violence, to hysteria, to nymphomania, or satyrism. Many are prone to lying, pilfering, and stealing. Several lapse into melancholia, or sink in a gradual decay of physical health—frequently owing to an uncontrollable addiction to intemperance. In other circumstances, they eat and digest well, and females have the catamenia regularly. Some imbecile persons evince signs of talent in particular pursuits, particularly in music and the arts. Some have retentive memories, learn languages, and are capable of other acquisitions, while, in all other respects, they are deficient in any talent, and generally in mental power. They commonly present much of the character, in manner and in the development of mind, of infants or children. They are deficient in affection, in application to any pursuit, in the powers of comprehension, of pursuing a train of ideas, and of entering into a rational or sustained conversation. They are without energy, to hystera, to nymphomania, or satyrism. The are incapable of reflecting, of contriving anything, or of accomplishing anything.

527. ii. Idiocy,—More or less complete privation of the mental faculties.—This is the highest grade of original deficiency of intellect. In this state, the moral, the reflecting, and the intellectual manifestations are altogether wanting; and sometimes the instinctive emotions of mind are altogether or totally undeveloped. Indeed, the different states of idiocy depend chiefly upon the extent of deficiency of this class of the mental powers. Those instinctive feelings and desires which are the most generally bestowed on the animal creation, and which especially subserve the preservation of the individual and of the species (see Classification, in note to § 66), are chiefly present—frequently in an inordinate degree—and are deficient only in the most extreme cases. Infants that become imbecile, have the development of the perfect features, take the breast with difficulty, are long before their eyes follow the light, and often squint. They are puny, lean, of bad complexion, have a feeble physical development and vital endowment, are incapable of instruction, cannot learn to walk until they are six or eight years of age, or sometimes till they attain the age of puberty. They articulate imperfectly, or learn but a few words, or are altogether incapable of articulate sounds, although they may possess the sense of hearing. When the
head is very small or very large, or flattened in any direction, or much deformed, death generally takes place early—generally long before puberty, or at any age between this epoch and the first months of existence.

528. Idiots, both children and adults, present not only these deformities, but all those described in the article Cretinism. Their features are irregular and repulsive; their eyes are blink- ing, and deeply set; their lips are large, thick, flaccid, and relaxed; their mouths are gaping, and admit of a drizzling of the saliva; their organs of sense are imperfect—they see and hear imperfectly, or are entirely deaf and dumb. Their taste and smell are also deficient, and they eat without distinction of food. If speech exist at all, it is extremely limited, and drawing or lisping, and capable of expressing only the most urgent physical wants. Their cheeks are narrow or contracted; their limbs ill-formed; and their gait, as well as all their movements and attempts at muscular exertion, unsteady and awkward. They are sometimes club-footed, and the muscles of the arms or legs contracted. They are commonly rachitic, or scrofulous, often partially or generally para lytic, or subject to epileptic fits. Not only are they without the reflecting and intellectual faculties, but even their sensibility is deficient; and sensation, when excited, is scarcely followed by perception of objects or ideas. They are incapable of directing their attention to anything. Owing to the defective state of their instinctive feelings, they appear far below the brutes in the scale of animal existence; and, as M. Esquirol remarks, are monsters or imbeciles—therefore subjected to a speedy extinction, if the tenderness of parents, or the compassion of others, did not prolong their existence. Yet idiots have the bodily appetites and sexual desires—sometimes in an inordinate degree and repulsive manner. They often exhibit signs of prematurity puerility, and are generally addicted to masturbation. They are often, also, subject to anger and rage. Some display faint glimmerings of intelligence, when their notice is excited by strong impressions on their senses. They then appear to look at certain things with a vague expression of pleasure, or of curiosity; they seem to desire some objects, particularly articles of food; they occasionally indicate, by gestures or cries, objects of desire or aversion, or the pleasure or pain which they feel; they come to know the persons who habitually take care of them; but they are incapable of dressing or undressing themselves, or of the common acts of cleanliness. Others are debased to the lowest state of being—are sometimes even unconscious of their evacuations, and incapable of commanding or restraining them; and enjoy only a vegetative existence, devoid of sensation and sensibility. Idiots of a higher grade of development are capable of moving from place to place; but are, like machines, made to repeat the same movements; they move their arms, as if to facilitate progress; laugh mechanically; utter inarticulate sounds, as if to amuse themselves; occasionally catch a few notes of a simple tune, which they constantly repeat; and become attached to particular places and positions.

529. i. The Complications of imbecility and idiocy are chiefly those already noticed (§ 523, 528), more particularly rickets, scrofula, general or partial palsy, epilepsy, contractions and malformations of the extremities, deficiencies of the organs of sense, gout, and, still more particularly, Cretinism, which, in its fully developed states, is always associated with more or less absolute want of the mental powers. (See art. Cretinism.)

530. iv. The Causes of imbecility and idiocy are of importance, both in a medical and in a social point of view.—A. The remote causes are, 1st. Those which are referable to the parents, and which operate previously to birth; 2dly. Those which are particularly belong to the patient, and which affect him subsequently to birth.—a. The causes which operate previously to birth are, whatever exhausts or debilitates the parents, or renders the reproductive acts imperfect; * as habitual debauchery, solitary vices, and drunkenness; sexual debility, or states approaching to impotency; the insalubrity of certain localities, particularly those observed to produce cretinism (§ 6); the serofulous and ricketsy diathesis; and the advanced age or debility of one or both parents. Esquirol states that idiocy is more common in the cities, especially in mountainous districts—than in towns. He, as well as numerous other writers, insists upon the influence of violent mental emotions, and moral shocks during the early or middle months of utero-gestation. Several modern writers have affected to doubt this cause; and, as they cannot dispute the frequent occurrence of arrest of development of the nervous system, and congenital deficiency of mental manifestations, conformable with what the mothers had been thus affected during the period of their fetal existence, yet consider the phenomena in no way connected, as coincidences merely, and as holding no relation of cause and effect. The vulgar opinion, however, of this matter is nearer the truth; and the evidence of the arrest of development having been produced by the mental, and the consequent physical shock of the mother during gestation, is much more conclusive than most of the evidence usually furnished in physiological and practical researches, or that they are, we are constantly acting in the discharge of our professional duties. It by no means follows that the phenomena which we cannot satisfactorily explain should therefore not exist, or that relations of which we cannot trace the connexion conclusively are on this account altogether wanting. Yet, even here, however difficult may be the explanation, or apparently loose the connexion, both the one and the other may be furnished with some evidence, in the same and this other articles. It is not improbable, even, that the means sometimes used to conceal pregnancy, or to procure abortion, may so affect the development of the fetus as to produce idiocy. The same causes which occasion

* A physician was consulted by a gentleman who was anxious to marry, to secure a fortune in his family, but had been some time deterred by marriage by a consciousness of weakened sexual powers, consequent upon masturbation in early life. As he was young, and his constitution had apparently not suffered seriously, he was advised to marry, under the conviction that a moderate exercise of the sexual functions would assist in restoring their energies. This advice was adopted; but the first child that was born was an idiot. The later children were sound: he had gradually recovered his powers.
congenital and chronic Dropy of the Brain (§ 283, et seq.) will sometimes cause more or less complete deficiency of the mental faculties. Inflammation, or tubercular disease of the brain or of its membranes during fetal existence, will disturb or arrest the subsequent development of these parts, and of their respective manifestations. Injuries of the head of the fetus, sustained during parturition, have also produced this effect.

531. b. The causes which operate after birth are, chiefly, injuries of the head; diseases of the brain—particularly acute and chronic hydrocephalus; inflammations of the brain or of its membranes; convulsions; dentition; exanthematos fever—especially when attended by cerebral affections; tubercular disease, with or without inflammation of the encephalon; remarkable paresis in connexion with a susceptible and irritable state of the constitution; and very early addiction to the vice of masturbation. This last cause is frequently productive of those states of imbecility, or sligher forms of mental deficiency, observed at advanced stages of childhood, or near the approach of puberty. To these causes may be added the use of improper coverings on the heads of infants and children, as ably illustrated by M. Foivre. (Déformations et anomalies de la tête des enfants. Paris, 1841.)

532. B. The pathological causes are chiefly imperfect, deficient, or interrupted development of the encephalon, and affecting it either partially or generally; sometimes associated with changes of the consistence and form of the brain, and not infrequently with some of the usual consequences of old or previous inflammation of the membranes—particularly the arachnoid, and of the cerebral structure. Morgagni and others found the brain harder than natural; in other cases, it was drier, and more friable than usual. Maligne states, that the convolutions of the brain are numerous in proportion to the intelligence, and that in infants they are always few. They are very generally smaller, less prominent, and less numerous in these persons than in others. M. Esquirol has observed the lateral ventricles uniformly very small in idiots. In some, one hemisphere is much less developed than the other; and, occasionally, one lobe is more deficient than the rest. In these cases, one or more limbs have been paralyzed. These deficiencies have been more frequently observed in the anterior than in the other lobes. The cerebral substance is sometimes softened in one part, and hardened in another. For further details, see the articles Brain, Cranium, and Epilepsy. *

*(The phenomena of idiocy, at least, would seem to prove that the mind is not independent of the brain, as maintained above, as a very small brain is invariably a cause of idiocy; and that the cerebral convolution on which we have been manifested vigorously by a very small brain. But idiocy arises not only from deficiency of size, but also from disease of the brain, or injuries, as already stated. Partial idiocy is also not unfrequently met with where an individual manifests one or several powers of the mind with an ordinary degree of energy; but, in a degree of far less extent, of the power of manifesting all the others. Our countryman, Dr. Rush, has particularly called attention to this partial development of certain mental powers in idiots, and the partial possession of the moral faculties, a phenomenon which, it would seem, can scarcely be reconciled with the doctrine of a single organ of mind.)

533. v. The treatment of imbecility and idiocy is rather preventive than curative. Prevention depends entirely upon the avoidance of the remote causes, and upon the employment of those means which tend to strengthen the physical powers of the parents, and of the offspring after birth. That much is owing to the constitutional powers of the parents, is shown by numerous facts, and by the circumstance of several idiots or imbecile persons being often met with in one family. Attention to the general health of the infant, good nursing, daily cold ablutions, frictions of the surface, a dry and temperate atmosphere, frequent changes of air, and due promotion of the several secretions and excretions, are the chief means by which a healthy development of the offspring of debilitated persons can be secured. In every case, a strong, healthy, and young nurse should be procured immediately for the infants of such parents. As dentition and childhood approach and advance, the means and the care advised in the articles Age and Dentition are especially required. The curative means are limited to physical and moral education, which may be of use in the slightest forms of imbecility, but which are of no avail in the more manifest states, and in idiocy.

X. INSANITY, PUERPERAL.—Syn. Insania Puerperalis, Mania Puerperalis; Puerperal Mania.

534. Defin.—Disorder or aberration of mind, of either a partial or general form, occurring in any period of the puerperal states.

535. i. Description.—Puerperal insanity may appear in a slight or partial, or in a severe and general form. It most frequently, however, assumes the form of mania and melancholia. In a few cases it presents a mixed character, or that of melancholia alternating with mania. Insanity may occur, 1st. At any time, during or immediately after parturition, or of pregnancy—Insania gravidarum; 2dly. From parturition to about three weeks or a month subsequently—the insanity of parturition—Insania post partum; 3dly. At any period during lactation, or soon after weaning—the insanity of lactation—Insania lactantium. In the first of these periods, it is usually slight or partial, chiefly affecting either the moral manifestations or the understanding. In the second, it most frequently assumes the form of acute mania, sometimes passing into a chronic state, but rarely assuming the character of dementia or fatuity. In the third, melancholia, slighter forms of mania, and partial insanity are the most common. Any of these states of disorder, occurring in any of the periods now specified, may be simple or complicated, in respect of succession, or co-existence with some other malady, particularly hysterical affections, epilepsy, convulsions, catalepsy and cataleptic ecstacy, uterine hemorrhage, disease of the uterus gravidum.

536. A. Insanity during Pregnancy—Insania Gravidarum.—Pregnancy generally occasions more or less excitement of the nervous and vascular systems; and sometimes gives rise to various morbid impulses or aberrations of mind, especially in females hereditarily predisposed to insanity. The mental disorder may appear immediately upon conception, and disappear on quickening; or it may occur at any period of utero-geutation, continue through, and cease
upon delivery, or it may persist through all the
circumstances consequent upon parturition. In
this latter case, however, it seldom retains the
same form or character, but passes into one
more general or severe; melancholia, or any
other partial disorder, being aggravated into
mania. In some cases, the mental affection
commences as hysteria, or in some one or oth-
er of its numerous states; and in two cases in
which I was consulted, it was preceded by cat-
alepsy and cataleptic ecstasy—affections inti-
ately allied to hysteria.

537. The most frequent states of mental dis-
order observed in this period are melancholia,
and the moral disorders described above (§ 69, et
seq.). The singular feelings and desires, the
whims and caprices frequently attending this
state, cannot be considered as amounting to in-
sanity, inasmuch as they seldom engross the
mind, and withdraw it from all other thoughts
and pursuits, or overwhelm the natural feelings,
or influence the conduct. As soon, however,
as any singular desire exercises such a sway as
this—when it engages the mind and influ-
ences the conduct, uncontrolled by natural sen-
timents and requisites occupations—it then
amounts to moral insanity, and requires both
moral and physical treatment. In some fe-
males, pregnancy occasions not only irrepress-
ible fears and melancholia, but also various dis-
ordered impulses, productive of crime or vari-
ous unlawful acts, either before the control of
reason can be exercised, or in opposition to the
feeble efforts of the understanding (§ 92). In
unmarried females, the melancholic feelings,
the irrepressible fears, and the morbid impulses
of the mind are often heightened by shame, re-
move, the abandonment of the seducer, the
consciousness of poverty, or the fears of ill
prevention. Under such affliction, the mind
may be so disordered as to perpetrate various
criimes, or even suicide. In this state, consciousness,
and memory, are in some degree, disturbed,
before it is restored, of the most flagrant na-
ture, and the most repulsive to the natural dis-
position and feelings. This is the more likely to
occur if the mental distress be attended by fits of
lethargy, or of fainting, or by convulsions. In
some cases, recovery from these attacks, or the
restoration of consciousness, is attended by a
short period of maniacal excitement, or a
state of momentary delirium, during which su-
icide, murder, or incestandram has been per-
petrated. In most cases of mental disorder oc-
curring during pregnancy, and in all that I have
seen, there was either an hereditary predispo-

tion to it, or the patient had been previously
subject to obstinate hysterical affections, and
had experienced overwhelming or intense emo-
tions of the mind.

538. B. Insanity after Delivery—Insania post
Partum—Paræphreny Pauperum, SAUVAGES.
— a. Insanity consequent upon parturition is
often observed during pregnancy, in conjunction
with fears and unfavorable presentiments. In some
cases, various hysterical affections, preterna-
nal susceptibility, great exuberance or depress-
sion of spirits, suspicions, irritability, a state of
stupor or sopor, and slight or short attacks of
mental aberration, have occurred during gesta-
tion. Generally the disease appears from the
second or third day to the sixteenth or seven-
teenth; but it may occur almost immediately
after parturition, or be delayed to the third or
fourth week. Some writers assign the third
and fourth, and the thirteenth, fourteenth, and
fifteenth days, as the most frequent periods of
its appearance. The chance of an attack, how-
ever, progressively diminishes after the third
or fourth day. The disorder may commence
with want of sleep, inquietude, sadness, anxiet-
y, or ill-grounded fears respecting some mat-
ter; the paroxysms of mania, or profound mel-
ancholia, supervening upon these symptoms.
Sometimes an explosion of mania takes places
more or less suddenly; but more frequently the
patient's manner becomes quick, the temper ir-
ritable, and the nights restless, for two or three
days before the attack. The form of the men-
tal disorder varies remarkably; but the mani-
aecal states are the most common. Next to
these are melancholia, and diversified forms of
monomania. During either of these disorders,
and in melancholia, especially suicide may be
attempted or committed. Mania may alternate
with melancholia, and this last with other va-

tieties of partial insanity. At first, and particu-
larly in cases occurring soon after delivery,
the disorder is maniacal. Sometimes the pa-
tient evinces a childish disposition for harmless
mischief; is gay and joyous; laughs, sings, and
talks loud and long, occasionally obscenely, and
is careless of the infant and of everything about
her. She is often, also, suspicious; imagines
everything poisoned; and is busy with some
idea, illusion, or some fancied object. In oth-
er cases, the maniacal excitement is much more
intense; and the conversation and conduct
more violent. These states may pass into mel-
ancholia, but very rarely into dementia or fa-
tury.

539. b. The physical symptoms are referable
chiefly to the digestive organs, and to the ner-
vous system. The bowels are torpid, the secre-
tions and excretions are unprepared, and the
stools are unhealthy, and generally very dark
and offensive; and, from inattention or obsti-
nacy, sometimes passed without regard to the
natural calls. The tongue is moist, white,
furred, or loaded; and as the disease proceeds,
it sometimes becomes brownish, mucous sordes
accumulating on the teeth and lips. There is
little or no appetite, and rarely much thirst.
The pulse is frequent, small, weak, compressible;
and sometimes it is but little, or not at all
accelerated, or it becomes less frequent as the
disease proceeds. The skin is relaxed and
moist, particularly about the neck, and gener-
ally cool, especially on the extremities.
The head is often hot, or is warmer than usual;
but the heat is not always permanent; it frequent-
ly occurs at intervals, and is sometimes greatest
when the rest of the body is cool. Occa-
sionally the scalp is cool throughout. The

general heat of the body is rarely increased, unless
when the disease is coincident with the first
or second, or even a fourth, expulsions; or when
the patient is torpid, or when the breasts,
or sometimes when caused by the violent

exterions of the patient. Pain, sense of pres-
ure, or tightness of the head, is often felt, with
uneasiness of the scalp, noises in the ears, and
sometimes throbbings of the temporal arteries.
There is little or no sleep. The face is gener-
ally pale, unless when the maniacal excitement
is great, and then it is often flushed or turgid.
The eyes are vivid or slightly red; but both
they and the face are occasionally pale, although the patient is most violent. The abdomen is usually soft, cool, and free from pain on pressure, unless sometimes in the hypogastric and iliac regions. The breasts are generally flaccid, and the secretion of milk either obstructed or arrested; but the milk, in some instances, is not materially diminished, although it is generally deficient in its healthy and nutritive properties. The lochia are often deficient, but they are sometimes abundant or offensive.

540. c. The insanity of females recently delivered commonly assumes the form now described; but its character varies remarkably in some cases, it nearly resembles sub-acute phrenitis, delirium supervenient as in the form of the disorder described by Dr. J. Burns, in which the symptoms of morbid vascular action in the encephalon precede the mental disorder. In other instances, the insanity verges in its character towards low nervous fever; it is then generally preceded by watchfulness, fever, the supine posture, heat of scalp, and injection of the conjunctiva. Images or illusions supervene, the ideas become rapid, and the delirium, passing into a muttering delirium, is soon confirmed. The pulse becomes quick, and the milk and lochia are usually suspended. Enough has been stated to show that, as regards puerperal insanity, as well as many other maladies, the marked lines of demarcation attempted to be drawn by authors and nosologists do not exist in nature; but that there is a gradual approximation of character observed in this, to other diseases of the nervous system—that the transition from puerperal insanity to phrenitis on the one hand, and nervous fever on the other, is often manifest; cases occurring in practice of an intermediate nature, and referrible to one malady as much as to another.

541. C. Insanity during or after Lactation—Insania Lactantium—Mania Lactea, Sauvages—is generally gradual in its approach; or it is preceded by symptoms premonitory of its occurrence. When, however, violent impressions are made upon the mind, or the secretion of the milk is suddenly disturbed, the disorder may burst forth unexpectedly. Generally, however, a change of temper or disposition is remarked for some time previously. The manner becomes hurried, sleep disturbed, the temper irritable, the countenance suspicious or distrustful, and the patient volatile and negligent of her infant. At length, sleeplessness, incoherence, or violence of language and conduct, and delusions, supervene. Occasionally, various hysterical and cataleptic symptoms are associated with these; and sometimes acts of violence, or attempts at suicide, are perpetrated, even before the nature of the malady is suspected by her friends. The disease may occur at any period of lactation; but it is more frequent on weaning, or very soon afterward, than at any other time. The melancholic and monomaniacal forms of insanity are oftener observed during this period, than violent mania: and when the latter occurs, it is apt to pass into melancholia, or to terminate with it. Insanity during this and the preceding periods may present some one or other of the complications noticed above (§ 166, et seq.).

542. ii. Diagnosis.—The diagnosis of puerperal insanity is sometimes difficult, especially after delivery. Some modern writers have endeavoured to point out differences, rather than to describe the relations really subsisting between it and other diseases, especially phrenitis and low nervous fever. But, as I have already stated, the distinction of the one into the other is not infrequent, or the pathological condition of these maladies are very nearly the same in many cases. The absence of fever has been considered as particularly characteristic of puerperal insanity; but fever accompanies a considerable proportion of cases, especially those commencing about the fourth or fifth day, when the secretion of milk excites some degree of febrile commotion in the system, and, at a later period, when the lochia disappear. Still, it is a rapidly as possible, and an irregular distillation of blood, with increase of heat about the head, rather than fever, that are more commonly observed.

543. a. In phrenitis, the patient has headache, vertigo, throbning in the temples, a beating noise in the ears, flushing of the face, injection of the conjunctiva, intolerance of light and of noise, heat of the scalp, rapid pulse, dry skin, suppression or sudden diminution of the milk and of the lochia, constipated bowels, and scanty and high-coloured urine, before delirium appears; and very frequently these symptoms are ushered in with chills or rigours. In proportion as these phenomena are manifested before the mental disorder appears, the disease may be viewed as possessing an inflammatory character. Puerperal phrenitis, moreover, soon passes into stupor, coma, subsultus of the tendons, catchings in the limbs, and unconscious evacuations, and often terminates unfortunately as early as the third, fourth, or fifth day, and rarely passes the eighth; whereas puerperal mania, even in the most febrile and unfavourable cases, generally is prolonged beyond this period, unless very injudiciously treated. In the former, the physical disease is manifest and developed before the delirium appears, and is evidently the cause of it; in the latter, the mental disorder is coetaneous with, or even previous to the physical disturbance.

544. b. When low nervous fever occurs after delivery, or during lactation, it will hardly be confounded with this disorder, as the febrile commotion precedes mental disturbance for several days; muscular power is prostrated, the patient preserving the supine posture, or being incapable of continuing any other; the pupils are but little sensible to light; the tongue is turgid; the patient is sleepless, and complains of confusion and giddiness, rather than pain of head; and when delirium supervenes it is of a more moderate, fourth or fifth kind, and very rarely violent or attended by muscular excitation. The pulse is very quick and small; the bowels are readily moved; and the lochia or milk is suppressed. As the malady proceeds, coma, startings of the tendons, pickings of the bedclothes, unconscious evacuations, and the usual phenomena of nervous exhaustion, terminate life.

545. These maladies the discriminating physician will never confound with true puerperal mania, and he will carefully distinguish such cases as present an intermediate form between either of them and the latter disorder. He will, moreover, keep in recollection the circumstance
of these diseases frequently leaving, as the physical disorder subsides, more or less of mental disturbance behind them, which may assume the form of chronic mania, or melancholia; and the risk of this result will be great in proportion to the evidence of a hereditary predisposition to insanity, and to the nervous or melancholic temperament of the patient.

546. c. The relation of puerperal insanity to delirium tremens has not been adverted to by writers, although the connexion is so obvious as to be of great practical importance. I have been called to several cases which, in their remote causes and essential features, were instances rather of delirium tremens occurring in the puerperal state than true puerperal insanity. In some cases, the tremor is hardly to be observed, or is present only for a short time; and yet the affection presents the other characters of that disorder, and has arisen chiefly from the abuse of intoxicating liquors. Puerperal insanity, as far as it is observed, is attended by delirium tremens, and generally appears soon after delivery, and is to be imputed chiefly to the effect produced on the system, already injured by excesses, by the shock of parturition, by the consequent evacuations, and by the abstraction of accustomed stimuli.

547. iii. Prognosis.—Opinions of the result of puerperal insanity were either stated in too favourable terms, or imperfectly ascertained previously to the appearance of the works of Esquirol, Haslam, Burrows, and Goon. M. Esquirol states, that of 92 cases, 53 recovered and 6 died, leaving 31, or 1 in 3, as incurable. Of 85 cases, admitted at Bethlem, Dr. Haslam observed 50 recover, and 35 incurable. Dr. Burrows mentions 57 cases, of which 37 recovered, 28 within the first six months; 10 died, 1 committed suicide, and 11 remained uncurable. Dr. Gooch observes, that these statements present a prospect unnecessarily gloomy and discouraging; for, of the many patients about whom he has written, only two, who are now, after many years, disordered in mind, and of them, one had already been so before her marriage. It should, however, be recollected that only the more obstinate and severe cases are sent to asylums, and until medical treatment had been already employed; hence the more unfavourable results furnished by Esquirol, Haslam, and Burrows. Of those not sent to such institutions, a much greater proportion than that assigned by these writers recover under judicious management, particularly of the non-febrile form of the malady, which is, fortunately, the most common. Cases attended by much febrile disorder, more especially those approaching either to the character of phrenitis on the one hand, or to that of nervous fever on the other, are attended by more danger, and frequently either terminate fatally, or in permanent insanity, particularly if a hereditary predisposition to insanity exists. Of the 10 cases which ended in death, out of 57, recorded by Dr. Burrows, 7 occurred within twelve days, 2 within seven weeks, and 1 after four months. Two had active uterine disease, and 2 others died in consequence of relapses.

548. The causes have a considerable influence on the result. Of the cases which I have seen in the Queen's Lying-in Hospital, and to which I have been called in private practice, a much larger proportion of incurable and fatal cases has existed among the unmarried than in the married. Previous distress of mind is sufficient to account for these results. Of the cases of married females that have occurred in the above institution since I became consulting physician to it (1822), two were represented to me by the matrons as having been caused by remorse consequent upon incestuous intercourse, and both these terminated fatally. It may be inferred, from the result, testified by several practitioners, that about four-patients in five recover their intellects; and that about one in eight die, generally within the first month of the disease, the greater number within a fortnight. The proportion, however, of unfavourable cases is manifestly greater than this in unmarried females. The chief danger in this disease, especially in the more pure, or non-febrile form of it, arises from debility and exhaustion of nervous power. And this is the more to be dreaded when the disorder follows hemorrhage, or improper bleeding, when the pulse is very rapid, weak, or small, or fluctuating; and when there are great restlessness and long-continued want of sleep. Recovery is generally more likely to take place, the more remote the attack from the period of parturition, or when the disorder occurs during lactation. The appearance of the disease during pregnancy should lead the physician to anticipate a severe form of it after delivery. Moral causes, also, may give rise to more severe and dangerous attacks than physical causes; and the maniacal form terminates favourably more frequently, and in a shorter time, than the melancholic, in as far as the recovery of reason is concerned; but deaths are more likely to occur in it, at least after a short period from the attack. Of 55 recoveries, M. Esquirol states that 38 took place within the first six months. Of 35 recoveries, recorded by Dr. Burrows, 28 occurred within the same period. When the delirium is the result of a gay character, and the patient sings, laughs, talks wildly, and is a little mischievous, it rarely lasts long; but when it is attended by great suspicion, apprehension of poison, and sullenness, or when suicide is meditated or attempted, it then assumes a more serious character, and is not soon cured. Upon the whole, this disorder requires a very cautious and guarded prognosis.

549. iv. Causes.—A. The predisposing causes of puerperal insanity are nearly the same as favour the occurrence of other forms of mental disorder, the puerperal states being superadded causes of predisposition to these, and the period immediately following delivery being the most influential of these states. Hereditary influence, constitutional debility, and susceptibility of the nervous system, most powerfully cooperate with the puerperal states. Of the 92 cases noticed by Esquirol, 16 were attacked from the first to the fourth day, 14 from the fifth to the fifteenth day; 17 from the sixteenth to the sixtieth day; 19 from the sixtieth to the twelfth month of lactation; and 19 after forced or voluntary weaning. Dr. Burrows remarks, that of the 57 cases which he has observed, the disease commenced on or before the fourteenth day in 33; and after the fourteenth day, and before the twenty-eighth, in 11 instances. As to the age at which the disorder most frequently occurs, he observes,
that from the age of twenty to thirty it is more frequent than at any other age, in the proportion of nearly two to one. M. Esquirol states, that of 92 females, 22 were from twenty to twenty-five years of age; 41 from twenty-five to thirty, who have produced their effect chiefly; 11 from thirty-five to forty; and 2 from forty to forty-three. The comparative frequency of this disease in married and unmarried females has not been duly attended to. Nearly one third of the cases adduced by M. Esquirol were of those of unmarried women; while a fourteenth only of those observed by Dr. Burrows were unmarried. There can be no doubt that the disease is, relatively to the number of pregnant single women, more or less, depended upon them than in the married. This is to be imputed to the more general and intense operation of the moral exciting causes on the former than on the latter. M. Esquirol imputes the frequency of this malady in the unmarried, in great measure, to the influence of suppression of the lacteal secretion, and premature weaning, comparatively few unmarried females suckling their children. In this country, however, the majority of them find situations as wet nurses. Perinatal causes have been subject to hysteria, particularly its more severe and obstatinate forms, previously to pregnancy, are very liable to pu- erperal mania; and those who have been once attacked are highly predisposed to the disease on each successive return of the puerperal states. Of the predisposition arising out of hysteria, I have met with several remarkable instances. Some writers have remarked, that nearly one half of the cases which have been treated, more or less, depended upon hereditary predisposition. Of the instances which I have seen in the lower classes, a large proportion has occurred in those who had been addicted to the inordinate use of spirits or malt liquors.

550. B. The exciting causes are also very frequently the same as produce mental disorders in other circumstances; although there are others which especially belong to the puerperal state, or which produce their effect chiefly in these states. There are some, also, of a physi- cal or pathological kind, consisting of changes in the sexual organs and nervous system, connected with impregnation, parturition, and lactation. The most common exciting causes are, moral emotions and errors of diet and regimen. Of the latter, improper food, stimulating or heating articles, exposure to cold air or currents of air, damp clothes, the evaporation of liquid perfumes, the suppression of the lochia, or the undue eruption, the use of cold fluids, and neglect of the abdominal secre- tions and excretions.

[Insanity also results from lactation unduly pro- tracted, especially where previous predisposition to mental disease exists, and which bears close resemblance to puerperal mania. The latter, as is well known, occurs most commonly in women of weakly, hysterical, and irritable habits; and in the same class, mania from over-lactation is most frequently witnessed. Where it arises from protracted lactation, it commences by pe- culiarity of sentiment or temper, and is plainly evinced by pertinacious adherence to an opinion once formed, however erroneous. If the child is not taken from the breast, the pulse, notwithstanding a more generous diet, becomes quick and sharp, the skin parched, and the whole system deranged. Drs. Laycock and Ashwell think that insanity from this cause is rarely of a serious nature, except in cases where generous diet and wine are injudiciously administered. We are acquainted with the pathology of this functional result of undue suckling in an impaired and attenuated condition of the blood, and a consequently depressed state of the nervous system, especially of the organic system of nerves. Dr. Ashwell supposes that any prolonged, undue lactation may induce organic changes in the brain, lungs, and uterus. (* A Practical Treatise on the Diseases peculiar to Women, &c., Am. ed., p. 514.)

551. III. This state has also been reflected upon both the nervous system and the se- cretions during the puerperal states—great in proportion to the nearness of their occurrence to the period of delivery. The comparative influence of the moral causes has been attempted to be estimated by M. Esquirol and Dr. Bur- rows; but the application of numbers to the estimation of the separate value of individual influences in the production of disease, espe- cially when diversified combinations of exciting and predisposing causes generally occur in it, leads rather to erroneous than to correct conclusions, and is, at best, a parade of accur- acy in respect of matters which admit only of approximations to the truth. Besides, the relative influence of particular causes vary with the age, constitution, modes of living, previous health, and occupations of the patient; and with seasons, weather, epidemic states of the air; and with climate, situation, and peculiar circumstances of the country. The country states that 46 or 92 cases of puerperal insanity were caused by moral emotions, while Dr. Bur- rows estimates the physical as being ten times more influential than the moral causes. My observations lead me to infer that M. Esquirol is very much nearer the truth, even allowing

* [Case of insanity resulting from undue suckling.—Mrs. P., aged 28, of four complexion, blue eyes, and light hair, at the age of 17, suffered from chlorosis; but, under a course of tonic herbs, and recovery, she was placed, and again recovered under the same treatment. At the age of 19 she married, and before her 50th year she had a living male child. She nursed this child for 12 months, and was again confined soon after she had reached her 21st year. Since this period she has borne four living children, and has miscarried twice: she has nursed every child. Her last infant was born eight weeks before I saw her. Her at- tendance was requested on account of her having been weak, very desponding, and sharp in her manner. On vis- iting her, I was struck with her pale, anxious countenance; the pupils were dilated; the pulse was small, quick, and irritable. She complained of thirst, of a pain at the top and back of her head, of cold in her legs, and thirst at the corona. I obtained answers to my questions with some difficulty, although, in general, she was exceedingly com- municative. Tonics, change of air, &c., were ordered, and the child was partially weaned and fed. The symptoms, however, became worse, and her conduct was exceedingly violent, and more than once, to destroy both her hus- band and child. The latter was immediately removed, her head was shaved, nutritive, but stimulating diet was ordered, the medicines and sedatives used were diligently professed; but at length it was thought right to remove her to an asylum. Here she continued four months, and returned her entirely recovered. The nurse subsequently she was again confined of a living child, and within five months her insanity returned. After a fruitless employment of sedatives, she was again removed to an asylum, having remained there five months, she was sent home quite well. Twelve months from this period she gave birth to another living infant, and, at the suggestion of her medical attendant, she did not attempt to nurse it, and her intellect has continued unimpaired. —Loc. cit.)
The hereditary predisposition, which exists in a very large proportion of cases, to be a physical cause.

The most frequent mental errors are those which have been already noticed (§ 549) as operating chiefly on the minds of the unmarried; also fright, fear, anxiety, chagrin, anger, domestic dissensions, grief at the desertion of the father, or at the death of the infant; dread of the malady after having experienced an attack, &c. The influence of terror and fear was shown by the cases which came under the care of M. Esquiro in 1814 and 1815. Of 18 which he admitted in the first year, 15 were convulsions on account of fear. A sudden shock, or whatever startles or alarms the patient, as a sudden clap of thunder, will often occasion the disease, especially soon after parturition. The abuse of intoxicating liquors exerts both an exciting and a predisposing influence, and it has not only a direct, but also an indirect effect. These liquors either excite the malady by immediately stimulating the nervous and vascular systems, at periods when susceptibility is augmented and vital force diminished; or else, they indirectly cause it, by the sudden abstraction of the accustomed excitement they have afforded, at a time when the frame is depressed by the suffering and by the evacuations attending parturition.

When puerperal insanity proceeds from this source, it may either assume more or less of the characters of delirium tremens (§ 546), or vary but little from its usual forms. In order that the treatment should be successful, care ought to be taken to ascertain the existence or non-existence of this cause from the attendants most competent to furnish the information.

552. v. Pathological States.—A. The appearances observed after death, caused by pure or true puerperal insanity, particularly when it occurs soon after delivery, or during suckling, consist chiefly of deficiency of blood in the brain and its membranes, and, in some instances, of slight effusions of serum between the membranes and in the ventricles. There are signs of inflammation, or even of congestion, excepting in such cases as have approached in their characters to phrenitis on the one hand, or to nervous fever on the other; and in these appearances of an inflammatory or of a congestive nature, with or without effusions of serum, are often observed. The pure cases of the malady present little besides anaemia of the brain and its membranes, and of the system generally. Morbid changes in other parts of the body, especially in the sexual organs, are coincidences or accidents only.

553. B. The morbid condition more immediately occasioning the malady seems to consist of increased nervous susceptibility and greatly impaired power, frequently associated with deficiency of blood. The balance of the circulation is also often disturbed, and irregular determinations of it take place, especially to the brain and to the uterus. While the circulation is more active in one quarter, it is deficient in others, and the function of the brain arc thus directly or sympathetically disturbed. After impregnation, the organic nervous influence of the uterus and ovaria is more or less developed and exalted, and the excitement of these organs often extends to, or reacts upon, the cerebral-spinal nervous system and its manifestation, exciting and disordering it and its functions. After delivery, the susceptibility of the brain, and of the nervous system generally, is increased, and the disposition of these to be sympathetically affected by the states of the mamma, uterus, and ovaria proportionately augmented, the susceptibility being great in proportion to the shock which the system has sustained from the parturient process, and to the loss of blood and exhaustion. The occurrence of the disease during lactation is to be imputed chiefly to exhaustion, debility, and vascular insufficiency. The morbid state, occasioning, to a disturbance of the balance of the circulation, a greater determination of blood taking place to the brain than to other parts, upon the cessation of the secretion of milk, as well as upon the premature cessation of the lochia.

554. vi. Treatment.—A. Insanity occurring during pregnancy is generally either partial, or of short duration when it assumes a maniacal form. In either case, the treatment should chiefly depend upon the state of the vascular system as to fullness, action, and temperature. When the circulation is deficient in none of these conditions, and particularly when puerpera exists, a small blood-letting will then be useful; but in doubtful, or other circumstances, cold applied to the head, warm and stimulating pediluvia, refrigerants, and refrigerating diaphoretics, cooling aperients, and antispasmodics, combined with narcotics, as hereafter prescribed, must constitute our principal means of cure, asked, however, by judicious morbid management, and by appropriate diet and regimen.

555. B. Insanity occurring soon after parturition requires the utmost discrimination in ascertaining, 1st, the presence of the disease in its pure or unmixed character; 2dly, those mixed states which partake either of the character of phrenitis, or of that of low nervous fever, and the greatest care in the selection of remedial agents. In this disease it is always most important to consider the state of the vascular system, in connexion with nervous excitement, and to inquire as to the dependence of whatever degree of vascular action that may be present upon the condition of the nervous system, and upon the mental disorder and muscular efforts. In all cases, moreover, it should never be overlooked that the frame has received a shock during the parturient process, that the nervous system has endured great excitement and suffering, and that the vascular system has sustained a loss, sufficient, in many cases, seems to disturb the balance subsisting between the state of the vessels and their contents, and to disorder the balance of the circulation in different parts of the body. These considerations will generally guide the practitioner in the treatment of the more difficult, doubtful, or mixed cases: the more simple and pure instances of the disease will present neither difficulty nor doubt.

556. a. Blood-letting in any mode is most injurious in puerperal mania and melancholia, and in such cases as are attended by fever, or where the symptoms approach those of delirium tremens. Indeed, puerperal insanity, occurring in the lower classes of society, not unfrequently is very closely allied to that disorder, owing to the circumstances already noticed (§ 546, 551). In those cases which assume the form of ner-
rions fever, vascular deprecation is also pernicious. Where, however, the malady approaches, in some of its features, a phreatic form—when the head is hot, the face flushed, the pulse hard or strong, and the secretions suppressed—the propriety of blood-letting might seem to be obvious; yet even in these cases the practice, although cautiously resorted to, might be injurious or fail of benefit. When the physical symptoms are sometimes fallacious, for they are occasionally produced by the violence of the nervous and mental excitement, or of the physical exertion, relatively to the power of the system, and are of short duration, dangerous exhaustion soon supervening. In such instances, even a small blood-letting would only hasten and increase the consequent depression. In cases which commence with headache, fever, flushing of the face and eyes, diminished secretion and excretion, and occasional preceded by chills or rigours, and in which the mental disorder is clearly consequent upon the inflammatory and febrile symptoms, a recourse to blood-letting, and to other antiphlogistic means, is obviously requisite; for the disease is more or less inflammatory, or consists of a state of active congestion approaching inflammation. Yet, even in these cases, the practitioner will be guided, in some measure, by the rapidity with which the fever or pulse is followed by physical disturbance, by the previous condition as well as by the existing circumstances of the patient, by the evacuations attending and consequent upon parturition, and by the several phenomena characterizing the case. Whenever the mental affection follows quickly upon the cerebral and constitutional symptoms, vascular depletions of any kind are seldom of service, unless very prudently prescribed.

557. When there are much heat of the scalp, flushing of the face, beating of the carotid arteries, and no indication of urgent debility or exhaustion, the previous condition and evacuations of the patient furnishing no sufficient reason for the existence of these states, then may lachees be applied behind the ears, or around the occiput, and cold to the head, with great advantage. While ice, cold lotions, &c., are placed around the shaved head, the feet and legs should be frequently bathed in warm water, to which mustard or scraped horse-radish has been added. In the majority of cases, where inflammation is dreaded after delivery, there is only active determination of blood to the head, the circulation in the extremities and in other parts being impaired; and in these the continued application of cold to the head, and the frequent or persevering use of derivatives to remote parts, or to such as experience an insufficient supply of blood, will generally remove the disorder. The application of blisters to the nape is not observed by all observers, but they are seldom of much service in the maniacal states of disorder. In the melancholic form, or when there is a tendency to stupor, rather than to high excitement, blisters on the nape, or behind the ears, are generally of use.

558. b. In a great proportion of cases of puerperal insanity, facial accumulations have formed in the alimentary canal, and morbid secretions have collected in the gall-bladder, hepatic ducts, in the cæcum, and in the coils of the colon. The existence of these collections is indicated by a loaded, foul, or furred tongue, by a foetid breath, by a lurid or discoloured state of the skin and of the complexion, by more or less fulness in the regions of the cæcum and sigmoid flexure, and by dark and offensive evacuations. The propriety of purgatives in all such cases, and of enemias in many of them, is undoubted. The latter, however, should not be used when debility or exhaustion is extreme, when the face is pale, the skin cold, and the pulse very quick and weak. Ipecacuana is the best emetic in ordinary circumstances, but when vital depression is considerable, any of the warmer emetics prescribed in the Appendix (F. 402, 403) may be used. After its operation, calomel may be given with camphor and some cathartic extract, and a few hours subsequently, a draught, with rhubarb and magnesia, or any other purgative, may be taken. The full operation of these when the bowels should be secured either by their repetition or by the administration of enemata, and especially of those containing castor oil and spirits of turpentine. In most cases, the stomachic apertum, consisting chiefly of the compound infusions of gentian and senna (F. 256), or the compound aloetic pill or decoction, will be the most appropriate remedies.

559. a. Having evacuated morbid secretions and final evacuations, it is next requisite to support the constitutional powers and allay nervous excitement by antispasmodics or diffusive stimulants, conjoined with narcoties or sedatives. Where debility, exhaustion, or vascular innervation is urgent, it will generally be necessary either to combine restoratives or stimulants with alvinal evacuants, where the latter are requisite, or to give the former in the intervals between their exhibition. Narcoties are more beneficial in puerperal than in any other form of insanity, particularly when conjointed with camphor, ammonia, or aromatics. Since 1815, I have usually prescribed five grains of the extract of hyoscyamus, with an equal quantity of camphor, in the morning and afternoon, and double this quantity of each at bedtime. Where there are much heat of the head, flushing of the face, and thirst, these symptoms should be removed by cold applications, purgatives, refrigerants, and external derivatives, before camphor or ammonia is exhibited; but, notwithstanding their presence in a moderate degree, the camphor and hyoscyamus may be exhibited, provided that these means are persisted in, and the enemata already advised are occasionally administered. In still more urgent cases, the camphor may be given more frequently, conjointed either with hyoscyamus, or with opium or morphia, a larger dose being given shortly before bedtime. I have rarely found the following draught to fail in giving repose, and in counteracting the nervous excitement: to half a fluid ounce of camphor and spirits of turpentine, and half an ounce of camphor and spirits of ammonia, be poured into a mixture of an equal part of spirits of camphor and spirits of ammonia, and the whole be taken by the patient in bed, in the course of an hour, after the requisite alvinal evacuations, and when the head is kept cool, and the lower extremities warm: the enema has also proved very generally of service.

No. 578. R Camphoræ raue gr. x.; Aquae Aeth. 2as.—.5.; Extr. Rhizi tis.; tere cum Olei Terebinthi f.5.; Olei Reini f.5. (vel Olei Olibri f.5.); Decoct. Avenæ tis. 2a.
560. d. It is important to administer due support to the system during the treatment of the disease, more especially when there is neither a febrile state of the pulse, nor heat of the head or surface; and this support, whether medicinal or dietetic, should have due reference to the previous modes of living and habits of the patient. When puerperal insanity becomes chronic, a rule which it appears is the course of suckling, and particularly when there is a total absence of inflammatory or febrile symptoms, tonics, especially the infusion or decoction of cinechona, or any of the bitter infusions, may then be given with ammonium and aromatics, the secr- etions and excretions being promoted by the usual means; change of air and of scene, and appropriate moral treatment, being brought in aid of the physical remedies. When the patient has been addicted to the use of intoxicating liquors, and especially if the disease assume a form approaching to delirium tremens, then opium, with camphor or with ammonium, may be freely administered. Brandy or wine may be given in arrow-root; or even warm, spiced, or mulled wine, or ale may be occasionally allowed.

561. c. The diet requires much attention. Drs. Prichard and Gooden remark, that patients incur some risk of being starved in this disease, through the mistaken notions of their attendants, who are apt to consider the excitement of the malady a reason for withholding food; when this very state, owing to the exhaustion often produced by it, renders due support especially necessary. Farinaceous fluids of a nutritive quality, as rice, arrow-root, sago, &c., should be given at short intervals, when febrile symptoms preclude the use of animal food. Warm milk, or broth, may also be allowed, and should be taken in small quantity at one time. In protracted cases, solid meat, malt liquor, wine and water, bottled porter, or the bitter ale usually sent to India, will often be of service. Patients who have been accustomed to live fully, and to the use of stimulating liquors, must be allowed such food and beverages as their physical symptoms will permit, without reference to the state of the mental disorder. When suckling is concerned in producing, heightening, or perpetuating the mental affection, by draining an already weakened constitution, a nurse must be procured, and a nutritious nourishing diet and regimen prescribed, with change of air, and the use of chalybeate waters.

562. C: When insanity appears during suckling, the treatment is nearly the same as that just described; a nutritious and cordial diet should be immediately allowed, and meat taken daily, with about four ounces of wine. Purging in such cases is injurious, but the bowels should be kept in a regular state by the compound decoction of aloes, or by the infusion of senna and cascara. The mental disease may occur after sudden weaning, and particularly if it assume a maniacal form, and if there be any reason to infer that an inflammatory affection of the brain has supervened upon the sudden suppression of the milk—if the symp- toms already mentioned, as indicating this state, appear, then appropriate means should be prescribed; but this is not to be determined, nor is the treatment to be regulated by the disorder of the mind, but by the bodily symp- toms.

563. When the milk becomes scanty, or ceases to be secreted, and the mental disorder seems to be aggravated by this circumstance, or has supervened upon it, the secretion should be encouraged by keeping the child to the breast. If the lochia disappear prematurely, means should be taken to procure its return. For this purpose, the warm bath, the semicu- pium, or the hip bath, may be used; and, if these fail, leeches may be applied on the insides of the thighs, near to the groins, and the hip bath be subsequently employed. Warm fomentations may also be applied to the pudenda, or over the pubes. At the same time, cold applications around the shaved scalp ought to be assiduously employed.

564. The constant attendants on the patient should be quiet and obliging, but effectually; not irritable, but protect her from self-injury: servants, or monthly nurses, can seldom do this; they ought, therefore, to be removed, and a nurse accustomed to the care of deranged fe- males placed in their stead. The patient should never be left alone, and everything with which self-injury can be effected should be carefully removed; the windows ought also to be secured. The husband or near relations ought never to be left alone with the patient, but should be excluded until the state of the disor- der permits their admission. It is generally necessary to remove all persons who are sources of excitement of any kind. Seclusion, in some mode or other—partial or complete—is generally necessary; at least, for some time. There is often, however, great difficulty in carrying this into effect in such a way as will tend to the comfort and speedy recovery of the patient. Removal to an asylum is not so fre- quently requisite for the mental disorders of puerperal patients as for insanity occurring under other circumstances. It is principally required in the more obstinate and prolonged cases, and after other measures of partial or complete se- clusion have been tried. Dr. Gooden remarks, that, where seclusion has been adopted, there may come a time at which some interruption to this solitary life may be advisable. When the disease has lasted long, when the patient expresses a strong wish to see some near friend, when she entertains illusions which the sight of some one may effect, the admission of such person should be tried. It is well observed by Dr. Haslam (Moral Management of the Insane, p. 14), that confinement is too indiscriminately recommended and persisted in. An intercourse with the world has dispelled, in many instan- ces, those hallucinations which a protracted seclusion, in all probability, would have added to and confirmed. In its passive state, insanity has been often known to wear off by per- mitting the patient to enjoy her liberty, and to return to her usual occupations and habits. There is obviously a period of the malady approaching convalescence, in which the bodily disease is loosening its hold over the mental faculties, and in which the latter are capable of being drawn out of the former by judicious ap- peals to the mind, and by a salutary moral management.

INSANITY, PUERPERAL—TREATMENT. 635
INSANITY, SUICIDAL.—Occasions of.

[Out of 511 cases of insanity admitted at the Bloomingdale Asylum from physical causes, 43 cases followed parturition, and assumed the different forms of mania, monomania, melancholia, and dementia; two cases occurred during pregnancy; four during lactation; 20 cases originated in functional and organic disease of the uterus; eight were attributed to the final cessation of the mensae: making a total of 77 instances of mental derangement dependent on the peculiarities of the female system. (MacDonald.) M. Esquerter states that there were 92 cases of puerperal madness out of 1119 insane females admitted during four years at Salpetrière; he found the proportion, however, far greater in the higher classes of society, being as high as 21 out of 144. Dr. Haslam enumerates 84 cases of puerperal mania in 1644 cases admitted at Bethlem; and Dr. Resh reckons five such cases in 70 received into the hospital for lunatics in Philadelphia.]

XI. Suicidal Insanity. SYN.—Suicide.—Self-Homicide; Suiheadium, Autochiria; Melancholia Suiheadium; Selbstmord, Germ.; Le Suicide, Fr.; Selbstmord, Itali. 565. Under suicidal insanity, I proceed to consider self-destruction or self-homicide, whether it be seriously entertained, or attempted, or perpetrated.

566. The religion, the laws, and the manners of a people contribute in a remarkable degree to the opinions entertained respecting suicide, and to the frequency of it among them. Of the influence of the laws on self-destruction, sufficient proofs have been furnished in recent times; and the restraints formerly imposed by them upon minds naturally influenced by rational views of religion, being now, in a great measure, removed, this crime has become much more common, and has assumed an importance equally great, in a moral and social, as in a strictly medical point of view.

567. The ancients, in general, condemned suicide, unless on occasions calculated to benefit the common weal. Several stoical writers, however, attempted to justify it by reasoning and by example, while the opinions of others respecting it were either contradictory, or insufficiently expressed. Legislation regarding it was formerly, and still remains, very different in different countries, it being in some places allowed by the laws, in others tolerated only in certain circumstances, and in some condemned as a crime. The Christian religion, of whatever sect, and the doctrines of the Koran, regard it among the greatest of sins; while it is permitted, even encouraged, by numerous pagan rites. At the present day, the opinion,* by no means generally receiv'd, although very commonly acted upon in this country, that suicide is always an insane act, leaves every member of the community at liberty, without any degrading penalty attached to the act, to dispose of his own life as he pleases, without reference to the claims of those depending upon him, or of society in general. The knowledge that no indignity will result to his body, and no discredit to his memory, thus becomes an incentive to self-destruction; and, even when it is not an incentive, it cannot, at least, impose any restraint upon an impulse to commit this act when a weak-minded person is subjected to chagrin, passion, and misery.

568. That suicide is frequently, or even generally, entertained by some one or other of the numerous forms of insanity, may be admitted; but that it is thus occasioned in all cases, is not so manifest. It may be said that it is an act of moral insanity; and, as far as immorality and passion may be viewed as temporary insanity, so far may it be considered as such. But that it alone constitutes insanity, or that, in a considerable proportion of the cases of it, especially those wherein mental sanity has been disturbed, the mind is disordered even to the extent contemplated for, in respect to the forms of moral and partial insanity described above, is not so evident. That the mind is impaired, and the judgment so far weakened as to be swayed by morbid feelings and impulses, or to be unable to withstand the suggestions of passion and chagrin, may be allowed; and, as far as a weakness of mind, permitting the impulses of passion their full career, may be considered as insanity, so far may suicide be viewed. The manner already weakened by indulgence of the petted and spoiled child to have the weakness and susceptibility natural to the early stages of its development increased by the indulgence, and remark the effects produced upon it when a desired object is withheld. In like manner, the adult mind, unexercised and imperfectly strengthened by opposition and disappointments, and pampered by enjoyment and success, experiences a sudden revulsion upon unexpected or indiginitions, is thereby irritated as well as depressed, and accuses itself—suicide is then a rational idea; the impulses excited by these feelings being sometimes carried into effect before the sober dictates of reason can withstand them, or these impulses more or less quickly overthrow the efforts which reason may make. In most cases, these efforts are too feeble to counteract the impulses arising out of outraged feelings, or to subdue the sufferings of wounded self-love, or the stings of injured honour. That suicide, when strongly urged by the passionate and morbid passions, is the easier overthrown by these emotions, the more intensely feels the shock, more quickly sinks before it, and is the less capable of making an effort to recover itself, the less it is swayed by the dictates of religion and principle, and the less it is deterred by fears of any indignity, or of the reprobation of opinion. All these sentiments come in aid of the mind in adversity, or during contrariness, when duly regulated, although weakened, and conducted to a healthy improvement, but when they can have no influence where they have never been habitually entertained.

569. I. Occasions of Suicide.—A. The exciting causes, or the circumstances determining self-destruction, are very diversified. Whatever may be the motives or incentives to this act, they promise to the imagination something preferable to life, or a lesser evil than existence: 1st. Suicide may be committed in circumstances, with motives calculated to excite admiration, or, at least, to preclude the imputation of blame; but such occasions are rare; and although not infrequently recorded in ancient history, they rarely or never occur in modern

* In respect of suicide, opinion is as strong as a legislative enactment, insomuch as it determines the coroner's jury as to their verdict—this act being always found by them as that of insanity.
times, or in the present state of society. 2dly. Suicide is often caused, in some countries, by religious rites or institutions, by received notions respecting injured honour, and by hopes of thereby passing into a happier state of existence. 3dly. It is very frequently occasioned, in barbarous communities, by a species of nostalgia, by forcible removal from home, or by slavery, and by ill usage, in connexion with a belief of thereby returning to former abodes in another state of existence. 4thly. It occurs very frequently during delirium and mania, in consequence generally of some illusion, false perception, or error of judgment. 5thly. During melancholia it is very frequently adopted, either from the several suggestions committed by it generally entertained long before it is perpetrated. 6thly. It is sometimes, also, attempted in almost all the other forms of partial insanity, and particularly those attended by depression and anxiety respecting a state of future existence, or by unsettled views of religion. 7thly. Suicide often is suggested by the emotions consequent upon reverses, wounded self-love, chagrin, and contrarieties of all kinds, and by the violence or intensity of passion and anger; the enraged feelings, being inexorable or incurable, exhaust themselves upon the object which excited them, recoil upon themselves, and often thus originate a suicidal impulse, which is not always successfully resisted. 8thly. A suicidal suggestion may arise from various circumstances of a negative or passive kind, from satiety, from ennui, from the want of excitement, from the excess of gratification, and the exhaustion of all its sources, &c. In such circumstances, the idea may long be entertained, until, ultimately, either carried into effect or laid aside from a change in the mental or physical state of the individual. 9thly. It may proceed from a mental infection or sympathy—from the details contained in the public cuterers to the gratification of the more debased of our moral sentiments, of various modes or instances of self-destruction—and from a desire, during states of chagrin or disappointment, of obtaining notoriety by the manner of carrying it off, and from the idea of an effect which may result from doing it, and from the avowal of the motive or the public or private observation of the delusion or the impulse, and from the wishes of some who are present, and from the desponding moods and slumbering resolution of others. 10thly. It is often committed in order to avoid public exposure, and from the consciousness of unmerited guilt, or as an atonement of a severe or lasting kind. 11thly. It is more rarely had recourse to in order to escape from violent pain, or the various miseries attending want and destitution, and from feelings of despair. 12thly. From remorse or self-reproach. 13thly. From a morbid or insane impulse, without any other obvious mental disorder. 14thly. From a species of fascination, as when looking down from great heights. 15thly. By weak minds in a state of relaxation and chagrin, in order to incur the feelings, to occasion regrets, and thereby to revenge slights or contrarieties on those who caused them. 16thly. Suicide may be mutual and reciprocal, caused by the same feelings, and by the same or different means. 17thly. It may follow murder. 18thly. It may be simulated. Certain of these require farther remark.

570. a. The instances of self-destruction or of self-devotion caused by patriotism, or by a wish to benefit the community, or to escape disagreeable consequences, have been generally viewed as excluding blame, and as hardly deserving to be ranked as suicidal. The cases of Cebes, of

Decius Mus, of Curtius, of Otho, of the citizens of Calais and of Rouen, may be referred to as being of this kind. Zeno and his followers inculcated that a wise man should be ever ready to die for his country or his friends; and the Stoics, in general, taught that suicide was preferable, not only to dishonour of any kind, but even to the enduring of severe pain or lingering disease. Among the Greeks and Romans, self-destruction was preferred by many to subjection to a victor, or to a state of slavery. Isocrates, Demostenes, Brutus, and Catiline terminated their own lives, rather than fall into the hands of conquerors. 571. There are cases in which the virgus of Macedon committed suicide to escape dishonour; and numerous instances of a similar kind have occurred in ancient and modern times. Lucreta would not survive the dishonour she could not prevent. Lycurgus and Charondas sacrificed their lives in order to maintain the inviolability of their own laws and institutions. Most of the above instances of suicide may be viewed as precluding blame, and some of them may claim our admiration. But other instances of honourable suicide, which have been considered as excusable by Montaigne, Dr. Donne, Rousseau, Hume, and others. When Josephus, who commanded the Jewish army, wished to surrender to Vespasian, from a conviction of the hopelessness of resistance, his soldiers insisted upon their having recourse to suicide, rather than to yield to a conqueror. But he resisted their importunities, and concluded his arguments by observing that 'self-murder is a crime most remote from the nature of all animals, and an instance of impiety against God, our Creator.' 572. a. The victims of religious rites, as in India, and in the Canaries in former ages—of national customs and manners, as in the Isle of Ceos, Japan, &c.; and of ignorance; and of those persuasions which constitute a part of religious belief, also—are not to be viewed as instances of suicidal insanity, but as proofs of the influence of high moral and religious considerations and expectations, of the tyranny of custom, and of false notions of honour, and that they proceed legitimately from the training or education of the mind from an early period of its development. They are altogether different from the suicides which were so frequent during the decline of Roman greatness, and which proceeded chiefly from vice and licentiousness, or, rather, from the sentiments and impulses which are generated from these sources—sources so productive of suicide in some countries at the present time. 573. a. Suicides in states of mania, or of delirium, occur either from some involuntary or blind impulse, or from some delusion, hallucination, or false perception—as when a person, in either of these states, throws up the window of his room, and walks out of it, in the persuasion of his going out at the door. Maniacs, also, attempt to destroy themselves at the commencement of the malady, under the influence of the moral despair which caused it; and others commit the act from the distress caused by a knowledge that the disease is approaching or is returning. A patient for whom I was consulted during an attack of mania, from which he recovered, experienced, after a time, similar
symptoms to those which ushered in the former attack. His friends were directed to take the necessary precautions regarding him; but these he eluded, and committed suicide. This act is occasionally, also, attempted during convalescence from mania, in consequence of reflecting upon the excesses committed during the attack. It may even be accidental, owing to attempts at escaping from restraint or seclusion.

574. d. In melancholia and monomania, suicide is occasioned by illusions, or by the violence or intensity of some passion or sentiment, or by a sudden impulse which reason is incapable of restraining, or which induces the act before reason can be exerted, as more fully explained above (§ 91, 92). In some cases, the morbid impulse is partially or fully carried into effect; and, either in consequence of the nature of the means of self-destruction employed, or of a person having at last come to the rescue, attempts are made by the individual himself to counteract them, these attempts either succeeding or not, according to circumstances. The suicidal impulse is occasionally developed in an early stage of congestion of, or of inflammatory determination of blood to, the brain; and either previously to, or contemporarily with, such impulse, insane delusions or acts may be manifested. If, in such cases, the means of destruction shall have the effect of removing the morbid physical condition before extinguishing life, the patient will make efforts at self-preservation. This is not infrequently the case when suicide is attempted by dividing the vessels in the neck. When self-murder is resorted to during melancholia, from a fear of becoming insane, and with the feeling that it is the patient's fate or destiny to commit it, the conviction is sooner or later completely verified. Indeed, when it is contemplated or attempted in any form of partial insanity, the intention is generally persevered in, although it may be variously concealed, until it is accomplished in one way or another.

575. In melancholia, and other states of partial insanity, or even previously to any symptom of insanity being sufficiently prominent to attract notice, or in consequence of some mental shock or perturbation, the patient may conceive that an internal voice calls upon him to commit suicide, and may act in conformity with it; or he may entertain the idea long afterward, either without being able to divest his mind of it, or resisting the impulse to perpetrate it with the greatest difficulty, and with the utmost exercise of his reason. A lady consulted me on account of headache, during which she could not look upon a knife without experiencing a strong desire to use it against her own life; but her reason had always resisted the impulse, which disappeared after treatment. In such cases, if the morbid impulse has not appropriately employed, and often notwithstanding the aid of both, the morbid impulse is ultimately carried into effect. Among persons who have been but little accustomed to self-control, or to listen to the dictates of moral and religious principles, such impulses are often soon acted upon. M. Esquirol furnishes several instances. A monomaniac, he states, heard a voice within him say, "Kill thyself! kill thyself!" and he immediately obeyed the injunction.

This writer remarks, that he has never known an instance of suicide from an irresistible impulse without some secret grievances, real or imaginary, serving as motives to the suicidal propensity. There are few states of partial insanity that may not be attended or followed by this propensity. Of the delusions which characterize melancholia, there are none more productive of self-destruction, as Dr. Darwin has remarked, than the fear of future damnation and of present poverty.

576. e. Suicide may be committed under the influence of passion, of violent anger, or of self-accusation or remorse. When intensely excited by anger, the mind, for the time, is in a state truly maniacal; and acts of violence to others, or to the person himself, may be committed in the height of the paroxysm, according to the nature of the circumstance or occurrence causing the excitement. Suicide from this cause, is most likely to be the fate of those who have not been sufficiently taught to curb their feelings, and who have been improperly indulged in early life, as Childe Harold describes himself:

"My brain became,
In its own eddy boiling, and o'erwrought,
A whirling gulf of phantacy and flame:
And wreath, untaught in youth by heart to tame,
My springs of life were poisoned."

Remorse and self-reproach frequently lead to self-destruction, as the only mode of escaping from the enduring agonies they occasion. The passions which "madden to crime" are often followed by the most anguishing feelings of self-accusation, which not infrequently arm the hand of the sufferer against his own existence. Shakespeare has powerfully and naturally illustrated this state of mind in his delineation of the character of Othello. The victim of remorse is often haunted by dreams, from which he awakes with an idea of suicide, or of remorse, in which attempts at suicide are sometimes fully carried into effect; and in his waking hours, his mind is haunted by recollections which become his domestic furies, and lash him on to madness. "Sua quemque fraus," says Cicero, "et suus terror maxime vexat; suum quemque scelus agitat, amentiaca affict; suae male cogitationes conscientiisque animi terrent. He sunt impii assiduae domasticaeque furiae." But, while remorse thus leads to suicide, by at first more or less obviously disordering the mind, this act as frequently is the proximate result of the moral sentiment; the attempt, or the commission of it, being preceded by no other morbid manifestation of mind than the moral torture proceeding from the consciousness of having committed a crime, great either in itself or in relation to the various circumstances connected with it.

577. f. Reverses, mortified pride, impatience under misfortune, and disappointment, are often the cause of suicide, especially in commercial countries, and under free governments, where there is a constant straining, among the more educated classes, after wealth, honour, and other direct or indirect means of power. Many of the ancient, as well as modern instances of self-murder, are to be attributed as much to the effects of reverses and mortified pride upon the mind as to the higher motives to which this act has been referred. The suicides of Brutus, Antony, and Cleopatra, of Fe-
TRONITUS and *SARDANAPALUS*, may be viewed in this light. Instances of self-destruction from mortified pride, consequent upon the failure of attempts at becoming conspicuous at public meetings, in the senate, or at the bar, or even upon the boards of a theatre, are not rare in modern times. The passion for notoriety too frequently entertained by silly or weak persons, when suddenly or rudely humbled, is often followed by a state of extreme mental collapse or depression, which sometimes terminates itself in suicide. The shock produced by the failure of long or warmly cherished hopes, of whatever kind, either suddenly overwhels all efforts of reason and judgment—the suggestions and impulses of passion and feeling being followed without control—and thus induces at once a state of moral insanity as harbingers of the suicidal act, or more slowly and surely develops some one or other of the forms of mental disease above described. In either case, the entertaining of the idea of self-destruction is an indication of insanity, inasmuch as it is connected with, or dependant upon an overthrow of reason and judgment in the one, and a manifest disorder of mind in the other. But, in many instances, the act is perpetrated after the first shock of a reverse or disappointment has subsided—after Reason has resumed her sway, and has been more or less exerted in calmly combating the feelings and suggestions which such reverse may have called into activity. In these cases, the suicidal act is the result of a weighing of the present and consequent misery—of the wretchedness attending upon existing and prospective emotions, against the contingencies following the commission of this crime; and whatever of insanity may be present consists only of the excessive emotions which reverses occasion, relatively to the strength of moral and religious principles by which they are, or should be, controlled. Hence it follows that a number of suicides are committed after disappointments, losses, &c., in a state of mind not absolutely subject to insanity—during an impatience under misfortune, unrestrained by these principles, owing either to their weakness or absence. Various kinds and grades of disappointment or misfortune will lead to the commission of this crime, according to the susceptibility of the mind, the early education, the previous trials and tutoring of the understanding, the preceding career of success or amount of distinction, and various accessory circumstances connected with existing states of society or existence. The most common, however, are losses of fortune or of reputation, losses from gambling or from transactions of this description, moral and worldly humiliations, disappointed affection, and the losses of friends, several of these being combined in their operations upon the mind.

578. g. One cause of suicide, of no infrequent occurrence in the present state of society, has been insufficiently considered by medical as well as psychological writers: this is, the *society* and *creed* consequent upon excessive sensual gratifications, felt by minds imperfectly or viciously educated, and unaccustomed to those pains, privations, and contrarieties of life that impart happiness to the enjoyments by which they generally are sooner or later followed. Continued and excessive gratifications destroy the susceptibility and excitability of the nervous system, and exhaust its manifestations. The languor consequent upon enjoyment is not allowed to subside, or to be succeeded by renewed vigour, before the indulgence is repeated; and as languor and exhaustion increase with the repetition of the gratification which occasioned them, so the desire of escaping from these unpleasant sensations becomes also increased, and the want of varied and augmented excitement is experienced. Thus gratifications begot desire, and desire calls for gratification, until all its sources are exhausted, all its varieties, and grades are enjoyed; and the sated mind, no longer finding objects capable of exciting it, or of enabling it to emerge from the languor or depression consequent upon inordinate enjoyment, and deriving pleasure no more from the numerous sources which afford it to better regulated minds, feels most bitterly that “all is vanity and vexation of spirit.” In the career of gratification, moral and religious principles are gradually, at first, departed from, and ultimately altogether despised; and once the mind is no longer able to receive enjoyment from the usual means, and has exhausted all the sources of it within its reach, it has also approached the lowest grade of moral degradation, which either takes refuge in suicide, or is ready to have recourse to it, in moments of deep depression, or on occasions of severe contrariety or disappointment. The restraining inducements of principle, and of regard to reputation, have ceased to influence the conduct; and as soon as the continued and varied indulgence has exhausted vital and mental power, and dried up every spring of enjoyment, circumstances which depress or vex the mind will often give occasion to suicide, or suggest it; or the mind, no longer being capable of gratification, entreats, at first, the idea of suicide, and ultimately has recourse to it, in order to escape from the misery of the extreme languor which it is incapable of dissipating. While most of the causes of suicide, and especially those already noticed, are of an active kind, this may be viewed as altogether passive. While the former acts by violently exciting and disturbing the mind, the latter results from a defect of such excitations as will rouse it, and afford those gratifications without which it either cannot exist, or prefers not to exist at all.

579. It has been said that a society for the mutual encouragement of suicide existed in Paris, the members of which undertook to terminate their own existences when life becomes insupportable; and the circumstance is almost verified by the character of the prevailing literature, and of the drama, in that capital. Numerous are the instances, not only throughout France, but also in this country, of persons who, having run an unbroken and rapid career of sensual gratification, and either exhausted its sources or their own means of enjoyment, have therefore put a period to their existence without any further reflection, and without any previous超出 of their insanity beyond the inordinate indulgence of their desires and passions, and the predominant sway these had obtained over all their sensations and actions.

580. A. Closely allied to the preceding is the occurrence of a *morbid* or *irresistible impulse* to *commit suicide*, without obvious mental disorder,
or any moral cause sufficient to account for the act. Suicides of this kind occur most frequently in persons belonging to families hereditarily prone to insanity or suicide; and hence, in some instances, may be viewed as the first manifestation of the mental disorder. But they likewise are committed by persons who are not thus predisposed, and under circumstances which require a brief examination. 1st. From a species of mental sympathy or infection, caused by perusing the details of cases of suicide furnished so circumstantially and injuriously as respects the minds of the community, by the weekly and daily press. Instances are often occurring, of not one only, but of several suicides being committed during the first few days following the publication of some notorious case of self-murder—notorious as respects either the rank of the individual, or the mode of perpetrating it, or other circumstances connected with it. Such instances have been long remarked, and are of increasing frequency, owing to the existing state of society, of which some notice has already been taken (§ 272, 329), and to which a brief reference will hereafter be made; 2dly. Suicide is, in rare instances, perpetrated from a species of fascination. The very keen and decision of the mind in an important matter, or by a single step the power of self-destruction, may give occasion to the impulse of committing it, which may even be instantly carried into effect by the weak, susceptible, or the morbidly disposed mind. I have had, on several occasions, to prescribe for highly nervous persons—those labouring under a morbid sensibility of the nervous system, and anxious, susceptible states of the moral feelings—who could not handle a razor or sharp knife without being distracted by thinking of or the idea of attempting suicide. Such persons, also, are unable to look down from great eminences, or over a precipice, without experiencing a desire of throwing themselves headlong. Byron has noticed this feeling, and ascribed it to

"The lurking bias, be it truth or error, To the unknown; a secret prepossession, To plunge with all our fear—but where? you know not, And that's the reason why you do—or do not."

The bias to the unknown, here noticed by the poet, has little or no influence in originating this singular feeling, which is sometimes experienced by persons both physically and morally sane, as well as by the weak in mind and body. This desire or impulse to precipitate one's self, when looking downward from a very high precipice, obviously arises from no process of reasoning. Probably the suggestion of contrast may be conceived in producing it; and something tending to the unusual impression made upon the mind through the nature of the situation—to the nature of the sensation itself. That this sensation is even pleasurable—that it is attended by a sort of fascination—is admitted by those who have experienced it; and, with many persons, the desire is so strong as to require the active exertion of reason to overcome it. That it causes a physical as well as a moral effect—that it affects the circulation in, as well as the manifestations of the brain, is shown by the vertigo which accompanies it, and which often occurs without the desire of self-precipitation or destruction. Indeed, I doubt much whether or not the feeling produced in the mind by this impression on the sense of sight is primarily attended by such a desire. It would seem that the sensation is pleasurable, and that it excites a desire to throw one's self headlong in the gratification of it. But reason immediately dictates that this act would be attended by self-destruction; and from this the same mind recoils with a shudder—recoils from the consequences of enjoying the feeling which the nature of the sensation had thus suggested.

This subject, although noticed by Falret, Andral, and others, has not been hitherto investigated with reference to suicide. But it is not improbable that persons who have entertained the idea of self-murder, and yet have not been able to summon resolution to commit it, knowing the influence of the sensation of looking down from a precipice upon the mind, have had recourse to it, in order to aid their weak resolves. Others, probably, in states of high susceptibility and extreme weakness of the nervous power, have followed the impulse or fascination thus produced, before reason had time, or recovered power to counteract it.

581. i. Suicide may, under certain circumstances, become almost epidemic. Indeed, an epidemic of suicides is not the least alarming phase of the subject; not that it is more frequent than it has been, without any other causes beside those just stated to account for it. Sydenham has mentioned such an occurrence, and others have taken place in more recent times. During the atrocities of the French Revolution—atrocities the most humiliating in the history of the human mind—the "damned spot" in the annals of France, which neither her science can obliterate, nor her military glory can conceal—suicides were most prevalent, owing to a variety of causes, and often to a combination of circumstances and feelings: the loss of honour, fortune, and friends; the impulses of passions, and of remorse, despair, &c. The frequency of suicides at certain periods and in particular places is caused chiefly by political changes and by commercial crises, affecting the position of numerous individuals in society, mortifying their pride and changing their prospects. Something, also, may be imputed, on certain occasions, to mental sympathy or imitation, and somewhat even to a passion for notoriety; but impatience under misfortunes and disappointments is the most common cause. M. Andral states, as proving the influence of imitation in causing suicide, that one of the inmates of the "Inвалидов" was found hanged in a particular corridor. Two days afterward, a second was found in the same place; then a third, and even a fourth.* This corridor was shut; after which no more hanged themselves. He further remarks that, not long ago, it was the fashion for people to throw themselves from the top of the column in the Place Vendome. This was, however, only a fashionable mode of committing an act which is always common in Paris, and which was not the more frequent because this mode was preferred to the other means more usually adopted. It has often been noticed, in most civilized as well as uncivilized countries, and particularly in communities closely associated by feelings and interests, as in regiments, &c.,

* [It is related that 1300 people destroyed themselves in Versailles in 1793; and that in one year, 1500, sixty perished by their own hands in Rouen.]
that a single instance of self-murder is soon followed by many. Self-murder has been often perpetrated in order to escape exposure and punishment consequent upon detected crimes. Indeed, this is one of the most common moral causes of suicide in this and other civilized countries, and instances of it are of daily occurrence. Many of the actors and prime movers in the unprecedented atrocities of the French Revolution committed or attempted suicide when they eame, in their turn, to experience a direful retribution. Criminals of all grades, by a morbid depreciation of the value of life, have sought refuge in self-murder from the accusations of conscience, the shame of exposure, and the extreme wretchedness attending conviction and the last penalties of the laws. Detection of, as well as remorse caused by conjugal infidelity, has been followed by suicide. In the one case, this act is resorted to in order to avoid the exposure and shame consequent upon detection, although remorse influences the mind more frequently in the case of the deed, than in the other, self-reproach is often the sole cause.

583. The desire of escaping from moral or physical pain, or from anticipated or impending want, is not infrequently productive of self-destruction. Under this head may be comprised seduction and despair, however produced. How numerous are instances of suicide caused by the despair consequent upon seduction, the desertion of the seducer, and all the contingent miseries, heightened by the fancied anticipations of the deserted, by the desertion of friends, and the scorn of society. Physical pain is much less frequently a cause of suicide than moral suffering. Many, however, of the ancient Stories put an end to pain by terminating their lives: thereby following the example of Zeno, the founder of their sect; and several Romans have been mentioned by Pliny and others as having adopted this course. Dr. Haslam states that a gentleman destroyed himself to escape from the pressures of guilt; he have been told by several persons that, while suffering the pangs of neuralgia, it required the utmost efforts of their moral principles to restrain them from perpetrating self-murder. Numerous instances are on record of persons who, having believed themselves suffering incurable maladies, have had recourse to suicide as a more pleasant mode of dying; this crime being committed by them under the impression that a natural death is more painful than that inflicted by themselves. It has, however, been long known, and shown by Hufeland and W. Phillips, that death from disease, even when the mental faculties are retained to nearly the last, is attended by a gradual abolition of the general sensibility that is by no means painful or distressing; the patient ceasing to exist as happily and calmly as when falling asleep, unless under peculiar circumstances.

584. 1. Suicide is often committed in states of irritation and chagrin, particularly by persons of a morose, sullen; or irritable temper. It is sometimes suggested to such persons by a desire to excite regrets or self-reproach in the minds of those who have offended them, by a feeling of revenge. Most of the suicides committed by children are caused by a desire of this kind, particularly when they follow punish-
INSANITY, SUICIDAL.—Occasions of.

moves. M. Falket mentions, among other causes of chagrin producing suicide, that of having been calumniated; and he states, that a considerable number of persons commit this act chiefly with a desire of vindicating their reputation, no other means of vindication being in their power.

548. The state of desperation into which a person influenced by the passion of love may be thrown by disappointment is actually that of insanity, at least, of moral insanity. A gentleman endeavoured to obtain the favourable notice of a lady, of whom he had become enamoured, but had not succeeded. He committed suicide by opening a vein in his arm, and, while the blood was flowing, he wrote a note with it, acquainting her with his act. She was soon after attacked by nervous fever, which was followed by insanity, during which she fancied that she heard a voice commanding her to commit suicide. Other instances of a similar kind may be adduced.

547. Some persons, during intoxication, have a remarkable disposition to commit self-murder. This disposition may be the consequence of either habitual or occasional intoxication; and it is sometimes connected with delirium tremens, or, rather, depending upon the illusions attending that disorder. Some persons, who have received at a former period of their lives severe injuries of the head, experience this disposition when even but slightly affected in other respects, by intoxicating liquors, especially if they suffer any contrariety or opposition at this time. Cases of this kind have been noticed by M. Falket and others, and by the author.

548. In instances of mutual or associated suicide are not rare, particularly in recent times. The instances of Lucius Verus, Sextia, and Polluita, during the reign of Nero, and of Sarbanapales, may be noticed among the many instances recorded in ancient history. During the French Revolution, and the wars consequent upon it, associated suicides were frequent. Nine consorts who had concealed themselves, having been discovered, determined to destroy themselves rather than serve: they drowned themselves together. The most common causes of this mutual crime are, opposition on the parts of persons who have agreed to marriage engagements entered into by young persons, want or disappointments in the married state, and family dishonour. The bodies of two young persons were found in the Seine with a piece of paper attached to them, testifying to their ardent affection, and that they perished together that they might be eternally united. Occurrences of this kind are, however, not unfrequent in this and other civilized countries; and instances are not rare of lovers committing mutual suicide, even where there was no opposition to the consummation of their wishes. In this latter case, some cause of chagrin or disappointment has occurred, and maddened the mind already disordered by one dominant passion, the suicidal intention entertained by either being adopted by the other. From the accounts of several cases of mutual suicide attempted in recent times, there is every reason to suppose that the attempt was merely simulated by one of the persons who had agreed to commit this crime: and that it had been contrived entirely with the intention of getting rid of an object no longer one of endearment. This is more likely to be the case when a young woman has become pregnant by one of those drunken, debased workmen, who prey upon females in large or manufacturing towns. This and similar instances have appeared in the public prints. A man out of work, and his paramour, have been agreed to commit mutual suicide, procured some laudanum (about four ounces), and divided it into two equal quantities. The man proposed that they should turn back to back while taking it, in order that they might not falter in the act. The female died soon after, but the man did not appear to be affected. From the evidence at the inquest, it did not appear that he had actually entertained an intention to destroy himself, or had taken any of the laudanum. Analogous cases have occurred, where carrying the suicidal act into effect, one of the parties having escaped.

549. Want and other causes of distress, and even more petty grievances, may, in states of mind but little influenced by moral and religious principles, induce husband and wife to commit mutual suicide. In the present state of society, especially in Paris, where the passions are roused and excessively gratified before reason and religion, these are so frequent that a recent instance has been related by Mr. Huxley, in his lives of self-homicides, that the attempt was made by a variety of circumstances, indeed, by all which occasion suicide or insanity. The following instances are fully detailed by Mr. Winslow: M. De Pon-
TALLA, whose son was a most distinguished officer, and married to a most extravagant woman, saw with distress the ruin she was bringing upon him. In order to save the son, the father shot the daughter-in-law, and afterward himself. A gentleman of Laveynan was married in the country to the object of his affections. He had drawn the charge from his pistols the previous night, but his servant had loaded them again the following morning without acquainting him. After the ceremony he took up one of the pistols, which he knew he had unloaded the night before, and playfully rallied the lady on her cruelty, saying, "You shall die, you tyrant! you shall die with all those instruments of death about you—" with that enchanting smile, those killing ringlets of your hair?" "Fire!" said she, laughing. He pulled the trigger, and she was shot dead. He called up the servant, and, upon his entering, locked the door, and inquired if he had loaded the pistols. "Yes," was answered; on which his master shot him with the undischarged pistol. He wrote* to his wife's father, explaining the calamity, and then threw himself upon his sword.

591. Instances are not rare of a parent or parent's conniving at, or otherwise encouraging, by homicidal monomania, killing their children, and then committing suicide. Although extreme wretchedness is sometimes the chief occasion of these occurrences, yet it is seldom the only occasion. More frequently some form of partial insanity is either the principal or concurring cause; some circumstance having occurred to excite the homicidal propensity. Dr. Gall mentions the case of a soldier, of whose wife an officer had become enamoured without succeeding in his wishes. The soldier appeared dejected and morose, but the following day appeared quite tranquil. A few days afterward he and his wife attended the confessional and took the sacrament; they dined in good spirits, and went out to walk; he expressed his strong affection for her, and inquired if she had made a full confession to the priest. He then plunged a poniard in her breast. He repaired to his house, and seizing his children, killed them with a hatchet. He afterward went to the parish guard, and deliberately detailed the whole particulars, concluding with the words, "Let the officer now make love to my wife, if he pleases!" He then stabbed himself to the heart.

592. Suicide is often simulated, with a view of obtaining a desired end; the lover threatens or seems to attempt it, to induce a return of his affection; the spoiled child, to obtain a compliance with his wishes; and the indulged wife, submission to her caprices. In such cases, either a small portion of laudanum is usually procured, and this is diluted with some fluid, to increase the apparent quantity; or a large quantity is taken, when seen by some person, or when instant aid may be obtained. Females have resorted to this plan to try the affection, or to compel the fulfilment of the engagements of their lovers; but, in cases of this kind, little more is necessary to be known than that such acts are sometimes resorted to; and that a poisonous dose may be actually taken, in order to appear the more in earnest, knowing that assistance is near, and that it will be successful. Dr. Gall considers it may be feigned in similar circumstances. I have, however, seen two cases in which fatal results very nearly followed this experiment upon the endurance of affection.

593. B. Predisponent Circumstances.—Besides the above exciting occasions of suicide, others, which powerfully predispose the mind to their influence, and to which attention has been imperfectly directed, require to be briefly noticed, namely, hereditary predisposition; states of education, of disease, of manners, and of society; exciting circumstances; injuries of the head, and physical disease; the influence of climate, of seasons, weather, and states of the air on the nervous system, and of age, sex, and temperament, &c.

594. a. The influence of hereditary predisposition in occasioning suicide is well established. In a very large proportion of instances, either self-murder has been perpetrated by one of the older members of the family, or some form or other of insanity has appeared in one or more of them. Very frequently one or both parents of the suicide have been noted for eccentricity, or the waywardness, instability, or violence of their dispositions and tempers. Instances have occurred of the children of a parent who has committed self-destruction perpetrating the same act when they have grown up, or at later periods of their existence. Even more than one—several—of the offspring have experienced this fatal disposition upon arriving at nearly the same epoch of life as that at which it was committed by their parent. Dr. Gall has observed the suicidal predisposition in several successive generations. I have known it in three generations. M. Palbet considers suicide to be more intimately dependant upon hereditary predisposition than any other form of insanity; but this is chiefly the case in respect of suicide connected with melancholia and other forms of partial insanity.

[We could relate several instances of a hereditary predisposition to suicide that have occurred under our own observation. Dr. Gall relates the following very remarkable case: "The Sieur Gauthier, the owner of various houses built without the barriers of Paris, to be used as entrepôts of goods, left seven children, and a fortune of about two millions of francs to be divided among them. All remained at Paris, or in the neighbourhood, and preserved their patrimony; some even increased it by commercial speculations. None of them met with any real misfortunes, but all enjoyed good health, a competency, and general esteem. All, however, were possessed with a rage for sui-

* The letter will show the state of mind produced by causing the death of a much-loved object, particularly as leading to suicide. This gentleman had written immediately upon the performance of the ceremony, and had concluded the note as follows: "The bride gives her duty, and is as handsome as an angel. I am the happiest man breathing." This soon afterward was written: "Two hours ago, I told you that I was the happiest man in the world; my daughter lies dead at my feet, killed by my own hand, through a mistake of my man's charging my pistols unknown to me! I have murdered him for it. Such is my wedding-day. I will follow you without her grave; but, before I throw my self upon my sword, I command my distraction, so far as to explain my story to you. I fear that my heart will not keep me. Write to me. None of them, I wish you to believe, can mention the member that he who killed your daughter died for it. In death, I give you thanks, and pray for you, though I dare not pray for myself. If it be possible, do not curse me. Farewell for ever!"
cide; and all seven succumbed to it within the space of thirty or forty years. Some hanged, some drowned themselves, and others blew out their brains. One of the first two had invited sixteen persons to dine with him one Sunday: the company collected, the dinner was served, and the guests were at the table: the master of the house was called, but did not answer. He was found hanging in the garret. Scarcely an hour before, he was quietly giving orders to the servants, and chatting with friends. The last, the owner of a house in the Rue de Richelieu, having raised his house two stories, became frightened at the expense, imagined himself ruined, and was anxious to kill himself. Thrice they prevented him; but soon after he was found dead, shot by a pistol. The estate, after all the debts were paid, amounted to 300,000 francs, and he might have been 45 years old at the time of his death."

596. b. The influence of systems of philosophy and a direct current of reasoning on the frequency of suicide is undoubted. The doctrines of Zeno and Epicurus encouraged it among the ancients. Since the revival of learning, Montesquieu, of Rousseau, of Goethe, De Stael, and others, probably contributed less than is supposed to the increase of this crime. It is, however, not to be disputed that the loose principles disseminated, and the violent feelings displayed and exerted, by the warm and passionate writings of Rousseau and Goethe, promoted this end much more than the metaphysical and moral arguments urged in favour of it. Madame De Stael has stated that the Sorrows of Werter caused more suicides, at one time, in Germany, than all other circumstances combined. Whatever of mischief has arisen in this direction from modern writings has been indirect—has proceeded chiefly from the injurious influence exerted upon the mind by an exciting, profligate, and debauching literature, for which the state of society and manners has procured a very extensive circulation; and not so much from the arguments adduced by a few metaphysical writers of more confined, although more lasting reputations. The poison instilled continually, and in wide profusion, into the minds of all classes of the community, through the media of the numerous works of passion and imagination with which the pressess of the civilized world at present labour; the taste for their perusal, which numerous circumstances of the times conspire to diffuse; and the moral contamination which they spread, or render still more deep and malignant, most sensibly dispose the mind to suicidal impulses, when subjected to the exciting causes already noticed. That the doctrine of Materialism, however, and the general skepticism to which it leads, disposè the mind to suicide, inasmuch as it weakens the belief of a future state of re-

wards and punishments, cannot be disputed. The infidelity so widely diffused towards the close of the last century, by means of the skeptical writings of that, and of a somewhat earlier period, doubtless contributed to the frequency of suicide, especially in France, during that eventful epoch; and there is every reason to believe that its influence is still exerted, although to a somewhat less extent than then.

596. c. Education and states of manners and of society may be such, as to favour, or to counteract a tendency to self-murder. If education be conducted without regard to religious and moral principles—if the knowledge of words, of things, of facts, and of phenomena be made to supersede sound principles of conduct and of belief—if the amount of knowledge communicated rise above, or reach beyond the sphere of utility and of enjoyment—if, in short, education be conducted in the manner in which I have already shown it (§ 271, 272) to be generally conducted, it will still further tend much more to increase the number of our wants, to develop our desires and passions, to augment their intensity and violence, at the same time that it removes from them those salutary restraints which prevent them from becoming dangerous to others or destructive to ourselves. The influence of education thus loosely conducted, upon the pseudo-liberal principle of rendering it acceptable to all creeds—to the Churchman, the Romish, the Presbyter, the Baptist, the Socinian, and all other persuasions, e.g. to Christian, Turk, and Jew"—proves injurious, not only in the way just stated, but also in giving rise to forced, unnatural, over-reaching, ambitious, and unprincipled states of society; and these states, in proportion as they are developed, are the parents of crime, insanity, and suicide. Throughout the community, and particularly in the middle classes, there is a constant effort to rise above the ranks which Providence has assigned, and to partake of all the pleasures and luxuries which are far beyond the means of some, and are conducive to libertinism and profligacy in many of those who enjoy them the most. The end of excessive indulgences, and of debauchery in every form, particularly when early pursued, is suicide or insanity, or the unequivocal combination of both, in many instances.

597. There can be no doubt of the pernicious principles recently inculcated, particularly among the lower orders of society, and to which the name of Socialism has been given, having already conducted, in several cases, to suicide. This doctrine, inasmuch as it unlooses the ties of society and of consanguinity, as it admits of no moral responsibility, and as it allows no expectations of future rewards and punishments, is opposed to all moral and religious obligations—it favours vice and profligacy, overthrows all virtuous and salutary restraints upon the feelings, and, by allowing without control the indulgence of the desires and passions of that what has just been shown to be the ultimate consequences of this course. In this state of society, the endearments of friends, of connexions, and even of relations, cease to exist. The ties which bind society together in harmony are broken asunder; and as soon as the race of selfish indulgence is run—as the power of enjoyment is exhausted—the mind, having no
of information and discipline, sometimes occur so much distraction as to give rise to suicide or some form of insanity. Several instances of suicide have occurred from the pursuit of subjects too abstract either in themselves, or in relation to the power of the individual’s mind. In such cases, an extreme state of irritability of temper is often evinced before the suicidal act is attempted. Indeed, the irritation produced by any difficult and perplexing circumstances, as well as by great losses and disappointments, is very apt to terminate itself in self-murder, when experienced by the weak, the indulged, the fortunate, or the undecided and wavering mind. In the present general scramble for wealth, often merely for existence, and as often only to obtain the means of retaining a position falsely usurped, or too sanguinely entered upon, the irritation and distraction which often necessarily result, not infrequently lead on to suicide. The rich man gambles in the funds, foreign and domestic, in joint-stock shares, [railroad projects] or in the prices of foreign and domestic produce, in order to double by a single speculation what he had slowly acquired by prudence or application. The poor man places his last or only stake, and his own and his family’s happiness, upon a contingency not more secure than the hazard of a dice. In either case, adverse fortune brings distraction, which reason is not always able to calm. A gentleman, who had acquired a large fortune by a long life of prudent application to business, ventured the greatest part of it in the foreign funds: he might, at one time, have sold with great advantage; but they fell rapidly; and, under the contemplated loss of £70,000, he terminated his existence. Another, similarly circumstanced, went repeatedly with the intention of selling at a time when he might have gained many thousands. His want of decision prevented him on each occasion from selling at his own advantage. The period of extricating himself had passed; and, in a state of irritation at his loss, and at his wavering state of mind, he committed suicide. But such occurrences almost daily take place; for trading and commercial transactions very generally possess, in the present day, very much of the same gambling character. Even the small capitalist is desirous of investing, or of speculating with the savings of years, in some one or other of the numerous schemes, promising large returns, conceived by those who are well aware of the existing passion for gain, and who know well how to turn it to their own advantage, but to the loss, misery, and destruction of their dupes, many of whom, in a state of distraction occasioned by their ruin, commit suicide.

600. c. Inquiries of the head, and physical disease, sometimes either predispose, or directly give occasion to suicide. Inquiries received at a remote period may give rise to it, without having previously excited any marked state of disease, or even mental disorder; and yet, upon examination after death, lesions of structure have been, in some instances, detected either in the brain or its membranes, or even in both. More frequently, however, physical disease, often slight, but still manifest, shows itself; or some degree of mental disorder, or some illusion, is evinced, of which the suicidal impulse
is only a symptom or a concomitant. In most cases, the injury which originated the mischief has been so slight as to be considered unimportant by both the patient and his friends.

601. Visceral disease has a similar influence in causing suicide, as I have shown it above (§ 309, et seq.) to exert in producing insanity. When the abdominal viscera, particularly the digestive organs, are chiefly in fault, hypochondriasis and melancholia are first developed; the disorder of these organs acting upon, or disordering the circulation in the brain. When the intention or the impulse to commit self-murder originates in primary disease of the brain itself, some form of monomania, or of mania generally either precedes or attends it. In most cases of suicide arising from visceral disease, either organic nervous energy has been remarkably depressed by exhaustion, as in the commonest cases of masturbation, drunkenness, and libertinism; or this disease has been only an accidental or concurring cause, one or more of the circumstances or occasions already noticed having been more or less concerned in producing the suicidal determination.

602. f. Seasons, weather, and climate have been generally supposed to exert some influence in disposing to suicide. M. Villeneuve considers this question. In a large number of the acts, both in Paris, Rouen, and Copenhagen, increased the number of suicides in Paris, Marseille, and Rouen; and that stormy weather seemed to exert a similar influence. The effect of warm and humid states of the air upon the nervous system is often very manifest in depressing its energies, in weakening the mental powers, and in lowering the spirits. The greatest number of suicides has been said to occur when the thermometer ranges above 75°. Dr. Berkley observes, that, on examining the tables kept at Westminster in 1812 and 1813, the number of suicides in both cities was greatest in July, and least in October. A similar result has been remarked in respect of Rouen and Copenhagen. From 1817 to 1826, the number of suicides committed in Paris amounted to 3203; of which 997 were perpetrated in spring, 933 in summer, 267 in autumn, and 618 in winter; the following being the numbers with reference to the months: January, 213; February, 218; March, 275; April, 374; May, 328; June, 336; July, 301; August, 296; September, 248; October, 198; November, 131; December, 217. November has been said to occasion greater despondency and despair, and more suicides, than any other month; yet this month, both in London and in Paris, presents the smallest number of self-murders, with the exception of October. Notwithstanding the influence of warmth and humidity of atmosphere in increasing the number of suicides, this act is much more common in the colder than in the warmer countries of Europe—France, Germany, England, and Denmark being the kingdoms in which it is most frequently committed. In the summer of 1806, 60 cases took place in Rouen, and nearly 300 in Copenhagen; the weather being warm and moist. In Berlin, 500 instances occurred in six years and a half; while at Naples it is reported, that in 1809, only 7, in a population of 319,000; and in all Spain, in the same year, there were only 16 cases. Dr. Kampf, of Berlin, has assigned the proportion which suicides bore to the population, in several places in Europe, for the year 1817. I abstract only a few cities:

<table>
<thead>
<tr>
<th>City</th>
<th>Number of Suicides</th>
</tr>
</thead>
<tbody>
<tr>
<td>Berlin</td>
<td>57</td>
</tr>
<tr>
<td>Brussels</td>
<td>58</td>
</tr>
<tr>
<td>Copenhagen</td>
<td>51</td>
</tr>
<tr>
<td>Paris</td>
<td>300</td>
</tr>
<tr>
<td>London</td>
<td>10,000</td>
</tr>
</tbody>
</table>

No just inference, however, can be drawn from returns of the suicides commited during one year only in different climates or countries; as several circumstances, either uncommon or fortuitous, may have occurred, in one or more of these climates, at that period, to increase or diminish the usual numbers, as great prosperity or adversity, plenty or scarcity, political combinations or revolutions, &c. Nor is it to climate or season that much influence is to be imputed in general; but chiefly to the various circumstances already noticed in connexion with religion, commercial speculation, and states of society. It is sufficiently established, however, that, throughout the most of Europe, and in the United States of America, suicides have become much more frequent than at the above, or at almost any preceding period, unless during the French Revolution. The number has increased in Paris from 300 in 1817, to 511 in 1818, 533 in 1819, 578 in 1820, 503 in 1821, and in the first five years of the nineteenth century, to 319 during the first five of the nineteenth century.

603. The admitted increase of suicides, more especially in this country, is not to be altogether referred to the more general influence of the several occasions already mentioned; but in a great measure, also, to the increased numbers and circulation of those prints which abound with the disgusting details of profligacy, crime, and suicide. Dr. Bowles justly remarks, "that the noble taste has become more and more vitiated and debased by this species of gratification; and nothing is found so attractive as tales of horror and of wonder, every inquest that is held upon a person who has destroyed himself being read with great avidity." The ludicrous police reports of criminal acts furnished by the daily panderers to our more debased desires, scenic representations of successful vice and crime, and the constant circulation of suicidal acts in all the periodical prints, serve most essentially to familiarize the minds of the lower classes especially with these acts, and to diminish the detestation with which they are generally viewed at first, until the moral sensibility becomes altogether blunted by their perusal. The repeated presentations of these crimes to the minds of the ignorant and vicious, often not only divested of their attendant horrors, but even clothed in attractive garbs, readily suggest a recurrence to them in circumstances which cannot disgust, irritate, or distraction. Literature, if, indeed, the trash vomited hourly from the steam-press should be dignified with the name, has become the most debased of modern ways of traffic; and its chief end, in the present day, is to encourage those feelings and desires by means of which its diffusion and profitable returns may be augmented. In order that this may be the more surely effected, it is requisite not only to produce and circulate to the community, and of pecuniary profit to the writers and proprietors—that the criminal appetite may be pampered and increas-
ed; that each successive meal of criminal indulgence may be followed by a greater relish and a more craving desire for its repetition—foreign countries are ransacked to furnish what our own cannot supply in sufficient frequency and piquancy.

604. g. Age and Sex.—The frequency of suicide varies at different ages. During the early epochs of existence, the sanguine expectations, which are generally indulged, and which soon take the place of temporary despondency and distraction occasioned by disappointments and losses, tend to diminish the number of suicides. In the middle and more advanced periods of life, sensibility becomes exhausted or blunted, whilst cares and anxieties increase in number and intensity; and the attachment to life is much impaired. The desire of life afterward increases, and frequently in proportion as old age advances. M. Falker has shown that it is from 35 to 45 that the greatest number of suicides occur. Of 6782 cases, 678 were under 20 years of age; and of this number 487 were between 15 and 29, and 181 below the age of 15. A child of nine or ten years old* wishes to destroy itself, but this is the only case of so early an age. After 45, suicide becomes more and more rare; and above 70, there are scarcely any instances of it. The father, however, of the celebrated Barthez killed himself at the age of 90; and his son, when he was old, wished to follow his example.

605. Both sexes display the suicidal tendency, but the male sex most frequently. M. Esquirol considers that the proportion of male to female suicides is nearly equal; but there are differences according to countries, arising from the greater or less influence of many of the circumstances shown to favour this act. Thus, in France, there are more suicides among women than in Germany. It has been observed, both in England and on the Continent, that nearly two thirds of suicides are unmarried. This state, therefore, is much more favourable to self-destruction than the married condition.

606. Hand and naval officers, in particular, among persons of the melancholic temperament and bilious constitution, with a pale or sallow, or yellowish complexion, and hard or sharp features. Such persons are more liable than others to disorders of the biliary and digestive organs. But this crime is not infrequently committed by the nervous and irritable, and even by the sanguine and plethoric. Females of this latter constitution occasionally attempt or perpetrate self-murder just before or during the catamens, or from some irregularity of this evacuation. M. Esquirol states, that the scrophulous diathesis is remarkable in a number of suicides.

607. i. Several tables, showing the frequency of the several causes of suicide, have been published, but are obviously deficient in precision, as well as in the truth of the data upon which they are based. Moreover, this act is not generally prompted by a single circumstance or cause only, but by the combination, concurrence, or succession of several. With great allowances and reservation, the following may be adduced, in the absence of more accurate information, as to the comparative influence of the circumstances occasioning this crime. The suicides committed in London, between the years 1779 and 1830, have been stated (London Med. and Surg. Journ. vol. v. p. 51) to be 3357 men, and 2853 women; and the causes have been thus assigned:

<table>

According to M. Falker, of 6782 suicides committed between 1797 and 1834, 254 were from disappointed love, 157 being in women; 92 from jealousy; 125 from the chargin caused by calumny; 49 from a desire, without the power, of vindicating character; 122 from disappointed ambition; 222 from reverse of fortune; 16 from self-love; 150 from gambling; 287 from crime and remorse; 728 from domestic distress; 905 from poverty; 16 from fanaticism. Upon comparing this table with the preceding, very great inaccuracy will be apparent, proving the very little dependence to be placed upon numbers in medical details. Of 500 suicides committed in Berlin during six years and a half. Dr. Caspar states that 14 were caused by offended honour; 61 by insanity; 54 by drunkenness and dissipation; 39 by dread of punishment; 18 by debt and domestic trouble; 12 by love; 11 by matrimonial strife; 3 by disgust of life; 12 by disease and pain; 1 by religious excitement; and 282 by causes which were not specified.

608. C. The modes selected of quitting life may be briefly noticed. These, in many instances, have some reference to the occupation or profession of the suicide. Thus, military and naval men, over a considerable proportion of these modes, select poison, the convulsion, or other violent means of destroying life. Fire-arms and sharp instruments, particularly pistols, razors, knives, and daggers, are most frequently employed by men. Drowning, hanging, poison, and precipitation from windows or great heights, are the means of self-murder most commonly resorted to by women. In France, asphyxia, by the vapour of burning charcoal, is selected by females, and more of late by males, particularly in cases of associated suicide. Hanging, drowning, and poison are, however, the means most frequently resorted to by both sexes. The choice thus made does not always depend upon what may be supposed to cause the easiest or the most rapid death; but, probably, upon that mode which offers the greatest facility, or is the most readily carried into effect in moments of irritation, distraction, or depression. It is remarked that a very large proportion of suicides by drowning in London are committed by persons residing in the vicinity of the river and of the Regent’s Canal.

609. Dr. Caspar states that of the 525 cases of suicide already noticed, 231 were committed by hanging; 163 by shooting; 69 by drowning.
17 by cutting their throats; 20 by stabbing; 19 by throwing themselves from windows; 10 by poison; 2 by opening an artery. M. Esquirol gives the following details of 205 cases of suicide in females: 49 by hanging and strangulation; 45 by precipitation from windows, &c.; 2 by fire-arms; 18 by sharp instruments; 7 by poison; 5 by asphyx y; 48 by starvation; 31 by drowning; 49 by stab-wounds 45 to heights, 15 to unascertained, 60. Of the cases of suicide by poison, 26 were by arsenic; 19 by opium; 3 by oxalic acid; and 113 by other poisons. During the year 1841, 184 cases of suicide were published in the Journal of Commerce of this city, as having occurred in different parts of the United States; of which 154 were men, and 30 women—the ages ranging from 16 to 81. The largest number occurred in the month of July—26. The quarter commencing with July numbered 66; that commencing with April, 48; October, 36; January, 32. They were distributed through the different states of the Union in very unequal proportions; New-York having furnished 44; Pennsylvania, 25; Massachusetts, 29; Louisiana, 13; Maine, 9. In 29 cases, mental derangement was assigned as the cause; in 9, habitual intemperance; in 12, depression of mind; in 4, domestic trouble; 3, Milkerin; in 3, dissipation; weariness of life, jealousy, and remorse, each 2; while dyspepsia, ill-health, seduction, indemnity of wife, murder of neighbour, delirium tremens, apprehended insanity, fever, dread of death, want of employment, poverty, violent passion, love, disappointed love, unlawful love, gambling, orphanage, each, is assigned as the cause of one case of suicide. In 101 cases no cause was assigned. In 64 cases, suicide was committed by hanging (54 men, 10 women); in 26, by drowning (17 men, 9 women); in 25, by shooting with gun or pistol (all men); in 25, by cutting the throat (21 men, 1 woman); in 8, by taking laudanum; in 5, by opium; 1, morphi ne; 2, narcotic poisons; stabbing with poisoned stiletto, 1; by arsenic; 4; prussic acid, 1; corrosive sublimate, 1; opening an artery, 2; by cutting the arm nearly off, 1; by jumping from height, 1; by wounds and exposure, 1: total, 142. By 38 men and 16 women were foreigners, the rest Americans: 89 were married, 20 single; 1 widow; 1 widower; the remainder not stated.

No accurate estimate, however, can be made from these data as to the number of suicides committed throughout the country, or in any particular portion of it, as a large majority, it is presumed, are never published. Besides, those found dead and drowned are not included among suicides, and yet we know that drowning is one of the most common modes of terminating life in the suicidal. The annual number of suicides in the city of New-York for the last 33 years, according to the Reports of the City Inspectors, is as follows:

<table>

These, however, constitute, it is believed, but a part of the actual number of suicides committed, as many reported under other heads, as "sudden," "accidental," "apoplexy," "unknown," &c., doubtless belonged to this class. The population of the city was, in 1805, 75,770; in 1810, 96,373; in 1815, 100,919: in 1820, 123,876; in 1825, 165,706; in 1830, 202,250; in 1835, 270,989; in 1840, 312,553.

610. ii. Arrangement of the Causes of Suicide.—A. Circumstances predisposing to this Act. —Hereditary predisposition; the melancholic, bilious, and irritable temperaments; the middle period of life; the male sex; the unmarried state; indulgent and injudicious education, without reference to moral and religious principles; masturbation and sexual excesses; drunkenness; immoral amusements and exhibitions; the perusal of loose productions, and of criminal and suicidal details; idleness and indolence; habitual recourse to powerful mental excitement; idiocy, or a disbelief of a future state of rewards and punishments; states of the air, or of the season, or weather, occasioning depression of the nervous energy.

611. B. Circumstances exciting this Act, or occasional exciting Causes.—A. Direct occasional Causes.—The passions and feelings, particularly love, conjugal affection, jealousy, ambition, humiliated pride, sentiments of dishonour, loss of female virtue, feelings of shame, violent anger, fear, terror, and remorse; gambling, either from want, or a desire of strong emotion and excitement, or covetousness; imitation, or mental infection; fascination on looking down from precipices; chagrin, desperation, or distraction; reverses of fortune; disappointments, domestic unhappiness, and family dissensions; the several forms of moral and partial insanity, especially melancholia and religious insanity; the different states of general insanity, particularly mania and puerperal insanity; and the delirium consequent upon numerous physical maladies.

612. b. Indirect occasional Causes.—Bodily diseases of various kinds; violent pain, and incurable maladies; the abuse of intoxicating liquors, of opium, of mercury; diastase of life connected with the change of life in females, and the loss of attractions from smallpox, &c.; ennui, or treadmill, consequent upon an effeminate and indolent state of existence,
or a state of mind in which the passions are without an object to excite interest, or are incapable of being roused to feel an interest; want, and its attendant miseries; anticipated exposure or punishment; motives of revenge. 613. c. General Causes.—Governments which furnish numerous examples of violent deaths in the execution of their laws, or which possess a sanguinary penal code; the military spirit, and military governments; republican and democratic constitutions; political combinations, revolutions, and catastrophes, especially those which, as breaking out in 309 B.C., of excitation and turbulence has passed away; religious fanaticism, and, still more, the want of religion; superstitious doctrines; unsound religious and philosophical opinions; depraved states of society, of manners, and customs.

614. C. Causes most influential in this and other Free and Commercial Countries.—The range given to the social passions; the hazards and losses in mercantile speculations in the funds, and in joint-stock companies and consuls; the enmity of a nation and the debasement of families; habits of dissipation; the indolence and ennui consequent upon wealth and sated enjoyment; the importance attached to public opinion, and the instability of that opinion; the violent shocks and collisions of opposing parties; the inactivity to which military and naval persons are reduced during times of peace; the enthusiasm of religious and philosophical sects; the immorality of the literature and scenic representations of the age; and the details of crime and of suicide, which constitute a principal part of the daily reading of all classes of the community.

615. iii. Pathology.—The Lesions observed in Suicides upon Dissection.—These, in many cases, will necessarily be the same as have been already described in cases of manifest or fully-developed insanity. In many instances the lesions will have no reference to the production of the mental disease, but in others in the enucleated vascular lesion, and in others the consequences of previous disease, which had nothing to do with the subsequent occurrence of a suicidal impulse. The physical disease may have, in some cases, predisposed to the indulgence of a suicidal intention, by weakening the vital manifestations, and particularly the powers of mind; but, even in such cases, the mental emotion is to be looked upon as the efficient cause of the act. Without, however, attaching much importance to the influence of the structural alterations in producing it, as far as they have been yet investigated, unless when it is unequivocally dependent upon insanity, I shall briefly state those which have been most frequently noticed. Heister observed lesions of the liver, gall-bladder, and pancreas. Falset considers alterations of the liver to be rare; M. Esquirol remarked displacement of the colon; Osanger, congestion of the vessels of the brain, and chronic inflammation of the intestines; Cuvier, Alberth, and Osanger, diseases of the heart; Greneau and Gall, thickening and condensation of the cranial bones; Home, dilatation of the sinuses of the dura mater, and effusion of serum in the ventricles, and between the membranes; Recamier and others, thickening of the arachnoid and dura mater, with osseous depositions in the latter; Falset and Fouril, trusses of vascular irritation and excitement in the membranes and substance of the brain; and Frank and Esquirol have failed, in many instances, to detect any appreciable lesion of any organ. From 1333 inspections of suicides, the following results have been given, but with little appearance of precision or accuracy: Thickening of the cranial bones in 150; bony exarctances from their inner surface in 50; disease of the membranes of the brain in 170; inflammatory appearances of the brain in 90; simple congestion of the brain, or the brain in 10; softening of the brain in 100; disease of the lungs in 100; lesions of the heart in 10; disease of the stomach in 100; alterations of the liver in 80; lesions of the intestines in 50; suppression of the natural secretions in 15; syphilitic disease in 8; and no apparent structural change in 100. (See § 223, et seq.)

616. B. Physiological Pathology.—Suicide may be viewed, in many cases, even when proceeding from the presence of mind, as the result of deranged action of the vessels of the encephalon and of its membranes, consequent upon altered sensation or excited emotion; but it cannot be considered as essentially and exclusively depending upon this pathological cause. The intellectual and moral phenomena, which either directly or indirectly give rise to the suicidal determination, cannot be shown to be always the consequence of vascular lesion, or even of excited vascular action, although they often lead to such lesion, from the intimate connexion existing between the mental manifestations and the organic actions. The numerous instances in which suicide is attempted, from ebullitions of temper, or gusts of passion or feeling, and in which the means of self-destruction fail of accomplishing the intended end, leaving those who made the attempt calm, resigned, and happy at having failed in their intentions, fully prove the absence of established difference between these and cases depending upon real and confirmed insanity, which we never find so immediately and permanently cured as those instances of attempted suicide fortunately are, and cured by the same means as so generally fail in every form of suicide proceeding from manifest insanity, wherein it may be presumed that lesion of vascular action in the encephalon, as well as of organic nervous power, actually exists. We are therefore obliged to conclude that mental power may be, hereditarily or originally, or from the influence of the predisposing causes of suicide, so weak, or so morbidly impressee or susceptible, as to give way to the impulses to this act, arising out of any of its exciting causes, either before the controlling powers of mind have had time to react and to resist the suicidal impulse, or from the circumstance of those powers having been so weakened as to be incapable of sufficiently resisting this impulse when excited by powerful or by combined causes. In these cases, this act is to be imputed to the state of mental energy—to a constitution of the mind arising out of hereditary conformation, and the prolonged operation of predisposing circumstances, rather than to any appreciable disorder of the cerebral circulation.

617. On the other hand, it ought to be ad-
mitted, that incessant application to study, to business, to political events, to the views and interests of parties and sects, to the discharge of public duties, or to the support of public measures, as well as many of the numerous causes above specified, will so far overturn the equilibrium of the circulation as to occasion an ephelism of the vessels of the brain and its membranes, verging upon inflammation, if not actually amounting to it. Such excess of this organ may betray itself by a slight delirium, or partial or slight form of mental alienation, by general irritation or nervousness, or by slight fever, or by burning headache, with little other disturbance of the system; or it may evince itself by a peculiarity of manner, by the unusual direction of ideas, or by the state of temper and feelings. If, during this condition of disorder, the ideas should be led to self-destruction, or if any circumstance, whether domestic or public, should occur, which, by exciting the temper or affections, may suddenly increase the cerebral disorder, as well as the consequent morbid ideas or resolution, suicide may be attempted; or if, either after or before the ideas prompting to this act have suggested themselves, the individual should be placed in a state of comparative inactivity, and his ideas be allowed to flow in a direction most likely to suggest to him the resolution to resort to self-murder, the event, although more maturely contemplated, may not be the less certainly accomplished.

618. Suicide, viewed in this direction—the only one in which it can be considered with propriety as a physical disease—may be attempted by the strongest and most accomplished minds, although much less frequently than by others educated without just principles, and undisciplined in the school of difficulty, disappointment, and misfortune. It is, under these circumstances, like other mental alienations, the result of vascular disorder in an organ intimately connected with the intellectual and moral manifestations. We cannot, therefore, be surprised that persons subjected to the most important and harassing duties, and undertakings, and anxieties, should suffer in that organ which is the medium or instrument of all these distracting operations; and that the consequences resulting from them, both to the organ itself, and to the faculties related to it, should be exactly those which these causes are most likely, both from theory and experience, to produce.

[This subject derives great importance from the fact that policies of life insurance are held to be valid in cases where suicide has been committed in a state of insanity, but forfeited if the act is done in an opposite mental condition. The doctrine that suicide is always the result of insanity must be abandoned as altogether untenable; and the same evidence of mental unsoundness, in doubtful suicidal cases, should be required as would be necessary, in a court of justice, to establish the validity of a will. Suicides must be divided into two classes, founded upon the different causes or circumstances by which they are actuated: the first, including those who have committed the act from the force of moral motives alone; the second, those who have been affected with some pathological condition of the brain, excited or not by moral motives. The act itself, apart from the circumstances under which it is done, should never be quoted as positive proof of insanity; although we believe that the cases are few in regard to which it would be safe to affirm that the excitement of the organic action of the brain and nervous system, which accompanies the perturbation of mind leading to the act, had not transcended the limits of health. Suicide, as an act of self-destruction. What renders the question a difficult and very complicated one, is the admitted fact, that suicide is often committed under the impulse of mental derangement, even when mental derangement would not otherwise have been suspected. But this subject will be discussed in the ensuing section. (See "A Treatise on the Medical Jurisprudence of Insanity," by J. Ray, M.D., 2d ed., 1844.)]

M. Andral remarks, "that man is sometimes possessed by a sentiment which tends to self-destruction. This feeling is designated 'Suicidal Monomania.' It is not always the result of mental alienation: some persons put an end to their existence who are not monomaniacs," &c. Now this is a contradiction, both in terms and meaning, not very consistent with the reputation which this writer has obtained in this country. After what has already been stated, it will be evident that suicide is either the result of some form or other of general or partial insanity, or of some state of excessive passion or feeling which does not, in the usual acceptance of the term, amount to insanity; although such passion or feeling may, at the moment, as completely overpower reason and self-control as any form of monomania. If moral insanity, which I have described above as constituting a form of partial insanity, be farther extended than it has been already, and be considered as being confined to those moral states of aberration which either are slowly developed, or are perniciously entertained, or both, be made to comprise those momentary states of excessive passion or feeling which are suddenly excited by intense moral causes, and which, in well-regulated minds, soon subside, without any very appreciable impairment of reason and self-control, but which, in impressionable minds accustomed to control, to disappointments, to losses, and distraction, often give occasion to insanity or suicide—then those cases of this act that thus originate, and that seem the least of all dependant upon insanity, may be considered as actually the result of the insane state; and to these the term suicidal monomania, or any other equally expressive of the insane condition, may be applied. But if we thus extend the meaning of moral insanity, we must stretch it still farther, and make it comprise, also, every act of excessive passion or anger, even the act of just indignation aroused by insult; especially when insult is repelled by a rettributive blow which may endanger the life of the aggressor. It may be granted that, in a few cases, suicide is the first symptom of insanity, the patient having been previously undisordered in mind. But this is an assumption rarely admitting of proof, unless where the act has been attempted only, and not carried into effect, other insane acts being afterward committed. M. Andral, as just noticed, admits that persons destroy-them-
selves as the result of other circumstances than the want of reason; and yet he terms suicide thus occasioned a form of partial insanity, and designates it “suicidal monomania.” Self-murder may depend on many grades of insanity, and may, as I have shown, be the consequence of the several forms of moral insanity; but when no degree of this malady is manifest beyond this act, it will, much lead to a view of it as the consequence of intense passion or feeling—the impulse to self-destruction arising out of these emotions overpowering, for the moment, the dictates of reason and the control of the judgment. According to this view, the term here used may still be said to be appropriate; and it may be allowed to be so, if the word insanity be extended to the utmost, so as to comprise the momentary impulses of passion, feeling, and mental depression. Suicide committed, or even attempted, under such circumstances, may then be viewed as a proof of insanity, or be considered as a form of moral insanity, or, as M. Anderson has done, with various contradictions of himself, as a monomania—the aberration of mind consisting only of the impulse to self-destruction. If, on the other hand, insanity is to be viewed in a less comprehensive sense—if it is not to be extended to those momentary impulses of excited or desperate passions, which especially are probably the results of violence against others or ourselves, and which only for a time overpower reason and judgment—then suicide, committed or attempted in the circumstances referred to, cannot be justly viewed in the above light, but should be looked upon as an act of passion, that, like other violent acts, cannot, consistently with good morals, or even with the safety of society, be treated as an insane act. In the forms of moral insanity noticed above (§ 69, et seq.), it has been shown that, attempted or even committed, or less gradual development, the moral aberration is generally pertinaciously adhered to; and that, when suicide follows, the connexion of this act with such aberration, and with impairment of the mental powers, is very obvious; but where disorder of the moral manifestations, or of the judgment, is not apparent, suicide being attempted, from a desire to escape the punishment of crime, or from humiliations of any kind, or from divisions of the heart, distraction, or depression suddenly excited—from some moral shock, the dependance of this act upon a state of mind actually insane is not so manifest; and it will be to the benefit of the community not to consider it, in such circumstances, as the result of insanity. Numerous instances have been recorded of persons who have had recourse to suicide from imitation or fascination—-from the mental infection caused by the self-murder of some one, however little noted for station or character. In such cases, a predisposition to this crime may have already existed, or circumstances may have occurred to favour the suggestion of ideas of self-destruction; the suicidal disposition being confirmed or determined by perusing the details of this act, generally so lavishly furnished by the daily and weekly prints. In some of those occasions of imitative or epidemic suicide, the moral infection has been arrested by restricted unusual indignities on the bodies of those who perpetrated the crime; thereby showing that this act was not, as respected many of the cases which occurred in these circumstances, altogether the result of the absence of reason, or that the persons who had committed it could not be accounted irresponsible agents.

[Dr. Ray remarks, that when a person in good health, and surrounded with everything that can make life dear to him, deliberately destroys himself with his own hand, by striking an objection to the momentaneous consideration of motives or scrutiny of private circumstances can satisfactorily explain it, and we are obliged to consider it as a form of partial moral mania. Where a person labours under a suicidal monomania, we believe it may be generally recognised by other signs; as deep melancholy, eccentricity of conduct, &c. Most of these individuals labour under a constant dejection of spirits, pressaging nothing but evil; imagining they have committed some heinous offence; that their friends have forsaken them, and are watching their movements; that they are hated and despised by the world; they complain of neglect; become morose and taciturn; utter bitter complaints; weep; say they have committed the unpardonable sin; that their damnation is inevitable, &c. More or less bodily derangement is usually present in these cases, as a weak and irritable nervous system, quickened circulation, imperfect digestion, and especially derangement of the corporal parts. After this state has continued for some time, the mental derangement becomes more prominent, and the wretched victim begins to see visions, and to hear strange voices, and believes that he has communications from superior beings. All this time the idea of self-destruction is frequently, if not constantly, before the mind, and unless the patient be narrowly watched, he will finally succeed, after various attempts, in accomplishing the purpose. —R.]

620. Jv. Prognosis. — The suicidal determination is generally removed with difficulty; and more especially when it is consequent upon any of the forms of moral and partial insanity, or is connected with chronic mania. In the advanced stages of melancholia particularly, as well as in several other states of both partial and general alienation of mind, the determination to commit suicide may be concealed, frequently in so artful a manner as to lure the suspicions of the most careful attendants; but it is never removed, unless the mental disorder, of which it is the associate, be altogether cured; and even in this latter case, the incipient return of insanity, or even the occurrence of some of the symptoms usually preceding its return, may be attended by the suicidal attempt. When suicide, however, is the consequence of violent passion and feeling—of some shock which the mind is incapable of enduring at the time—when it proceeds from temporary causes, and more especially where the attempt has been made when the mind has been subjected to the first impression of the direct occasional causes (§ 661), and when the predisposing causes are not powerful, nor retain their influence in the mind—then well-grounded hopes of the removal of an inclination to suicide may be entertained. When this act has been attempted from causes favouring an unusual determination of放弃 to the head, or perturbation of the capillary circulation of the brain, as violent mental excitement, controversy, distrac-
tion, or intense mental exertion, the violent shocks of revolution, or the collision of oppo-
sing parties, &c.—then an appropriate physical

treatment, especially that directed to the
removal of, increased action in the brain, and
of the stopped secretion and excretion, will gen-

erally, also, remove every disposition to a re-
petition of the attempt; unless, indeed, similar
exciting causes again come in operation. In
all cases of attempted suicide from powerful
passion or feelings, the possibility of some form
of insanity, particularly melancholia and mania,
being soon afterward developed, should be antici-
pated, and the more especially if mental disor-
der or a suicidal propensity has appeared in any
of the members of the patient’s family. In fami-
lies thus circumstanced, the suicidal attempt is
sometimes the first manifestation of insanity.

621. v. Treatment.—The treatment of a
suicidal disposition in most cases, and espe-
cially in those which are connected with the
more obvious manifestations of partial or gen-
eral insanity, is to be conducted on nearly
the same principles as have been explained with
reference to these states of disease. In such
cases, the suicidal determination is only a part
of the disorder, requiring the increased care of
the attendants, and greater caution on the
part of the medical advisers, particularly during
apparent convalescence and recovery, and the
strictest precautions against a return of the
malady, and upon the appearance of symptoms
usually preceding this occurrence; but in other
respects demanding little or no modification of
the physical and moral means of cure already
advocated in the treatment of mental disor-
der. The few observations, therefore, which
it will be necessary to offer on the treatment
of the suicidal impulse or disposition, may be
divided into those which refer, 1st, to the
careful removal of the circumstances which
suggested or occasioned it; 2dly, to the physi-
cal means which should be resorted to; and,
3dly, to the preservative measures or means of
repression, moral and legislative, which may be
instituted.

622. A. The avoidance or removal of the cir-
cumstances or causes which suggested or oc-
saioned the suicidal attempt is the basis on
which both physical and moral means of cure
must necessarily be placed. This end, however,
cannot always, or even generally, be attained;
particularly where certain events have pro-
duced a powerful or moral impression on the
patient’s mind, or where the attempt has pro-
ceeded from an insane delusion. Under the
former circumstances, we can only endeavor
to counteract or to weaken the emotion pro-
duced: in the latter case the delusion will dis-
appear only upon the removal of the mental
disease. A knowledge of the several occasions
of the suicidal determination will sometimes
enable the physician to recommend means to
neutralize their injurious influence, even when
he finds that the patient is incapable of escaping
from their baneful influence on his mind.

623. h. Physical means should be
directed chiefly with reference to the symptoms
indicating the condition of the circulation in
the brain, and the state of organic nervous
power. These symptoms should be carefully
investigated and considered in connexion with
the phenomena more intimate connected with
the suicidal impulse, and with mental disorder.
If the impulse has followed any of the states of
moral insanity, or melancholia, or other forms
of alienation, the treatment, physical and mor-
al, is altogether the same as already described;
stricter precautions during the insane state, and
the moral upon the restoration of the patient to society,
being requisite. In many of these cases, parti-
cularly those depending upon melancholia, and
where the suicidal determination has appeared
in consequence of the circumstances which
have been shown generally to occasion in-
creased action of the cerebral vessels, and of
violent passion, chagrin, or distraction, general
or local vascular déplétion, purgatives, refriger-
ants, and any means suitable to counteract
all the symptoms of enervation and violent
emotion, tension, or constriction, and uneasiness so
frequently experienced in the head; the disorder-
ed action of the carotids and cerebral vessels,
and the appearance of the eyes; the tempera-
ture of the scalp, and the changes frequently
observed after death—all evince the propriety
of repeated blood-lettings, especially in the im-
mediate vicinity of the brain, or of the hemor-
rhoidal vessels. Cold affusions on the head,
cold applications, the shower bath, purgatives
conjoined with sedatives and repressants, re-
grerants with diaphoretics, occasionally pow-
erful or deobstruent cathartics, and sometimes
emetics, anodynes with antispasmodics, dry
cupping, setons, blisters, or other derivative
applications on the nape of the neck, or on the
hypochondria, and, after depletions and deob-
struent evacuants, restoratives and tonics—
constitute, in such cases, the chief physical
measures, but they require to be varied
appropriately to the peculiarities of individual
cases, and to be aided by hygienic and moral
measures, according to the circumstances or
motives occasioning the suicidal attempt, and
the form of insanity of which it may have been
a manifestation. In most instances, however,
exercise in the open air, manual and mental
occupations, travelling, active amusements, hunt-
ing and horseback exercise, visiting watering
places, &c., living in a dry and equable atmo-
sphere of wind, and of moderate intellectual influ-
ences (5 500, et seq.) already fully de-
scribed, should be brought in aid of the more
strictly medical agents.

624. After vascular dépletions, where they
are indicated, emetics, even a repetition of
them, are often of great service, where the
suicidal propensity has recently appeared; and
if much bilary disorder is present, a dose of
carbon, followed by stomachic purgatives,
and subsequently a vegetable, as the prepara-
tions of valerian, will often be useful. Warm
bathing, and cold sponging the head during the
bath, or the cold affusion on the head, and the
shower bath every morning, the feet being immersed in warm water, are also
important, and generally appropriate remedies.
The suicidal determination is very frequently
associated with, and sometimes the conse-
quence of prolonged sleeplessness, arising from
the remote causes of the mental affliction. In

* (That attempts at suicide are often occasioned by a
fullness of the cerebral vessels, is evident from the fact that
the loss of blood occasioned by an unnatural attempt to sev-
er the large vessels of the neck has effectually removed the
propensity to destroy life; the same effect, also, has fre-
quently followed a plunge into cold water for the purpose
of drowning.)
these cases, a recourse to narcotics becomes requisite; the selection and combination of them, as well as the particular indications connected with the use of them, being guided by the principles already explained (§ 473, et seq.).

625. C. Surveillanee and Restraint.—Whenever a suicidal propensity appears, the disease should be treated, as respects seclusion and control, in every respect as above recommended (§ 388, et seq.), and the patient be placed in the charge of an experienced and vigilant attendant. Care should be taken to remove from his person and apartment every article by means of which he may carry his design into execution, and the windows, doors, &c., should be secured. Even the bed-clothes should be carefully examined, lest portions of them should be torn off for the purpose of self-strangulation.

Although melancholic and other insane persons are not so likely to attempt suicide when others are present as when alone, yet the former circumstance is not always sufficient to deter them from it. Dr. Berrows adds an instance in which a medical man, while another person was present, attempted to open the femoral artery with a razor and wove. His father and grandfather had both destroyed themselves. He had never met with any circumstance to occasion him particular disquietude; but at the age of forty-five he became dyspeptic, low-spirited, and listless. He expressed extreme sorrow for the attempt on his life; yet, in three or four days, he seized a razor from the dressing-table, while his keeper’s back was turned, and at one stroke divided one of the carotid arteries.

626. A person who has once entertained a suicidal propensity should not be confined in, however strongly he may express his regrets at having made an attempt to carry it into effect, as long as the feelings continue either more than usually blunted or morbidly sensitive,—while the bearing of the patient continues embarrassed or perturbed, or his ideas confused, unsettled, or disturbed. If he complain of heats and flushings in various parts of his body, or partial sweats; if his eyes betray timidity, fearfulness, distrust, and restlessness, other attempts will be made. Although the patient may have recovered his serenity of mind, a return of these indications ought to call for the most watchful solicitude from the medical and other attendants; for, although the patient may not seem to entertain any ideas of suicide, or may actually not feel any inclination to commit the act, yet the occurrence of an opportunity, or the accidental sight of an instrument of self-destruction, may give rise to the impulse, which may instantly be carried into fatal effect.

627. Whenever a great calamity has overaken a person of weak resolution, of the melancholic, nervous, or irritable temperament, and especially if insanity or suicide have occurred in any branch of his family,—particularly if the affliction is sudden or recent, and productive of great mental distress, or of singularity of conduct or conversation,—the probability of his attempting suicide ought not to be overlooked. The design, however, in these circumstances may be concealed from superficial observers; but the physician will detect, in the expression of the eyes and looks, in the suppressed struggle to conceal his emotions, in the constrained respiration, and the accelerated pulse, or irregular pulse, sufficient causes to inspire the utmost vigilance on the parts of both friends and attendants. In such cases, the previous character and fortune of the patient may tell every fear; but the greatest talents and the strongest minds have yielded to intense emotion. The moral character and disposition of the patient may have been changed before the suicidal propensity was developed; many of the circumstances to which this propensity had been commonly imputed actually occasioning a state of moral or partial insanity, of which the suicidal intention was only an attendant or consequence. Moreover, character and disposition only should not afford any grounds of confidence in persons subjected to the more intense emotions, or to the more energetic occasions of this act; more especially if they have not formerly experienced events requiring the exertion of mental energy and fortitude. Many men, eminent for talent and courage, and carried to suicide when overtaken by adversity. Several instances of this kind occurred, during an early part of the present century, in this country, and have been adduced by some writers as proofs of the strongest minds being liable to give way to the suicidal impulse. But eminence and talent are distinct from fortitude in adversity; and even from that constitution of mind to which the terms strength of mind or force of character have been heretofore applied. It is doubtful how far these persons* were really possessed of these latter characteristics, inasmuch as they are usually acquired in combating difficulties, in patiently bearing adversity and disappointments, and in controlling the more poignant emotions which difficulty and adversity call forth. In this school, where true force of character and fortitude are chiefly, if not only to be acquired, these persons may not have been sufficiently disciplined; for, when the course of events has been unpropitious and rapid, however eminent the abilities which have contributed to it may have been, sudden adversity may endanger the perfect sanity or fortitude of a mind unaccustomed to sustain and unprepared to meet its shock.

628. There is no part of a physician’s duty which is so difficult, as Dr. Berrows has remarked, as to decide upon the exact time when he may place confidence in a convalescent suicide. If the patient’s mind be yielded prematurely, the act, which time and policy employed to avert, may be immediately perpetrated; while, if it be withheld when the patient feels that he has been labouring under a delusion, the effect may be as much as to endanger

* The distinguished acconcheur who attended the Princess Charlotte during her fatal confinement, destroyed himself under the sudden impulse of grief and mortification. The sight of a pair of pistols in the room to which he returned for repose was sufficient to a mind harassed by long and anxious attendance, and overwhelmed by the responsibilities of his situation, to provoke a desire, which he may never have felt before, to die by his own hands. Sir Samuel Romilly, the eminent English barrister, committed suicide immediately after sustaining a severe domestic bereavement—the loss of a beloved wife. In both these cases we should, perhaps, be warranted in believing that reason was temporarily overthrown.—(Rat.)
a return of his delusion, or of the suicidal propensity.

629. When the suicidal determination cannot be carried into effect by any other means, owing to the care of the attendants, the patient sometimes determines to starve himself. Management may do much in overcoming this intention. Kind entreaties and stratagems may be resorted to; and tempting articles may be set before him, or left within his reach, without any farther notice. If he partake of it, no reproof should be made, but the same course pursued. If these means fail, the stomach-pump ought to be resorted to.

630. M. Falet observes, that noisy or immoderate gayety irritates melancholic suicides, or, at best, affords only a transient pleasure, followed by increased misery. He states, that he has accompanied these persons to the theatre and to the hospitals, in order to compare the effects produced upon them by these opposite situations. The public mind is made to think the really afflicted were most useful, by suggesting the idea that others had still greater cause than they of being unhappy.

631. D. Prevention and Repression.—The increasing frequency of suicide, as well as of manifest insanity, requires some notice of the means by which it may be, in some measure, repressed, although no sanguine hopes of success from them can rationally be entertained in the present state of society. As long as education, manners, morals, and social intercourse continue as they now are; as long as crimes, murders, and suicides are seductively detailed and daily furnished to the public, through a thousand channels, for the purposes of private gain; as long as the perpetrators of crimes and of homicides are held out, both on the stage and from the press, as heroes of their day; as long as the overthrow of moral and religious principles and the infection or contamination of the public mind are made objects of gainful speculation, into which persons in place or authority are not considered dishonoured by entering; as long as the streams of moral pollution are allowed to flow without either strenuous, or well-directed, or combined efforts to confine or to counteract them; as long as the most instant and efficient agents of self-destruction are openly sold in every street, at little or no price, and to any purchaser, without either "let or hindrance," as long as the struggles of great parties in politics and religion absorb, in connexion with the details of every vice and every crime, the public mind, each party endeavouring to depress and ruin the others, without regard to the general weal; as long as provision for the pecuniary wants of the state, and the power and patronage of office, constitute the chief objects of governments; as long as justice is within the reach only of the wealthy, as laws protect chiefly the bad, as the weak are unshielded, and the deserving unrewarded; as long as

*The whip and scour of time, The oppressor's wrong, the proud man's shame, The pangs of despised love, the law's delay, The insolence of office, and the spurns That patient merit of the unworthy takes, shall continue to "puzzle the will;" as long as the lives of all classes are endangered, and their minds distracted by unprincipled and ig-

norant pretenders to medical and religious knowledge, who are allowed, and even encouraged, to take advantage of the credulity and fears of the weak-minded; as long, in short, as moral degradation and physical destitution exist, and as long as the safety of the people is not the supreme law of the state; as long as these several conditions of a country continue, and in proportion to their separate and combined influence, so long will suicides be frequent, or even increase.

[It is generally admitted fact that suicides are increasing to a most alarming extent in our country. But few find their way into the public prints, and yet our newspapers contain very frequent instances of the kind. The causes are to be sought for chiefly, we believe, in our defective systems of education, separating moral and religious culture from intellectual studies, and making the latter the great, if not sole object of public and private teaching. The distraction and proportionate attention to the cultivation of the intellect destroys the healthy balance of the mind; takes from it the support and influence of those high and holier motives, feelings, and aspirations, which support it under trials and losses, soothe it in affliction; which moderate the whisperings of selfishness and ambition, and enable us to await the events of futurity with composure and resignation. If the young were properly educated, "manners, moral and social intercourse" would take care of themselves; they would necessarily improve, and the other causes of suicide maintained by our author, as theatrical shows and a licentious press, would be comparatively harmless. Indeed, in a healthy state of the public mind and public morals, such streams of moral corruption would be checked at their very source. Hence we deem it the duty of every patriot and every philanthropist to use all possible exertions to reform our present system of public education—the jans et origo mali.]

632. The history of all nations has demonstrated the prevalence of this act, both as a disease and as a psychological phenomenon, during periods of surpassing luxury, of criminal debasement, of public commotion,* and of the decline of public and private spirit and virtue. In such circumstances, laws directed simply to this act, and without reference to the sources of the evil—to the various contaminating moral agents poisoning the minds of the community—will be of but little avail. It is obvious, that laws which, as at present, affect only the property of the suicide, are unjust, as they cannot punish the guilty, but fall exclusively on the innocent—on those already punished by the act of the suicide. The only means of prevention which have been found to succeed, on occasions of epidemic or imitative suicides, have been such as tended to impress the ignorant with the moral and religious turpitude of the act, to influence public opinion in its reprobation, and to convince the perpetrator of the crime that, although he escapes from feeling

* In the summer of 1793, upward of 1300 suicides were committed in Versailles and its vicinity! During "the reign of terror," or, rather, of crime, suicides were committed by the guilty, by the terrified, by infidels, and contemporaries of moral and religious principles, by public and private criminals, and by those distracted by losses of fortune and friends, in unheard of numbers throughout France.
the punishment it merits, every indignity which is compatible with the good of society will, as a consequence, be offered to his body, and to his memory. Each member of the community lives not for himself alone, but for the common weal, and in order to contribute to the general, the mutual, the public, and the private support requisite to the healthful constitution of society. As it is the chief purpose of good government to preserve innocence this principle of civil existence is, in its associations, ought every effort to contravene it, or to escape from the responsibilities it involves, to be repressed and punished in ways the most effectual, conformably with the spirit in which only should punishment be inflicted; and even those who either directly or indirectly aid in the commission of this act should be subjected to punishment. The difficulty, however, is to determine upon measures which may have any influence in diminishing the number of suicides, who are either irritable, violent agents, or only in that state of mind which is influenced by worldly considerations. There is every reason to believe, nevertheless, that many of those who commit this act without being manifestly insane—who entertain a suicidal propensity from depression of spirits; from mortified pride; from domestic chagrin or irritation; from excessive passion or feeling; from imitation, fascination, or mental infection; from extreme profligacy, debauchery, and satiety, &c.—would be deterred from it by the conviction that, if they perpetuated this crime, some indignity to their bodies, and disgrace to their memories, would be the result. If it were enacted that the body of a suicide, who had not evinced sufficient proof of previous insanity to require restraint, or whose relations had not seen sufficient proof of mental disorder to obtain medical aid, or other assistance requisite to the protection of others as well as of himself, should be made subject to medical inspection or interrogation; and in the general view, I am confident that the number of suicides would diminish, notwithstanding the increased and increasing sources of mental contamination, and of mental disease. Means of repression directed to the property of a suicide would have little avail, and would, moreover, punish the innocent without affecting the guilty; but such means ought to be strenuously directed against those who deal in poisonous substances, and ought to be rendered so stringent as entirely to prevent such substances from being procured unless by means of a physician's or surgeon's order or prescription. It is well known that suicide is often committed in moments of irritation or passion, and that as soon as the feeling subsides—in the course even of a few minutes—the suicidal impulse or intention may cease to influence volition so powerfully as to lead to the commission of the act. Therefore, if different were thrown in the way of resorting to it, during the periods of irritation and suicidal impulse, it might not afterward be entertained, or the sober mind would recoil with so great horror from the morbid idea, as to view it with increased dislike, or would endeavour otherwise to fortify or to protect itself against a return of the propensity.

633. Having thrown out these hints as to the only means of repression which can be suggest-
ed, after a consideration of those which have been enacted in this and in foreign countries, I would merely add, that the growing frequency of suicide requires that means, direct and indirect, should be taken by the Legislature to restrain it. As, however, many of the most influential causes of suicide can only be indirectly affected by legislative measures, and as some of these causes belong to the province of society, however; and apportioning chiefly to the most worthless parts of that liberty, but little hope can reasonably be entertained that the effect of this act will be much diminished, as long, at least, as the circumstances arising out of the education, morals, amusements, and social relations of the community, to it is in great measure referrible, to continue unchanged.

INTESTINE—\textit{Syn. *\textit{E}nterop} (ab \textit{int}ro, intus)\footnote{Intestinum (from intus, within)—\textit{Intestinum, Bogus, Fr. Darm, Ger. Intestino, Ital.—Boe- d; Gut; Intestinal Canal (in which the disorders and structural diseases to which the intestines, in general, are liable, are discussed in appropriate articles. The seat and nature of these affections required a separate consideration for them; and, at this place, it remains for me chiefly to supply whatever I may have omitted in these articles, and to treat of those subjects which have not been entered upon, under different and more appropriate heads.}

2. It need hardly be stated that the intestines comprise, or consist of the following parts, descending from the stomach to the verge of the anus, namely, the duodenum, the jejunum, the ileum, the caecum, the colon, and the rectum. As each of these portions of the intestinal canal presents most important connexions with, and relations to other viscera, that are not possessed to an equal degree, or in a similar manner, by the others; as they are, in many respects, and particularly as regards certain of their functions, distinct organs; and as they are often severally the seats of disorders, more or less limited to either of them, so I have treated of the diseases to which each of these portions of the intestinal canal are most liable under their respective heads. As there are certain maladies which affect in some degree or other more than one of these distinct portions of the bowels, and which do not implicate, or even originate in some one or more of the cololectal viscera, and in which not only the intestines, but the various related viscera, and even the frame generally, frequently are also disordered, although in different grades and forms, and to a varied extent, according to numerous circumstances connected with the cause of the disease, and state and constitution of the individual attacked, so I have treated of these maladies under the names commonly applied to them, but with strict reference to their seats, affections, and pathological relations. Thus, while I have considered the diseases individually seated chiefly in either the duodenum, caecum, colon, &c., under these heads respectively, I have likewise discussed colic and ileus, constiveness and constipation, diarrhoea, cholera, dysentery, gastro-enteric disease, flatulency, intestinal hemorrhage, intestinal concretions, and worms, &c., in these several articles, because these changes to which the intestines are liable in any one portion of the intestinal canal only, but often extend to several portions of it, although in different grades, and frequently depend upon disorder of the adjoining viscera, and sometimes even of distant organs, and of the system in general. Moreover, as the organic lesions which occur in the intestines are not peculiar to any one portion, but extend, in different maladies and persons, and in different degrees of frequency and severity, to all of them, and even also to the mouth and esophagus, to the whole digestive canal from the lips to the anus;

so I have considered these lesions under the head "Digestive Canal," and have thereby avoided the repetitions into which I should otherwise have been betrayed. It here chiefly remains for me to consider those maladies seated principally in the small and large intestines, in the ileum, jejunum, and colon, that are not discussed under different or more appropriate heads. The functional disorders and the structural changes to which the intestines are liable being fully treated of in the articles just mentioned, I now proceed to consider chiefly their inflammatory diseases. In the article on the peritonitis, however, much will be found more or less intimately connected with inflammations of both the small and large intestines, to which sufficient reference will be also made in those sections where inflammation extending to the peritoneal coat of the bowels, and the complications of enteritis, are considered.}

I. Inflammation of the Small Intestines—\textit{Syn. Xylophagia, Eilöz, Arétus, Galen. \textit{Febris intestinorum inflammatoria}, Hoffmann. Intestinum Inflammatico, Boerhaave.} Enter-
Inflammation but unless, for Order, it proceeded coats especially ecuation, temperament its are degree, mucous more part, with adhesion gifts, the inflammatory as it may exist long, or be extremely acute; but it often also, invades the surface of the coats more especially the connecting cellular tissue, until the peritoneal coat is at last inflamed, and all the phenomena of circumscribed or diffused peritonitis are produced. When all the constituent tissues of a portion of intestine are affected, the inflammation usually has commenced and proceeded in this manner; for it is but seldom that there is reason to infer that the inflammation has either simultaneously invaded all the coats composing a portion of bowel, or has proceeded in an opposite direction, namely, from the peritoneal to the external surface, unless, indeed, in cases of external injury, or of strangled hernia, or when the inflammation has extended from adjoining parts to the intestines.

5. Inflammation of the intestines, whether limited to one only, or implicating two, or all of their constituent tissues, may assume any grade of intensity and acuteness, from the most acute down to the slightest degree and the most chronic form. It may appear, in either of these states, as a simple or uncomplicated disease, or associated with other maladies. In this latter state, it may be either primary or idiopathic, or consecutive or symptomatic. In each of the above forms it will be here considered.

6. I. INFLAMMATION OF THE MUCOUS SURFACE OF THE INTESTINES.—Mucous-Enteritis of Armstrong.—Mucit-Entérite, Entérite Villeuse, of French pathologists. This complaint varies in its characters with its intensity, and with the temperament and habit of body of the patient: a slighter grade of it often causing, in irritable, nervous, and phlegtic persons, more acute symptoms than a severer degree in those who are melancholic or leukophlegmatic. The symptoms, moreover, are farther varied by the extension of the inflammatory affection, in some degree, to the duodenal or gastric villous surface on the one hand, or to the internal surface of the caecum and colon on the other; for the mucous coat of the small intestines is inflamed more frequently in conjunction with one or more of these than in an unassociated form; and not infrequently some of the adjoining viscera is also more or less disordered. Indeed, the enteric disease may be altogether consecutive of, and caused by derangement of one or other of these viscera. Thus, a discharge of acid or otherwise morbid bile into the duodenum may occasion or perpetuate inflammation of the mucous surface of the intestines, and often, also, of the large bowels.

7. A. Symptoms.—a. In the acute or sub-acute states of the complaint, the abdomen is usually distended, sometimes tense, and flatulent. A dull or heavy, deep-seated pain or soreness, occasionally with a sense of heat, is felt upon firm pressure, especially around the umbilicus, or towards the right iliac region; but this latter symptom is often absent, and is more generally found when the disease affects the large bowel.

In the more acute cases, the abdominal parietes are warmer than other parts of the body; and a feeling of internal heat of the bowels is also often complained of, with colicky pains, particularly after cold drinks, and the more heating or indigestible articles of food. Muscular power is much weakened, and the skin is harsh and dry. There is more or less thirst; and the appetite is impaired or lost. In severe cases, or when the disease is far advanced, there is often a jaundice or biliousness, and a symptom depending much upon the extension of the affection to the internal surface of the duodenum and stomach. The alvine evacuations are generally morbid, sometimes too frequent, at other times too rare and scanty; but usually preceded or attended by flatulence, borborygm, and the escape of much flatus. When the internal surface of the large bowels is unaffected, constipation is often present, but short attacks of diarrhoea, occasionally alternating with constipation, are frequent. These diarhoeas frequently vary in colour and consistence with the state of the biliary functions and the kind of the ingesta: when there is diarrhoea, they are generally pale, yeasty, and crude, or insufficently digested; when the bowels are costive, they are often offensive, dark, and scybalous. The urine is high-coloured and scanty, and often deposits a copious sediment. The mouth is clammy, with a bitter or unpleasant taste. The tongue is white or yellowish in the centre, but red at its point and edges. The pulse is accelerated, and sometimes small and soft; when there is diarrhoea, full, or even hard, when the bowels are confined.

8. In more intense or acute cases the foregoing symptoms are more prominent. The abdominal distention amounts almost to tympanitis; the pulse is quick and constricted; the thirst is great; the tongue is furred, loaded, and dry; the urine scanty and high-coloured, and all the secretions and excretions diminished. Pain, soreness, internal heat, and tenderness of the abdomen are greatly increased, and the surface is hot, dry, and harsh. The affection of the intestinal mucous surface extends its influence to the cerebro-spinal system, causing sleeplessness, restlessness, and ultimately, in the more unfavourable cases, delirium, startings of the tendons, and in young persons and children especially, convulsions and coma. In many of these more severe attacks, particularly in the sanguineous temperament and phlegtic habits, and in warm climates or seasons, the inflammatory affection of the mucous surface rapidly extends to the external coats of the part of the intestine chiefly diseased;
and the form of enteritis about to be noticed (§ 30) supervenes.

9. Acute mucous enteritis commences variably—sometimes slowly and insidiously, with impaired appetite, slight thirst, loaded or white tongue, a slight sense of heat in the abdomen, or colicky pains and slight disorder of the bowels. These symptoms, at first, are hardly appreciable, but they become gradually more and more severe, until the pulse and system become obviously affected. In other instances the attack is more sudden, and severer from the beginning, especially when caused by the more energetic causes—errors of diet and regimen, by irritating ingesta or intoxicating fluids, by irritating purgatives, by exposure to cold, to currents of air, and by damp or wet clothes. In these latter circumstances especially, it is sometimes ushered in by chilliness or slight rigours. It not infrequently follows some one of the various causes enumerated, especially the former, and is often attendant upon it; in such cases, however, the morbid action is seldom confined to the small intestine, but is extended, also, to the mucous surface of the large bowels.

10. The progress of mucous-enteric inflammation is seldom very rapid, unless when caused by poisonous substances and the most intense causes, and then dangerous cerebral symptoms often supervene, or the morbid action extends either to the adjoining portions of the alimentary canal, or to the more external tunics. Its duration most commonly varies from three or four days to thirty, or even forty; but thirteen or fourteen days may be said to be its medium continuance. It most commonly terminates in resolution; but when neglected, or improperly treated, and in faulty states of the constitution, it often passes into the chronic form (§ 11), or extends to the other tissues of the intestines, or to the adjoining visera. A fatal issue generally follows, as a consequence of this circumstance, or to consequent affection of the brain, which latter is a frequent occurrence in children, especially in infants.

11. b. Chronic inflammation of the mucous surface of the intestines is characterized chiefly by the presence, generally in a slight degree, of the symptoms already enumerated, for a considerable time—for six or seven weeks, or even longer. It may have been consequent upon a more severe state of the disease, or it may have been slight from the commencement, and hence prolonged from this circumstance or from neglect. In many instances, little or no abdominal uneasiness, or pain, or heat, or flatulence, or distention, is felt until three or four hours after a meal. Chronic mucous-enteris is exasperated by digestible articles of diet, by a heating regimen, warm condiments, and by stimulants. Thirst, dryness of the lips and mouth; harshness and dryness of the skin; flatulence, burr, in this circumstance, or to consequent affection of the brain, which latter is a frequent occurrence in children, especially in infants, which may mislead an inexperienced practitioner. In some cases, soreness and fissures of the lips, with exfoliation of the epithelium, are observable, and the cuticle often is thrown off in minute pulverulent scales.

12. c. In children mucous-enteris is one of the complaints most frequently observed. It occurs in either an acute, sub-acute, or chronic form. In slighter as well as in severer states, it is common in the youngest infants, more especially in large or manufacturing towns, and in the more delicate subjects; in whom, however, the morbid action usually extends to the stomach on the one hand, and to the large bowels on the other, in a more or less marked form, at some period of its course. Indeed, many of the diseases of infancy and childhood are merely consecutive upon neglected states of this complaint, more especially cerebral maladies and convulsions, infantile remittent fever, disorders of the liver, mesenteric obstructions and hemorrhages, scrofula, and diseases of the glands and joints.

13. a. In infants at the breast, mucous-enteritis may, even in the acute and sub-acute states, be attended by very little febrile disturbance. In them the symptoms vary with the parts of the digestive canal principally affected. When the small intestines are only implicated, there is generally vomiting, tympanitic distention of the abdomen, and tenderness upon firm pressure, with heat of skin, and slight or occasional diarrhoea. When the morbid action extends to the colon, there is more severe or continued diarrhoea, much less abdominal distention and tenderness, and less frequent or no vomiting. In many cases of this class of patients an erythematous redness is observable around the anus. The tongue is dry, or loaded, and red at the point or edges, and sometimes over the whole surface. The stools are various, but frequently consist of a yellowish substance. There are also thirst, dryness of the skin, and agitation; but the pulse is not much affected. During the period of death in infants are often attacked in a still more severe manner. In many the complaint commences insidiously with slight diarrhoea and flatulent distention of the abdomen, and proceeds in this manner for some time, until it assumes a well-marked form. The evacuations are occasionally not more frequent than usual; sometimes they are three, four, or five in the twenty-four hours, but they are loose, and more or less disordered; and all the local and constitutional symptoms are severe. In the fully developed state of the complaint there are heat of skin, fretfulness, thirst, dry tongue, disturbed sleep, sometimes vomiting, accelerated pulse, abdominal tenderness on firm pressure, and distention, crying and agitation before passing a stool, which is often forcibly ejected with much flatus. The evacuations vary remarkably in the course of the disease, from a healthy to a clay-coloured, yeasty, pale, and slimy, or to a gruel-like, or reddish-brown and fatty state. They sometimes consist of a dark fluid; at other times, of a dark or reddish-brown mucous. Their appearance is, however, much influenced by the food and medicine taken, much of the former passing off in the stools, but little or not at all changed. This acute state of disease may continue for some time; but great exhaustion, rapid pulse, dry or eructed tongue, sunk eyes, pal-
of enteritis in children seldom continues long without superinducing enlargement and obstruction of the mesenteric glands, and the usual consequences of these lesions. It is often, also, a complication of the more chronic states of Infantile Remittent Fever, and not unfrequently the former complaint is mistaken for the latter, the exacerbations attending it arising from the effect of food upon the character of the symptoms, or from the constitutional effects of irritations of a vital organ, and the periodicity which the slighter forms of febrile action are prone to assume, especially when the local affection commences in a slight form and advances slowly.

17. II. INFLAMMATION OF THE GLANDS OF THE INTESTINES—duodenal, intussusception, and true typhus fevers, and is Entirite Folliculose, of French writers. Inflammation of the solitary and aggregated (Peyer’s) glands and of the simple follices (Liebermann’s) is rarely observed as a primary disease, unless as a consequence of a peculiar class of causes, which operate not merely locally in respect of the alimentary canal, but also upon the system in general. It is scarcely ever a simple or an unassociated malady; but generally a consequence of an antecedent morbid condition, either of some other vital organ, or of the constitution—a result of an important lesion of the vital energy, and of the circulating and secreted fluids. Follicular or glandular enteritis is to be viewed rather as a consecutive or symptomatic affection, than as a primary and simple disease.

Yet it has been considered by several pathologists, and particularly by MM. Louis, Roche, and others, as a primary malady, and the essence of the typhoid forms of fever. That it forms a most important complication of continued, and even of remittent fevers, is undoubtedly, as I have already shown (see Fever, § 402), especially in certain epidemics, and in those localities where the causes which act more directly upon the alimentary canal co-operate with other predisposing and exciting causes of fever. Thus it was a most prominent feature in the epidemic Mucous Fever (see Fever, § 406), described by Roedeker and Walker, and in that denominated by M. Bretonneau duodenenteritis, and ileo-clysidite by M. Daily. It is frequently observed in a adynamic, purico-adynamic, and true typhus fevers, and is seldom absent when these fevers assume the enteric character or complication; and which they are prone to assume when they arise from those concurring or exciting causes, which either act injuriously on the alimentary canal, or contaminate the circulating fluids; as putrid food, water containing decayed animal or vegetable matter, &c. It exists also, but in connexion with inflammation of the follicular glands of the coecum, colon, and rectum, in the adynamic forms of Dysentery (§ 30, et seq.), as will be more fully shown in the sequel. Glanular enteritis, occurring consecutively of, or as a complication of low fevers (see Fevers, § 453, 174), necessarily assumes, in its course and consequences, an acute character; but it also occurs consecutively of other diseases, more especially of tubercular consumption, of tubercles in various organs, and of scrofulous disease of the joints, bones, and glands; and in all these symptomatic relations it presents a chronic form.

16. 3. Chronic muco-enteritis is also frequent in infants and young children. It is more generally attended by diarrhoea in them than in adults; the dejections being gluty, watery, and greenish. The belly is tympanitic and large; and, as the disease continues, contrasts strongly with the emaciation of the extremities. About one or two hours after a meal, fretfulness, or uneasiness with depression, may be remarked, occasioned by an increase of aliment when the ingesta are passing along the intestine. There are also thirst, dryness of skin, and often increased heat of the abdomen, especially towards evening. The pulse is sometimes accelerated, and generally small and soft. Tenderness and soreness are frequently evinced upon firm pressure of the abdominal regions, or upon examination of them by percussion. This state

bid or waxen countenance, coma, and partial or general convulsions frequently supervene and terminate existence. In infants and young children, this state of the disease may exist for a considerable time, and even with much severity, without fever being unequivocally developed. Vomiting, diarrhoea, colicky pains, flatulent distention of the abdomen, tenderness on firm pressure, and often increased heat, especially of the belly, are the symptoms which chiefly indicate, in this class of patients, the presence of acute muco-enteritis. Frequently the first two of these symptoms alternate. In infants who are either prematurely weaned, or are attempted to be brought up by hand, or otherwise insensitively or improperly fed, this complaint is very prevalent. Indeed, it is much more common than any other; and in it nearly all the other diseases, to which infants thus circumstanced are liable, actually originate; these arising consecutively in consequence of sympathetic disturbance, and the intimate connexion subsisting between the vital organs, by means of the organic nervous system. The complaint commonly called the "Weaning Brash" is merely a modification of acute muco-enteritis, in which the irritation of inappropriate or unaccustomed food not only induces a degree of inflammatory action, but also an increased secretion; this latter often, however, favouring the resolution of the morbid vascular action. In this complaint the essential symptoms are those just described, varying, however, in different cases, according as the inflammatory irritation is extended either to the stomach, in the form of Gastro-enteritis, or to the large bowels, in the form of Ileo-colitis, hereafter to be noticed. However modified this disease may be in children, by peculiarity of constitution, by combinations of the causes, and the extent or intensity of the morbid action, it has a most manifest influence, in all its forms, to induce sympathetic or consecutive inflammation of either the membranes or the substance of the brain, or even both, and disease of the mesenteric glands. After weaning or den- tition, acute muco-enteritis sometimes assumes a form which is with difficulty distinguished from the acute variety of Infantile Remittent Fever. Indeed, the one complaint often runs into the other; and the more severe state of the latter disease is frequently complicated, as will hereafter be shown, with the former, a fatal issue in these being generally owing to this complication.

The intestines of small—symptoms.
18. In its primary and simple states, glandular enteritis cannot be advantageously viewed without reference to its special causes. These are, as respects predisposition, the female sex; the earlier epochs of life, particularly those antecedent to puberty; relaxed and lymphatic constitutions; the scrofulous diathesis; and persons possessing a fine white skin, a fair complexion, and light hair. The more efficient or exciting causes of follicular enteritis are also peculiar. These are a cold and humid atmosphere; low and damp localities; an air contaminated with vegetable and animal malodors; the use of water control mercury by purgatives or volatile matters or exuvia; immature, or stale, or decayed fruit or vegetables; animal food passing into a state of putridity or decay; all septic substances taken into the stomach; immature or spoiled, or musty wheat or rice; damaged or mouldy bread, biscuit, &c.; the prolonged use of purgatives, and whatever impairs vital power, and deteriorates the chyle and the circulating fluid. MM. Bretonneau, Leever, and Gendron, consider that cases originating in one or more of these causes may generate an effluvium which may infect healthy persons. There can be no doubt that these causes, when they operate upon a number of predisposed persons, and in circumstances favourable to their injurious impression, and to the accumulation of the emanations proceeding from the diseased, will produce a disease capable of propagating itself in these circumstances; but the disease will either be dysentery, or fever with enteric complication, as shown in numerous instances, particularly where these circumstances have been aided by the endemic influences just alluded to, and by epidemic constitutions.

19. A. Symptoms.—a. In the sporadic and simple state of glandular or follicular enteritis, the patient frequently complains, at first, only of slight disorder of the digestive functions, consisting chiefly of want of appetite, colicky pains, and relaxation of the bowels, ceasing and recurring from time to time. There are also borborygm, flatulence, mucous stools, a relish, chiefly for the consumption of food, a white or loaded tongue, a soft and languid pulse, and a turbid state of the urine. In other cases the symptoms are more severe at the commencement. The appetite is lost; the tongue presents a grayish-white or yellowish coating, and is somewhat red at its point and edges; the mouth is clammy, occasionally aphthous, with an insipid, sickly, nauseous, or sour taste; the breath is disagreeable and fecid; and there is tenderness upon firm pressure around the umbilicus. Borborygm, and eructations of an acid and indorous flatus; colicky pains, often followed by flatulent and mucous evacuations, occasionally containing lumbrici; great depression of strength; dusky discoloration of the skin; occasional outbreaks of slight but acid perspiration; and a small, frequent, and feebile pulse, are generally also present at an early period. There is little or no heat of skin, and but little thirst. Shifting pains in the limbs are often felt. The urine is thick or turbid, and deposits a grayish or brick-colored sediment. Diarrhoea is neither severe nor of any continuance, unless the glands of the large intestines are also affected.

20. b. In its more acute or severe states, the affection of the glands is seldom confined to the small intestines, or to the solitary glands, or to Peyer's or the aggregate glands or to the simple follicles solely, although either may be chiefly diseased. In the more complicated cases, particularly those presenting the forms of admixaneous fever and dysentery, Peyer's or the aggregate glands are principally implicated; and the disease extends from the lower third of the ileum, where it is most prominently marked, to the simple follicles and solitary glands of the large bowels, on the one hand, and to those of the upper portions of the intestine canal, on the other. In these morbid states, severe pain in the abdomen, often extending from the navel to the right iliac or cecal region, and increased on pressure; a loaded tongue, with dryness of the mouth, and thirst; sym pathetic fever, which becomes increased towards evening, with a dry, harsh skin; depression of spirits; disinclination to move; a dull, and often a sunk state of the eyes, and discoloration of the lips and around the mouth, are usually present, and are commonly attended by fulness or flatulent distension of the abdomen in general, or more especially towards the caecal region; by nausea, and occasionally vomiting; and by frequent, mucous, offensive, ochre, or otherwise morbid stools and scanty urine. As the disease proceeds, it usually assumes all the characters either of Asthenic Dysentery, or of Mucous or Admixed Fever (see these articles), in a severe and more or less advanced form, according to the affection extends along the digestive canal, or gives rise to exhaustion of the cerebro-splanchnic functions, and to deterioration of the circulating and secreted fluids. When it assumes any of the forms of Asthenic or Admixed Dysentery (see Dysentery, § 20, et seq.), the evacum, colon, and rectum are especially implicated; and when it passes into admixed fever, the aggregated glands, particularly in the lower third of the ileum, are extensively diseased, ulceration extending from them to the more external tissues.

21. Inflammation of the intestinal mucous follicles often occurs, particularly in low and humid localities, and when occurring epidemically, or even endemically, as occasionally observed, especially on the Continent, either the form described under the article Mucous Fever, or that very closely resembling it, denominated by M. Petit Entero-mesenteric Fever, and which is described by him nearly as follows: There are at first debility, general uneasiness, anorexia, irregular attacks of fever, and diarrhoea. The countenance is dejected, the eye dull, and the skin covered with cold, offensive, and impure sweat, the lips and near the navel; delirium on the back; disinclination to motion; torpor, and some degree of prostration of the intellectual powers. The fever is slight or obscure during the day, but gradually comes on in evening paroxysms, without rigours or much heat, but with a dry, harsh skin, injection of the eyes, and slight delirium. There is great thirst; the teeth are dry; and the tongue is covered with a grayish paste. The stools are bilious or seious, variable in frequency and quantity, but are not such as to account for the prostration of the patient. The belly is soft and not swollen; and little or no pain is felt in it, unless on pressure towards the right side, between the
umbilicis and the crest of the ilium. The symptoms are gradually increased; the lips and alae nasi are slightly retracted; the cheeks become livid, the eyes sunk and injected, and somnolence and delirium constant, although the answers are correct or painful. Occasionally, a violent fever, with nocturnal exacerbations, petechiae, and subsultus tendinum, now appear; the pulse is frequent, and very compressible; the teeth are covered by sordes, and the tongue with a brownish or black crust. The abdomen becomes more painful; sometimes, however, the pain is confined to its first situation, and is unattended by distention; but in other cases it is more extended, and is accompanied with tympanitis. The stool becomes more serous, fetid, and frequent; the urine scanty; and excretions of the nates, or the situations of the blisters, are disposed to gangrene.

22. In many cases, glandular enteritis is consequent upon fevers, or occurs during convalescence from them. This sequela has presented itself more frequently after some epidemics, and in certain localities, than in others. It has been well described by Dr. Cheyne, in his Reports, as it appeared in Dublin in 1817. A patient who has become so much improved that a speedy convalescence is expected, but in a few days it is found that strength is not returning; the pulse continues quick, and the appetite, although sometimes restored, is often deficient or capricious. The patient expresses no desire to leave his bed, and he does not gain flesh. His tongue becomes dry, and he complains of a dull pain and uneasiness in his belly, with soreness on pressure, and a degree of fulness. These succeed loooseness of the bowels, with great weakness. Perhaps, on the next visit, the patient is found lying on his back, with a pale, sunk countenance, and a very quick pulse, and without mental energy. Mucous stools pass from him in bed, and the urine also. His breathing becomes frequent, and often hic-cough occurs. Death is now nearly at hand; opates, astringents, and cordials being alike unavailing.

23. In the more severe cases, and particularly when they assume either of the above forms, the disease occasionally become suddenly exasperated. The patient complains of violent pain in the abdomen, which is greatly distended, tense, and tender on the slightest pressure. He lies on his back, with his knees drawn up. His countenance is anxious and collapsed; his pulse is weak, small, remarkably accelerated, followed by extreme depression and sinking, by quick, laboured breathing, cold extremities, and occasional hiccough. Death in these cases commonly takes place within 24 or 36 hours from the accession of the severe pain and tympanitis; and is owing to ulcerative perforation of the intestines and consequent peritonitis rapidly extending over the greater part of the peritoneal surface.

24. In other instances, intestinal hemorrhage occurs in the course of the disease, and sinks the patient more or less rapidly, according to its amount relatively to his powers, &c. In these cases, particularly if the blood is poured out slowly in the small intestines, and in small quantity, it is more or less intimately mixed with the other matters passed by stool, and the evacuations are generally more frequent and abundant than in other circumstances. Intestinal hemorrhage, particularly when the blood is more or less pure, is, however, much more frequent when ulceration has taken place in the large intestine.

25. G. Follicular or glandular enteritis may, particularly when occurring in a simple and sporadic form, assume a more or less chronic or sub-acute state. But in either of these states it will hardly be distinguished from the more chronic forms of muco-enteritis already noticed (§ 11), unless by a more offensive mucous or muco-puriform state of the stools, and a weaker and more frequent pulse; but these cannot be relied upon. Very often, also, muco-enteritis and follicular enteritis are associated, especially in children. Enteritis consequent upon tubercular consumption is commonly seated chiefly in the follicles, and is chronic in its duration; but it is seldom limited to the small intestines, it generally extending, also, to the cecum and colon.

26. H. The progress of the simple and sporadic states of follicular enteritis is generally slower, and the duration of it, consequently, longer than the progress and duration of similar grades of muco-enteritis. It seldom proceeds to ulceration, or the ulcerative process rarely proceeds far in the situation of these glands without giving rise to inflammation and enlargement of the mesenteric glands corresponding to the diseased intestinal glands and follicles. Indeed, it is not improbable that consecutive inflammation, enlargement, and obstruction of the mesenteric glands often arise before the follicles and glands become ulcerated, and yet are owing to the primary disease of these follicles and glands.

27. I. In infants and children, glandular enteritis is a very frequent disease, particularly among infants that are brought up by hand, or imperfectly nourished, or injudiciously fed, and that live in close, low, and damp cellars and localities, especially in large and manufacturing towns. It is frequent, also, at the time of weaning, and in humid, cold, and misanthropic situations. It often assumes a slight and chronic form, and at other times is complicated with occasional mesenteric disease, which very frequently succeeds to ulceration. It is the continuation of the primary disease, and commonly enteritis, particularly the former. These two forms of enteritis are with great difficulty distinguished from each other in children or infants. Nevertheless, an opinion as to the presence of either may be formed from the descriptions furnished above (§ 12-19). In the follicular variety, the scabs are more generally mucous, and the diarrhoea is more marked than in the other variety. Indeed, mucous diarrhoea in children is very commonly caused by inflammation of the intestinal follicles and glands, or by a state of irritation which is very prone to pass into inflammation, which will assume either a slight and chronic, or a severe and an acute form, according to the constitution of the patient, and numerous concurring circumstances. In the more acute cases, there is more or less fever, which generally assumes a remittent character; and it is sometimes attended by nausea or vomiting, and always by thirst. The abdomen is tumid, uneasy, although not always painful or tender on pressure. Griping pains are...
often felt, especially before an evacuation; but there is no straining, unless the large bowels become implicated; and this often is the case as the disease proceeds; and it then assumes a truly dysenteric character, the stools often consisting of a reddish-brown mucus.

28. \textit{k}. The more \textit{acute} and \textit{chronic} states of follicular enteritis in children are apt to be overlooked, or seldom come under the eye of the physician until it has passed on to organic change, generally to enlargement of the follicles or to tuberculous affection of the disease of the mesenteric glands. The \textit{chronic} state of the affection is often the consequence of its slightness or its gradual increase, which causes it to be neglected, or injudiciously treated, in respect both of regimen and of medicine. It is frequently, also, produced in connexion with the more \textit{slight} or \textit{chronic} form of muco-enteritis; and it often proceeds from morbid states of the chyle and blood, or, at least, pre-existing morbid condition of the follicles, or the secreting parts they may affect. The \textit{chronic} affection is asserted with difficulty in children and infants, especially during its early stages. It closely resembles, not only the chronic form of muco-enteritis, but also \textit{infantile remittent fever} and \textit{mesenteric decline}. Indeed, the remittent fever may be altogether symptomatic of it; or it may be developed in the course of the fever. I have seen cases, both in public and in private practice, in which this \textit{chronic} affection of the mesenteric glands has been overlooked, or have not been under the observation of the physician.

29. \textit{l}. The \textit{chronic} form of glandular enteritis may terminate in \textit{perforation} of the intestines, and in partial or general peritonitis, the terminal disease having been previously developed, and more or less advanced; but I believe that perforation is a less frequent consequence of the \textit{chronic} than of the \textit{acute} or \textit{sub-acute} states of the disease. When consequent upon the \textit{chronic} form, it is chiefly when this form arises from tubercles in the lungs, or when it occurs in the tubercles of the lungs, or in the course of hectic or slow fever proceeding from the absorption of morbid matter or diseased secretions, or from local sources of irritation.

30. \textit{ii}. \textit{Inflammation implicating all the Coats.}—The \textit{Enteritis Phlegmonosa of Cullen; E. Rauca of Sauvages; Sero-enteritis of modern writers.}—\textit{Inflammation extending to the cellular, and affecting all the tunics, especially the peritoneal.}—This variety of enteritis is \textit{characterized} chiefly by the severity and continued duration of the pain of the abdomen, particularly around the navel; by frequent vomiting and great tenderness and tension of the belly; by the very accelerated, constricted, small, and even cord-like pulse; by the marked tendency to constipation; and by the severity of the accompanying fever. As the inflammation extends to the peritoneum, or when the \textit{peritoneal} coat is affected from the commencement, these symptoms are prominent, but in various grades of severity, according as the disease is consequent upon muco-enteritis, or upon strangulation, or upon inflammation of some adjoining viscus, and according to the causes which have directly produced it. \textit{Sero-enteritis} may thus be either \textit{primary} or \textit{consecutive}; \textit{acute} or \textit{sub-acute}; but very rarely \textit{chronic}, unless in diarrhoea, and in \textit{peritonitis} in connexion either with chronic ulceration of the intestines, or with chronic peritonitis.

31. \textit{Description.}—\textit{A. Acute sero-enteritis, or phlegmonous enteritis, may occur primarily, particularly in warm or in tropical countries, and in warm seasons in temperate climates; but it more commonly is consequent upon some grade or other of muco-enteritis, although the symptoms of the latter may have been overlooked, or have not been under the observation of the physician.} When it occurs primarily, it is generally ushered in by chills or rigours; but when it is developed more gradually, owing to the extension of inflammatory action from the mucous to the cellular tissue, and thence to the peritoneal coat, then it is evinced by the appearance of the more acute and characteristic symptoms. \textit{a}. In the early stage of the disease, more especially if it be ushered in by rigours, there is great vascular and febrile excitement, which is more or less proportioned to the degree of the previous excitement, and to the progress of the inflammation and of its consequences. Pain and tenderness of the abdomen are early felt, particularly under pressure, during which the patient winces, and evinces increase of pain or anguish by the expression of his face. The abdominal integuments become hard, irregular, tense, harsh, and hot, and the whole abdomen tense and distended, chiefly by flatus, which the patient feels to increase his sufferings. As the tenderness increases, he is more constantly on his back, with his legs drawn up, as if instinctively to relax the muscles and to keep off the pressure of the bed-clothes from the belly. If nausea, retching, or vomiting does not appear at the commencement of the attack, they are sure to occur as it proceeds, and to increase in severity with its progress. Constipation is obstinate in proportion as the more external tunics are affected; and the more it is so, the more urgent is the vomiting, which often occurs either without being excited by the ingesta, or a considerable time after substances have been taken into the stomach. The urine is scanty and high-coloured. The skin is hotter than natural, and always drier, except on the forehead and palms of the hands, where it is often moist. The pulse is very quick; generally from 100 to 120, or even quicker, in the
more intense cases, and at a far advanced pe-
r oid. It is small, constricted, resisting, and
firm; but as exhaustion comes on, it becomes
small, thready, and weak. The respiration is
quick and anxious, and chiefly effected by the
diaphragm and intercostals, the abdominal mus-
cles acting slightly or almost imperceptibly.
The tongue is covered by a whitish far, and
there is a pessive thirst.

32. As the vascular and febrile excitement
passes into exhaustion, the abdomen becomes
more distended and tense, and the pain and ten-
derness, which had recently been most intense,
subside more or less rapidly. The concentra-
tion of heat in the abdomen still continues,
while the temperature of the extremities sinks.
Respiration now becomes laboured; retching
and vomiting more frequent, and the counte-
nance more anxious and collapsed. As the
stage or period of exhaustion is more fully
evolved, the pulse is remarkably quick, general-
ly ranging above 120, and weak, small, thready,
or undulating. The heat of the surface falls
remarkably on the extremities, which are damp
and clayey cold, and, ultimately, even on the
trunk. The hands and feet often appear mottled
with dark-red or livid spots. Respiration is
irregular, embarrassed, or interrupted by
catchings or hiccough. Vomiting occurs with-
out retchings or effort, the contents of the atone-
ach being discharged by a retrograde action,
or by a gulping-like motion. The tongue is dry,
brown, and furred; the face is sunk, the orbits
hollow, and muscular power altogether pro-
strate. This state continues but a short time,
until the patient sinks, generally with a collect-
ed mind, and sometimes with hopes of recover-
ery entertained until almost the last moment,
or after all hopes have ceased to inspire the
practitioner.

33. B. Sub-acute sero-entitis differs from the
acute chiefly in the severity of the symptoms
and in their duration. The abdominal symp-
toms are less severe in this than in the acute
form; and the attendant fever is also less.
The acute variety is seldom protracted beyond
the sixth or seventh day, very often not beyond
the fourth; whereas, the sub-acute may be pro-
longed to twelve, fifteen, or even twenty days.
The rapid progress even of the latter, and still
more of the acute, should not be forgotten, nor
their almost constant tendency to terminate fa-
tally, as these circumstances most unequiv-
cally prove the necessity for adopting a most
active, decided, and a judicious treatment at the
commencement of the disease; for, when ex-
hauisiton begins to appear, every means will be
ineffectual.

34. Although acute and sub-acute phlegmo-
nous or sero enteritis most frequently arises
from the extension of inflammation from the
mucous coat to the connecting cellular tissue,
and thence to the external surfaces of the intesti-
nes, yet these tissues may be almost coetane-
oneously affected, or the inflammation may com-
ence in, or extend to, the serous coat, and
thence to the rest. This latter is most likely
to be the case when sero-enteritis appears con-
secutively upon external injuries, upon inflam-
mations of adjoining parts, and upon strangula-
tion. &c. Death, in the unfavourable cases of
acute and sub-acute sero-enteritis, is commonly
caused by the extent to which inflamma-
tion and its consequences have proceeded in a
vital organ, and by the shock imparted to the
organic nervous power by intense disease of a
viscus most intimately connected with this vi-
tal part of the nervous system.

II. Inflammation of the Large Intestines.—

Syne. Colitis, Colite, Fr. Entzündung des
Kolons, German. Classif.—III, Class, 1 Order (Author).

35. Defin.—Pain and tenderness in the course
of the colon, commonly originating in the region of
the caecum, and extending to the left iliac region
and sacrum; with frequent, and often inconstant,
efforts at forced evacuation, generally preceded
by eructation, and attended by tenesmus, the motions be-
ing mucous, and streaked with blood; symptomat-
ic inflammatory fever.

The colon is sometimes primarily inflam-
ated, without the disease advancing to a great
extent, either to the small intestines on the
one hand, or to the colon on the other. This
limitation of the inflammation to the caecum is,
however, comparatively rare, especially when
the mucous surface is the part of it affected.
Inflammation of the caecum, particularly when
thus confined, is fully treated of in the article
Caecum (S. 15). When inflammation commen-
ces in this viscus, it generally extends to the
colon, and even to the rectum; less frequently,
the ileum. When this latter intestine is inflamed,
especially when its villous surface or its follicles
are chiefly affected, the caecum often participates in
the disease, which frequently advances, also, to the colon and rec-
tum. Such is the case in the several varieties of
Dysentery, which, in most instances, either
commences with, or soon passes into, inflam-
mation of the mucous surface of the large in-
testines, extending often to the ilium. In the
purely inflammatory form of dysentery, the loc-
al morbid action is of the sphincter kind, and
the accompanying fever, also, of this nature.
In the low, asthenic, infectious, and epidemic
forms, the local action is asthenic, and the
attending fever of a low or typhoid character.
In most of the forms of dysentery, there are
portions of the large intestines somewhat more
severely implicated than others, and these
are the internal surface of the caecum, of the sig-
moid flexure of the colon, and of the rectum.
The other portions of the colon and the ilium
are likewise involved, but generally in a less
degree, unless in very severe or protracted ca-
es, where they also present very remarkable
lesions. In the different states of dysentery,
also, the follicular galls, as well as the mu-
cous surface itself, are affected, although prob-
bly in different degrees, particularly at the
commencement of the complaint, at which pe-
riod, however, dysentery is not always identi-
cal with inflammation of these parts, for dys-
entery, particular in its asthenic, endemic, and
epidemic appearances, usually commences with
indications of morbid secretion and of inor-
minate action of the muscular coats of the intesti-
nes—with signs of irritation chiefly; inflam-
matory action, either of a sthenic or asthenic
kind, being consecutive. However, in many of
the more acutely and sthenically inflammatory
cases, and especially in those which occur spo-
radicly, and from causes which will hereafter
be noticed, this disease is truly inflammation of
the villous surface of the large intestines,
seated, in some cases, chiefly in the colon and rectum; in others, in the cæcum and colon; and, in many, in these three parts equally, and extending also to the ilium; but in all, the morbid action is not limited to the villous surface itself, nor to the follicular glands solely of these intestines, although it may commence in either, or be more prominent in one or the other.

37. **Inflammation of the Colon—Colitis**—which will be chiefly considered at this place, as **Inflammation of the Cæcum and Inflammation of the Rectum** are discussed in separate articles—generally commences in the villous or mucous surface, or in the follicles, and comparatively seldom in the cellular or connecting tissue of the coats of this bowel, or in the peritoneal coat. It may, however, originate in either of these latter, as in the case of *phlegmonous enteritis* (§ 30), when it has been caused by wounds or external injuries, by strangulation, or has occurred consequent upon inflammation of an adjoining viscus, or of the peritoneum, or of the omentum or mesentery.

38. **A. Symptoms of Acute Colitis**—When the inflammation commences in the villous surface, as is usually the case, the bowels are, at first, loose or irregular, or mucous diarrhoea is present; scanty evacuations being first passed. In this state there may be neither chills nor rigours, or they may be slight. When, however, the coats of the bowels are more deeply and acutely affected, the disease is usually ushered in with rigours and chills. Pulsating tenderness on firm pressure are generally felt in the course of the colon, extending from the cæcal region to the right hypochondrium, across the abdomen, midway between the pit of the stomach and navel, to the left side and left iliac region. The pain occurs in paroxysms, is often griping, and followed by an inclination to go to stool, the evacuations consisting chiefly of mucus with blood. If there be straining or tenesmus, with pain in the direction of the saecum, the inflammation has extended to the rectum. If the inflammation of the large bowels assumes a sub-acute form, it is attended by the same symptoms, and it observes the same course, as stated in the article Dysentery, at the place where the sthenic or inflammatory states of that disease are described (§ 11–16). If it be very acute, it will differ but little, if, indeed, at all, from the variety of dysentery (§ 17, et seq.) observed so frequently in Europeans in warm and inter-tropical countries. Indeed, the chief differences between colitis, or inflammation of the colon, and inflammatory dysentery, arise from the extension of the morbid action, in the latter, to the rectum on the one hand, and to the cæcum, and even, also, to the ilium, in some cases, on the other. When, however, the rectum is unaffected, there will neither be straining, nor pain at the saecum, the other symptoms attending acute inflammatory dysentery resulting from the inflammation of the rectum, in connexion with colitis, occasioning some of the chief characteristics of inflammatory dysentery.

(See article Rectum.)

39. When inflammation has invaded all the coats of the colon, either by extending from the internal surface to the peritoneal coat, or from the latter to the other tissues, or by attacking them all nearly coëntaneously, the second and third modes being, however, comparatively rare; then pain, increased heat, and tenderness in the course of this viscus, become more severe and constant, and extend over the abdomen; flatulent distention of it increases, particularly in parts; the stools are preceded by tenesmus; are frequent, scanty, mucous, or slimy, very dark, streaked with florid blood; contain either sebaceous, or broken-down feces; are passed with much flatness; and are at last fetid, with shreds of lymph or muco-puriform matter in them. The tongue varies in its appearance, but it usually becomes covered with a dark sordes, which forms into a crust as the disease proceeds. The mouth is dry; there is constant thirst, and occasionally vomiting. The urine is scanty and high-coloured, and the calls to pass it, frequent and painful. The pulse is quick, hard, and small, and ultimately small and weak. The heat, pain, tenderness, and flatulent distention of the abdomen go on increasing, and the disease, in most respects, excepting the dysenteric symptoms, assumes the features of the worst cases of *score-enteritis* (§ 31), or passes into a state of *partial or general Peritonitis*, or becomes identical with the far-advanced stage of the most acutely inflammatory form of *Dysentery* (§ 17); the local and constitutional symptoms attending the unfavourable terminations of these, particularly of the last, also accompanying similar terminations of it. As colitis, however, appears more frequently associated with other diseases, than as a primary malady, especially with inflammations of other parts of the alimentary canal, or with those of the liver, omentum, peritoneum, &c.; and as it occurs in a variety of endemic and epidemic circumstances, and in various states of the constitution, so both the local and constitutional symptoms vary in different cases, and even in different stages of the same case. Still, the pain, heat, distention, and tenderness in the course, or in some part of the colon, in connexion with the state of the stools and the local and constitutional disturbance, will sufficiently mark the presence of the disease.

40. **B. Chronic inflammation of the colon—chronic colitis**—is either consequent upon the acute or sub-acute states of colitis, or is itself a primary disease, the chronic condition proceeding from its slight grade and slow progress. As it usually occurs in practice, it is identical with the *sub-acute or chronic forms of Dysentery* and *Dysentery* (§ 45, et seq.), the symptoms varying much according to its localisations, and the circumstances of the locality in which it prevails, and of the individual affected, as above stated (§ 39). Its most common complication, however, is with sub-acute or chronic disease of the liver, with abscesses in this organ, and with disease of the mesenteric glands; but it may attend other diseases, particularly tubercles in the lungs. The symptomatic fever, in this state of colitis, is very frequently of a remittent or hectic type; and it often, particularly in warm and miasmatous climates, occurs in the course, or as a sequela, of intermittent and remittent fevers.

41. Chronic colitis generally occasions, and becomes associated with, chronic inflammation of the ileum, the disease affecting chiefly either the mucous surface, or the follicles of this in-
testine; but in this case the cæcum also is more or less implicated. As this state of colitis proceeds, ulceration takes place; and the inflammation advances in parts, through the medium of the connecting cellular tissue, to the peritoneal coat, coagulable lymph being thrown out on its surface, and giving rise to adhesions, &c. Similar changes, although to a less extent, also take place in the adjoining portions of the alimentary canal, and the disease terminates either in partial or in general peritonitis, or in thickening and concretion of the coats of the intestine, or as more fully described in the article Dysentery (§48-50).

III. Illness of Both Small and Large Intestines.—Ileo-colitis.—Entero-colitis, of various authors. Ileo-colitis—Entero-colitis.

Fr. Entzündung des Ileums u. des Colon, Germ.

42. This is a frequent form of inflammation of the intestines, the morbid action affecting the ilium and colon solely, but in different grades in either, or extending also to the other portions of the small and large intestines, although in various degrees. It is probable, however, that the disease is not limited long to the ilium and colon without the rectum being more or less affected; and we cannot reasonably exclude the cæcum from an equal share of the malady when the ilium and colon are attacked. Indeed, there is reason to believe that the cæcum is sometimes the part first affected, inflammation extending to the colon on the one hand, and to the ilium on the other, especially when the mucous surface of the tissue primarily attacked.

43. Acute Ileo-colitis.—a. The symptoms vary according to the portion of intestine chiefly affected; but the most characteristic of the more acute states are, pain, aching, or soreness, with frequent gripings in the right iliac region, and between this part and the umbilicus, often extending across the hypogastrium, and occasionally above and around the navel; tenderness on firm pressure of these places; diarrhoea, the stools being thin, mucous, or watery; and symptomatic fever. At the commencement of the slightest diarhoea, there may be neither chills nor rigours; or they may be slight, or they may recur and alternate with feeble heat; but they generally usher in the more acute attacks. As the disease is developed in its acute form, the patient complains of a sense of heat in the above situations, particularly in the region of the ileo-caecal valve; and of flatulent distention, pressure frequently causing a gurgling sound in this region. The abdomen is hot, dry, and more or less tender upon pressure as the inflammation proceeds. The stools become more disordered, darker, more offensive, mucous, or watery, and occasionally streaked with blood, or contain imperfectly-digested substances. The complaint, when judiciously treated, will generally not proceed farther, all the symptoms gradually subsiding; but when it is neglected, and when it is complicated with disease of the liver or other organs, or associated with remittent or astatic forms of fever, or with it extends to the rectum, thereby giving rise to a most severe and dangerous form of dysentery (§17), the inflammatory action very often proceeds to disorganization, the peritoneum ultimately becomes implicated, and the several lesions described in the article just referred to (§69, et seq.), and in that on the pathology of the Digestive Canal (§84, et seq.), supervene and terminate life.

41. b. Inflammation of both the small and large intestines seldom extends, in temperate climates, to all the coats or tissues of all these viscerae in the same case. When inflammatory action attacks or extends to all the coats, or even to the peritoneal coat, portions only of either the small or large bowels are thus implicated; more rarely of both. Yet I have frequently observed, particularly in warm climates, all the coats of the mucous and peritoneal inclusive—infamed both in the ileum and in the colon, including the cæcum and even the rectum. In these cases, the disease commenced either as inflammatory diarrhoea, or as inflammatory dysentery, the morbid action existing in the mucous surface of the ileum and colon in the former, and in the rectum, also, in the latter, ultimately extending to all the tunics, in portions of these intestines, and giving rise to partial or general peritonitis, and to the other consequences of enteritis already noticed, with the symptoms attending them, in their most severe and most prominently marked forms, or in the form about to be described. When the inflammation proceeds thus far, the chances of recovery are very few, the change of structure already produced on the internal surface of the intestines combining with the intensity of the morbid action, and with its consequences in the external coats, in destroying the patient rapidly.

45. B. Ileo-colitis of Warm and Intertropical Countries.—a. Inflammation of the small and large intestines is of frequent occurrence among Europeans residing in intertropical countries, and, indeed, among the inhabitants of all hot climates. It generally commences in the villous coat, but it occasionally attacks all the intestinal tissues almost simultaneously, or the peritoneal coat chiefly, particularly when it is caused by exposure to cold in any way, or by sudden suppression of the perspiration. When it originates in the villous surface, it is often owing to, or, at least, connected with a morbid condition of the bilary and other secretions poured into the intestinal canal, the alvine evacuations being more or less disordered. It rarely commences in the peritoneal coat, unless consecutively upon
inflammation of the liver, with which it is often complicated, especially in India. At first, the bowels are seldom obstinately constipated, but they are sometimes costive; they are oftener, however, laxer than usual, and diarrhoea is present in many cases. Indeed, the disease often commences in the form of inflammatory diarrhoea, or of dysentery, and continues in either of these, particularly the former, as long as the violent coat and follicles only are affected. The consistence of the motions is various, and frequently change their appearance. They are offensive, often dark-coloured, watery, or serous—sometimes pale, fluid, and frothy, resembling fermenting yeast; at other times they are shiny-green, gelatinous, or mucous. As the disease advances, they are of a dark green, with lighter shades, or with brown or yellowish-brown streaks, and at last they become very dark and gummos, occasionally bloody, especially when the colon is much affected.

46. As the inflammation extends to the other coats, the griping pains, which manifestly, from the morbid appearances of the motions, arise from, or are increased by, the irritation of disordered secretions, are attended by more continued suffering, and by a sense of internal heat, or burning, with great soreness and tenderness of the abdomen upon pressure. The diarrhoea subsides, and the stools become scanty; and attempts at evacuation are more or less violent; with violent exacerbations of pain. The tongue is white, excited, red at its point and edges, and afterward very loaded at its middle and base. The strength, especially of the lower limbs, is remarkably prostrated. The pulse is quick, soft, and small. Vomiting occasionally occurs, particularly after cold fluids taken to quench the urgent thirst. The abdomen is generally hot, tense, and tender. As the disease advances through the varieties of the bowels, the above symptoms increase. The stools, which were previously, and while the internal surface of the intestines was chiefly affected, of a watery, serous, mucous character, sometimes streaked with blood, now become very scanty and morbid; the abdomen more timid, painful, and tender, and vomiting more frequent and distressing.

47. When the inflammation commences in what has been called the phlegmonoid form, seizing at once upon the different coats of the bowels, the symptoms are much more acute and violent from the first. The patient complains consecutively upon, or coetaneously with, cold chills or rigours, of sharp pains around the umbilicus, in the right iliac region, or between these regions, and extending down to the hypogastrium. The pulse is hard, quick, and constricted, or small. The tongue is loaded, clammy, and dry. The bowels are irregular or constipated, and inefficiently acted upon by cathartics, until depletions have been freely practised. When the disease commences in this form, its progress is very rapid. The face soon becomes anxious; the stomach irritable, and the vomitings frequent; the tongue deeply coated, dry, and brown; the abdomen very tense, tumid, and tender; the skin, particularly over the trunk, very hot, harsh, and dry; the calls to stool most distressing and unsatisfactory; the urine very scanty and high-coloured; and the respiration suppressed, and chiefly intercostal.

If the disease is now arrested, all these symptoms increase in violence. The features are sharp and anxious; the patient lies on his back, with his knees drawn up; the hands and feet are cold and clammy, while the abdomen is hot; the pulse is small and weak; the breathing laboured, hurried, and irregular, sometimes difficult, or attended by hicouche. The pain and tenderness are often more diffused over the abdomen, extending to the hypochondria and hypogastrium, and the muscles of the back.

At last, exhaustion, cold sweats, faintness, hurried respiration, singultus, with increased action of the alæ nasi, collapse of the features; a weak, small, thready pulse, extreme restlessness, and death, supervene.

48. C. Sub-acute and Chronic Ileo-coilitis.—a. The sub-acute and chronic states of ileo-coilitis, particularly in the slighter cases, differ in nothing from the serous and mucous varieties of diarrhoea. I have encountered this point of difference in my article, that these varieties of diarrhoea, although generally commencing in irritation, usually depend, especially in children, upon inflammatory action, seated chiefly in the mucous surface and follicles of the ileum, caecum, and colon; and that these, as well as some other forms of diarrhoea (§ 13-18), particularly when severe, of long duration, or attended by fever, pain, or tenderness in the situations stated above (§ 43), always present the usual consequences of inflammation of these parts upon examination after death. The symptoms, therefore, of sub-acute and chronic ileo-coilitis are identical with those described as attendant upon the inflammatory states of diarrhoea.

49. b. The more chronic states of ileo-coilitis are most frequently associated with visceral disease of a chronic, and sometimes obscure kind. They most commonly attend tubercular consumption, and in this case the mucous follicles and the solitary intestinal glands are chiefly affected, and contain, in the early stage, tubercular-like matter. Chronic disease of the liver, and enlargement of the mesenteric glands, are also frequent complications, the former generally preceding, the latter supervening upon the intestinal affection. The acute and sub-acute forms of ileo-coilitis are often associated with inflammation of the substance of the liver, and with certain endemic and epidemic fevers, of which, however, they are usually connective. Chronic ileo-coilitis is seldom a simple disease, but, in its different complications, the affections which precede or occasion it, as well as those to which it gives rise, should be ascertained before the intentions of cure be resolved upon.

When the disease affects the rectum and sigmoid flexure of the colon, the desire to go to stool is almost constant, and the straining often urgent. In this case, the complaint becomes identified with chronic dysentery.

50. c. The symptoms of chronic ileo-coilitis differ but little from those of chronic diarrhoea. When the colon is but slightly affected, the stools may not be very frequent; but if it be the chief seat of the disease, there will be more or less diarrhoea, the evacuations being yellowish, greenish, or clayey, or even mucous-puriform in a more advanced stage, or when ulceration has taken place. Uneasiness and soreness are usually felt in the abdomen, and sometimes pain, at one place acute, at another dull, or fixed, or...
moveable. These sensations are exaggerated some time after a meal, also by moral emotions, by violent exercise, or by the motions of the carriage. The tongue is often not materially affected; it is sometimes pale. The appetite, particularly when the disease is symptomatic of tubercular consumption, is often not materially impaired. At an advanced stage, the abdomen is usually large and tympanitic, contrasting remarkably with the emaciated extremities, especially in children. In this class of patients, mesenteric disease supervenes on the intestinal affection, and *marasmus* is produced. In some cases, however, especially in adults, the abdomen is either not swollen, or is even more than usually sunk. A short, dry cough frequently attends the latter periods of the disease. The duration of chronic ileo-colitis is indeterminate. It is often recurrent, intermittent, or remittent, presenting longer or shorter periods of remission, or of immunity from disorder, especially in its slighter states and earlier stages. But it generally recurs upon slight errors of diet or regimen, or after exposures to cold or humidity.

51. *D. Pseudo-membranous Enteritis.*— *Enteritis pseudo-membranosa.* Cruevihier. — a. This form of enteritis was first described by Dr. Powell. (*Med. Trans. of Coll. of Physic,* vol. vi, p. 106.) It has more recently been observed by Cruevihier, Andreau, Gendrin, Gubert, Berthonneau, and myself. It rarely appears in an acute, but generally in a *sub-acute* and *chronic* form—the latter especially; or, in other words, acute inflammation of the villous surface. 2. Of the bowels is rarely preceded by formation of a false membrane on its surface to any extent, although portions of coagulated lymph of considerable size are occasionally passed along with the other matters evacuated in the advanced course of the disease. Pseudo-membranous enteritis is most frequently *chronic* and *intermittent,* or, rather, it may be said to depend upon a latent and prolonged state of inflammation, extending along a very large portion, sometimes the greater part, of the intestinal canal, as evinced by the quantity thrown off; the most prominent symptoms subsiding for a considerable time, and reappearing afterward, and continuing, with more or less severity, until the false membrane produced by it is detached and discharged. I have met with two cases of this disease in its most severe forms, and several instances in a much slighter degree. Both the former, and most of the latter, occurred in females, in which sex all the cases observed by Dr. Powell also occurred.

The symptoms are usually slight, and consist chiefly of a sense of soreness, slight heat, and tenderness on firm pressure of the abdomen. The bowels are generally irregular, either too relaxed or too costive, and rarely natural, as respects either the times of evacuation or the state of the motions. After considerable intervals, sometimes of several weeks or even longer, colicky and violent abdominal pains are experienced, and the stools afterward passed contain shreds of false membrane of various sizes, occasionally formed into complete tubers of considerable length. These formations are occasionally white and soft, and sometimes yellowish, consistent, and even elastic. From their appearances, as well as from the symptoms preceding their discharge, there is reason to infer that they may be produced in any part of the intestinal canal, or in both the small and large bowels at the same time. While the symptoms are often so slight as hardly to occasion any inconvenience, they are sometimes much more severe in respect both of the intervals and of the painful attacks preceding the evacuation of these morbid productions. In these, the symptoms of *chronic mucous-enteritis,* or of *chronic ileo-colitis,* are generally present. Heat, soreness, aching; or dull or angina-like pains, are felt at intervals; but these pains are seldom increased by pressure, although soreness and aching are usually aggravated by it. After slighter or severer local symptoms of this kind being occasionally felt for some weeks, or even longer, and augmented by any error in diet, or departure from an abstemious regimen, a more violent attack occurs, and resembles either severe colic, or the symptoms attending the passage of biliary calculi into the duodenum. The bowels then generally become moveable, and the stools contain portions of false membrane, which continue to be voided for two, three, or four days, three or four evacuations often taking place daily. Occasionally the bowels do not act spontaneously, the discharge of these membranes being assisted by medicine. The severe symptoms afterward subside, until the morbid formation is again developed, and begins to be detached. The pulse is sometimes not affected, but is often somewhat accelerated. The tongue is usually coated with a whitish or yellowish-white mucous or coating, and is seldom red at its point or edges. The appetite is impaired; there are thirst, and much dulness of the stomach and bowels; but the temperature of the surface, the state of the skin, and the urine, are not materially affected. During the severity of the paroxysm, vomiting frequently takes place; and Dr. Powell observed jaundice precede it, probably owing to an inflamed state of the villous coat of the duodenum, or having prevented the discharge of bile into the intestine, or to the false membrane extending over or into the common duct.

53. Dr. Powell states, that in all the cases he observed there was indigestion, with frequent recurrence of pain; that the more violent seizures consisted in sudden and excessive pain, frequently increasing in paroxysms, and rather relieved by pressure, but leaving great soreness and tenderness during the intervals; and that this state continued for four days, the stomach being then free from pain, and the tongue clammy and coated. This physician justly considered the false membranes*.

* A lady, who came from Yorkshire to be under my care, and remained several months in London, was the subject of this complaint. Associated with *hepatitis* in its most severe and complicated form, and occasionally amounting to catlepy. She experienced a recurrence of the more painful seizures every four, five, or six weeks, followed or attended by the discharge of the false membranes in large quantity, and sometimes in the form of perfect tubes. The catarrh was always most painful, somewhat irregular, attended by vomiting and severe abdominal pains, yet abundant; but they were also accompanied with the discharge of shreds of false membrane from the uterus. The discharge of the membranes from the bowels and vagina was not, however, contemporaneous, although sometimes nearly so. The nature and the severity, the rare complication, and the persistence of the disease, led to consultations other physicians thus also witnessing this almost singular case.
thus discharged to have been formed in a similar manner to those observed in group, and, in a few instances, in bronchitis. (This subject is farther noticed in the article Digestive Canal, § 46, 48.)

54. IV. Associations or Complications.—Several of these have already been noticed. The follicular variety of muco-enteritis is often associated with adynamic or typhoid fevers, or, rather, it occurs as a frequent complication of these fevers, especially in certain localities, epidemics, and circumstances, to which sufficient allusion has already been made (§ 17). Its complication with tubercular consumption, also as a consequence of that malady, has likewise been stated (§ 17). With disease of the mesenteric glands it is likewise very often associated; but in this complication it is generally the primary affection. Muco-enteritis is very commonly connected with disorder of the biliary functions and with disease of the liver, particularly in India and warm climates. Either affection may be consequent on the other, but most frequently enteritis is the secondary disease. When matter is formed in the substance of the liver, follicular enteritis, with diarhoea, or a chronic form of dysentery, is produced; but not so much by the acrid or otherwise disordered bile discharged into the intestines as by a morbid state of the blood, caused by the absorption of a portion of the matter from the liver. The blood thus contaminated induces disease of the intestinal follicles, and particularly of Breyer's glands. It is only when the surface of the liver is inflamed that the disease sometimes extends to the peritoneal surface of either the small or the large intestines, inducing sero-enteritis, or sero-ico-enteritis, the omentum, and even the mesentery, being sometimes also implicated. It is, however, not improbable that disease of the follicles, particularly if ulceration have taken place, will occasionally be followed by the passage of morbid secretions into the portal circulation, inflammation of the portal veins and abscesses of the liver being thereby occasioned. Jaundice is also sometimes complicated with muco-enteritis, and may arise either from disease of the liver or ducts, or from extension of the inflammation to the common duct, or the occlusion of its opening into the duodenum, owing to tumescence of the surrounding tissue.

55. Inflammation of the internal surface of the small intestines sometimes extends from the intestinal follicles, and particularly of Breyer's glands, as respects the villous coat, being complicated with muco-enteritis. In some instances the disease proceeds in an opposite direction, and in others both the stomach and intestines are nearly coextensively affected; this latter occurrence being very frequent in fevers. Indeed, inflammation of the villous coat of both the stomach and intestines constitute one of the most common and important complications in many, malignant, and exanthematosus fevers; but this subject has been discussed in the article Gastro-enteric Disease (§ 10, et seq.). The various forms of enteritis, but especially muco-enteritis, very frequently appear as complications in the course of scarlatina, smallpox, and measles, although often in slight or latent states, or more or less masked by the other phenomena of these maladies. In scarlata, gastro-enteric inflammation is a part of the morbid conditions invariably present in some grade or other, or, in other words, inflammatory injection of the villous surface of the stomach and intestines is as constantly present as the same condition of the vascular rate of the skin, and most probably at a still earlier period of the disease, and to a much greater extent, when the eruption either is imperfectly developed on the surface, or disappears from it prematurely. This, indeed, is demonstrated by the symptoms of all cases, wherein they are carefully observed. The affection of the intestinal mucous surface, more especially in those cases just alluded to, is evinced by pain, tenderness, tension, and fulness of the abdomen, and by nausea, vomiting, or diarrhoea; the stools being scrous, dark-coloured, and containing flakes of lymph of a much lighter colour. In the complication of scarlatina with enteritis, the villous coat itself is the part chiefly affected; while in that of smallpox with enteritis, the mucous follicles are often implicated. In the advanced stages, however, of these maladies, sero-enteritis occasionally supervenes, either alone, or in connexion with peritonitis.

56. Enteritis may also occur as a complication of the advanced stages of measles, more especially upon the premature, or the regular decline of the eruption; but it is generally slight in degree, and rarely the cause of an unfavourable termination of that disease, unless when associated with general bronchitis, or with pleurisy.

57. In children, the different forms of enteritis appear each of them complicated with other diseases than in uncomplicated states; for they seldom continue long in those latter states without superinducing other disorders. In many instances the complication is either accidental or contingent; in others, it depends upon the nature of the predisposing and exciting causes; while in some, the associated diseases arise as consequences of the primary affection of the intestinal canal. Sufficient allusion has already been made to these complications with general bronchitis, or with contumacious fevers, or with encephalitis, or with cerebral affections, or with brachial affections, or with tuberculous, or with mesenteric glands, &c. It is not unusual to observe, particularly in some seasons, a form of fever very prevalent, or even epidemic among children, in which both the digestive and the respiratory mucous surfaces are affected by a catarrhal form of inflammation, and in which the state of irritation seems to predominate in these surfaces; it is one of those true inflammatory actions. It is difficult to determine whether the digestive canal or the respiratory organs are first affected; either may experience a priority, or predominance, of disorder; and the one may become free from disease as the other is more severely affected. These circumstances are of great importance in the management of this complication, which is exp-
Inflammation of—Diagnosis.

671

extremely frequent in infants and children in London, particularly in the poorer classes and in children insufficiently or improperly nourished and clothed.

58. V. Diagnosis.—Little need be added on this subject, as much has already been stated in reference to it; and as, both in pathological and in therapeutic points of view, it is as necessary to point out relations, approximations, or alliances, between diseases, as to assign distinctions between them, that exist only in the more extremely removed cases, and that cannot be detected in the majority of instances, or only partially, and in their incipient states.

Writers, who had little knowledge of disease from close personal observation, have been in the habit of stating certain distinctions between allied affections of the digestive canal, as if they were describing different genera, or distinct substances in natural history, or certain unvarying entities, or algebraic quantities; and hence misleading, more frequently than instructing, the inexperienced. The disorders which they have thus endeavoured to distinguish as the distinguishing characteristics of one, or, rather, from enteritis simply, as they have known but little of its various forms and associations, are colic, ileus, gastritis, perforitons, constipation, diarrhoea, cholera, and dysentery; and it must be obvious to the scientific and rational practitioner, that it is quite as important for him to trace the connexions between diseases, and the transitions of the one into the other, as to recognise differences, which are often more apparent than real, and which should be estimated as the effects of the same disease, rather than differences—as indications of something in common, but as something also peculiar or proper to each, which it is necessary thus to establish.

59. A. There are certain circumstances connected with the seats of enteritis to which some reference may be made, as being not without importance in practice; and these may be comprised in an answer to the following question: How far may the symptoms enable us to conclude as to what portion of the intestinal canal is chiefly or solely affected? Before any conclusion should be arrived at, the exact seat of pain, the part in which it commenced, the seat of tenderness or distension; the state of the stomach and bowels, and the periods after taking food when vomiting or purging occur; the sounds and sensations caused by percussion; the appearance of the evacuations; and the nature of the exciting causes, should be duly considered.—a. The seat of pain at the commencement of the attack is always deserving of attention from the physician, although not always correctly, the part affected. If the disease begin in the region of the duodenum, or if this part become consecutively affected, irritability of the stomach a very short time after food is taken, and either increased or interrupted discharge of the bile, are more likely to occur, and the calls to stool are not nearly so frequent as when the lower portions of the bowels are inflamed. (See Duodenum, § 7, et seq.) When pain, ten- derness, and fulness commence around the nav- el, or bend on their splinter or films, irritation of the ileum may be suspected; and if there be diarrhoea, and pain in the region of the cecum, the pains assuming a colicky or gripping character, and extending in the course of the colon, the extension of the disease to these viscera may be inferred, especially if tenderness exist in these situations, if there be little or no vomiting, and if the symptoms be exasperated two or three hours after a meal. When inflammation of the villous surface of the colon is sub-acute or chronic, even although it implicate the lower part of the ilium, or when chronic ileo colitis is present, the functions of the stomach are often but little affected, unless the attendant diarrhoea is suddenly arrested, or constipation occurs. It is clear, at the commencement of the disease, that it is limited to one portion of intestine, or to a single tissue. The rapidity of extension of the disease to adjoining parts is generally great in proportion to the depression of vital power, the state of this power in connexion with that of blood giving rise to the particular form or character of the inflammation, and of its consequences or products.

60. b. A serious state of the stools, particularly if abundant flaccid, or pieces of lymph, be evacuated from the bowels, often with a mixt appetite. The ileum is chiefly affected; while a mucous, or mucopuriform condition of them indicates disease of the follicular glands: a combination of these two states suggests the probable association of these affections. The presence of digested faecal matters in the stools, duly coloured with bile, evinces the performance of the functions of the upper portions of the alimentary canal; but when the food is imperfectly changed, impairment of these functions, and a great irritant, causing the general and local debility, and disease of the mucous surface, may be inferred; the inflammatory irritation generally extending, in such cases, to both the small and large intestines. If the stools are devoid of their peculiar or usual odour, the large bowels are probably affected. If they contain small but numerous streaks of blood, or if the blood be mixed in small quantity with the other matters, a severe form of mucous-enteritis is generally present. If the bowel be passed in large quantities; if the bowel be mixed with the other evacuated matters; or if it be greasy, or mucopuriform matter be also observed, ulceration consequent upon follicular enteritis is usually found. If it be voided quite pure, in large quantity, and but little mixed with the rest of the motion, it commonly proceeds from the large bowels.

61. c. Percussion should seldom be omitted in endeavouring to ascertain the seat of enteritis. It can rarely be endured when, or in situations where, the inflammation has advanced to the serious state. It assists in the diagnosis, the parts most distended by flatus, or obstructed by faecal accumulations, by internal strangulation, or by adhesions, or thickening, &c., of the coats of the bowel. As long as the disease is confined to the inner surface, it seldom causes much pain at the time, although soreness, or aching, is usually increased by it afterward.

62. d. Among other circumstances contributing to a correct diagnosis of the several forms and complications of enteritis, the nature of the causes, the constitution and the previous history of the patient, are not the least material, particularly as respects the character of the attendant fever, and of the local affection. If
INTESTINES—INFLAMMATION of—Diagnosis.

these causes are of a septic, contaminating, or depressing kind, such as already enumerated (§ 18), the mucous follicles will be especially affected, and the fever will present the adynamie state. If the powers of life have been previously sunk, or if the circulating fluids have become morbid or contaminated, or if there have been manifest cachexia conjoined with great debility, then the morbid and the constitutional affections will be such as just stated; and both the small and the large bowels will be similarly and almost coextensively affected. When inflammation in these cases advances to the serous surface, particularly after perforation of the coats, it extends rapidly over this surface, and gives rise to a more or less copious fluid effusion, the state of local as well as of constitutional action being, in such circumstances, rarely capable of producing coagulable lymph, as shown in the article VESSELS AND MUCUOUS MEMBRANE (§ 68).

63. B. If it be necessary to ascertain the parts of the intestines which are the seats of inflammation, it is still more requisite to determine whether or not inflammation is really present. This, however, is not always so easy as many have believed; for inflammatory action may exist in the digestive canal, so as to give rise to many of its most dangerous results, without those symptoms by which inflammation has generally been supposed to be indicated having been observed. Several of these disorders, usually viewed as functional merely, and which undoubtedly are such in many, or even in the majority of cases, often proceed from inflammatory action in a portion of the villous surface, that either extends itself in a gradual or rapid manner, or becomes resolved when the causes have ceased to act, or when the secretions from the part have had the effect of removing the irritation, or of unloading the congested vessels which have been viewed, from the character of the prominent symptoms, as flatulence, or constipation, or colic, or diarrhoea, have actually been some form or other of enteritis, or inflammatory states, in which certain portions of the intestines, or of the tissues composing their parietes, have been affected in a different manner, or in a modified form or degree.

61. a. Flatulence, constipation, and colic are chiefly functional disorders of the digestive canal; but they often depend upon inflammatory irritation of some portion of it, and are apt insensibly to pass into inflammation. They, moreover, both severally and conjointly accompanying, as prominent and important symptoms, the most severe and dangerous forms of enteritis. Hence the necessity of determining their sources, and their connexions with, or independence of inflammatory action. If the least tenderness or soreness on percussion, or on firm pressure of the abdomen, be felt or indicated; if distension afterward occasions soreness, pain, or increased tenderness, although neither may have been complained of at the time of making it; if the pulse be hard, constricted, or full, or accelerated; if the abdomen become tumid or tense, dry, hot, or harsh; if the tongue be white, the papillae erect, and its point or edges red; and more especially if nausea or vomiting occur, the connexion of either of these affections with, or their dependence upon inipient or developed inflam-

mation, should be inferred, and a strictly antiphlogistic treatment prescribed. I have met with instances where enteritis had been treated as simple constipation with colicky pains, and where the slightness of the above symptoms, or the presence of only one or two of them, had deceived the inexperienced practi-
tioner into the exhibition of aird and heating purge, which had aggravated the disease until it had proceeded too far to be arrested by the most judicious means, fatal symptoms suddenly appearing, and the patient sinking before the mischief was anticipated.

65. b. Ileo, like the preceding affections, may or may not be associated with, or be entirely owing to inflammation. It is shown in the article on Cole and Ileo (§ 37-45), that these affections are often thus related, the latter particularly; and that, even when depending upon the pathological states there enumerated, inflammation is very often either an associated or a superinduced lesion, generally implicating all the coats of a portion of intestine, or the serous coat more especially. In many of these cases, either some internal constriction, or strangled hernia, or an intus-susception, is the cause of suffering; but in these, as well as in those originating differently, inflammation soon supervenes, although it is not always announced by rigours or consequent reaction, or even by the general charactet of the symptoms. Indeed, the sufferings of the patient are frequently so great, and the vital power is so exhausted by the nature or extent of the lesion—the shock sustained by the constitution is such—as to prevent the development of the phenomena of general vascular reaction, and to extinguish life before the local changes characteristic of inflammation had proceeded far, or before symptomatic fever had supervened. These attacks, and particularly those varieties of cole accompanied by the location of the Lesions Macro colic (§ 16, 25), have been viewed as forms of enteralgia merely, or of neuralgia of the intestines, and described as such by several Continental writers. That the sensibility of the nerves of the intestines is morbidly excited or affected, will be admitted; but that these diseases consist only of altered sensibility, cannot be conceded. This is a part, merely, of the pathological states constituting these maladies; impaired and disordered secretion and excretion, a morbid condition of all the secretions poured into the intestinal canal, and diseased action of the muscular coats of the bowels, equally form a part, and often the most important and efficient part of them, various other associated functional derangements being also present.

66. c. Diarrhoea, Cholera, and Dysentery may be associated with intestinal inflammation, or may pass into it; and, equally with the foregoing disorders, require to be carefully considered, and in their symptomatic or complicated states. a. Diarrhoea, particularly its severe and mucous forms, has been already shown to be one of the earliest indications of enteritis, particularly when the mucous coat and follicles of the small and large intestines are the tissues affected. But the slighter and more evanescent states of diarrhoea are generally independent of inflammation, and proceed chiefly from irritation and increased
exhalation and secretion, caused either by the nature of the ingesta, or by checked cutaneous and pulmonary transpiration, or by the state of the secretions poured into the digestive canal; the irritation and increased secretion, however, often passing into inflammatory action whenever a predisposition to it is present. As soon as this change takes place, the states of the stools, of the abdomen, of the skin, of the pulse, and of the tongue, as described above (§ 5, et seq.), will generally indicate it to the careful observer.

67. d. The same observations apply to Cholera, which also may pass into enteritis; but it should be recollected that when muco-enteritis in an intense form is seated chiefly in the duodenum and jejunum, that the symptoms may nearly approach those of cholera; vomiting, diarrhoea, and sympathetic spasms of the muscles of the extremities, being often as severe in this state and seat of enteritis as in that disease. It has already been shown that bilious cholerae are a morbid state of the sphincter ani, in which the irritation of morbid or acrid bile exciting inflammatory action in the mucous surface, that either subsides without proceeding farther than this surface, or extends to the external coats when the inflammatory disposition is considerable. In either case, particularly in the latter, the physician will be guided by the symptoms evinced by the parts and in the manner already named (§ 59) in forming his diagnosis.

68. y. In Dysentery, more or less inflammatory action of the mucous surface and follicular glands of the large intestines is generally present, especially in the sphenic forms, and in the developed states of the disease. Still, the inflammation is often a superinduced and an associated, rather than a primary morbid condition in this malady, the abdominal secretions and excretions being the first disordered.* These secretions irritate the mucous surface and its follicular apparatus, and induce inordinate or spasmodic action of the muscular coats of the bowel, and particularly of the rectum and sphincter ani, causing the retention of the more hardened portions of feces, which further augments the irritation, until inflammation, with its various consequences, is produced. In such cases, it is not merely the existence and the exact seat of inflammation that should be ascertained, and which the description already given will generally indicate; but the characters of the local action and of the constitutional affection ought also to be closely observed and correctly estimated.

69. d. When inflammation extends to the serous coat of the intestines, it becomes identified with peritonitis; and whether it be limited to a small portion of this coat, or extend more or less generally, it is in all respects an intestinal peritonitis, of the diagnosis of which sufficient notice is taken under that head (see PERITONEUM), to which, and to the article STOMACH, where enteritis is distinguished from gastritis, the reader is referred for farther remarks on the diagnosis of these very intimately-related maladies.

70. c. As the complications of enteritis are so important, it becomes requisite that the diagnosis of them, and even the successions of their appearance should not be overlooked. This is still more important in warm climates, where enteritis is very often a complicated malady. When functional and organic diseases of the liver are attended by a morbid secretion of bile, or when this fluid has become acrid, enteritis is very commonly induced in one or other of its forms, and is then rarely limited to the small intestines, but passes this and ripens being often complicated, and hepatic dysentery developed. But chronic enteritis, or ileo-colitis, may occasion, as already shown (§ 49), disease of the liver, particularly of its internal structure, either with or without purulent formations in it. In this case, increased frequency of vomiting, tenderness and fulness in the right hypochondrium and epigastrium, chills, rigours, and jaundice, may supervene, and indicate the nature of the complication, or they may be almost or entirely suppressed. In acute enteritis, hepatitis, and dysentery are often associated, and without sufficient proof being furnished of their course of succession. In the Eastern hemisphere, however, the disease of the liver is most frequently the primary affection, although it sometimes is induced by either, or by both of the other maladies. Of the complication with gastritis, it is unnecessary to add more than that its existence should always be expected when enteritis is occasioned by stimulating, acrid, or poisonous ingesta, or by an excessive quantity of rich and heating food or drink. In these cases, the frequency of the vomiting, the recurrence of it instantly after substances are taken into the stomach, the constant or frequent eructations of flatus, the epigastric tenderness, soreness, pain, and fulness, in addition to the symptoms of enteritis, will indicate the morbid association. When this complication arises from the nature of the ingesta, the affection of the stomach sometimes subsides as that of the small or large bowels increases, and thus gastro-enteritis may pass into muco-enteritis, and thence into ileo-colitis or dysentery. This succession is not infrequent in warm climates, or in temperate climates in summer and autumn, and particularly in those who have partaken of unwholesome food, or who have exceeded in the use of spirituous or fermented liquors. Enteritis in connexion with gout, or in the gouty diathesis, and especially upon the disappearance of gout from the extremities, is not uncommon, and is always sudden and severe in its occurrence; but farther allusion will be made to it hereafter.

71. VI. Terminations of Consequences and Prognosis.—A. A favourable termination of enteritis is indicated by a diminished severity of the more prominent symptoms, by the decrease of fever, by a more natural state of the evacuations as to their appearance and their frequency, by a more copious discharge of urine, by a more clean, moist, and natural state of the tongue, by a less frequent pulse, and by a diminution of the tenderness, soreness, fulness, tension, and heat of the abdomen, the general surface becoming more moist and natural.

72. B. The unfavourable consequences or terminations of inflammation of the bowels are,
INTESTINES—INFLAMMATION OF—Lesions.

1st. Ulceration, with its consequences, intestinal hemorrhage, or perforation of the intestines; 2d. Various organic lesions of the coats of the intestines and of the mesenteric glands; 3d. Peritonitis in some one or other of its forms; 4th. Exhaustion of, or fatal shock to the vital powers; and, 5th. Spasmodic ulceration of a portion of the intestinal tissues or parietes.

a. Ulceration of the intestines is rarely a fatal lesion, although it is so with few exceptions; for ulcers have been found cicatrizated in this situation, the patient having died of some other disease which had occurred long subsequently to the intestinal affection. These cicatrices very rarely present any regeneration of the villous tissue, although this has been observed by M. Andral. Their bottoms consist of a cellulose-serous tissue, of a grayish white, without either villi or foliaceous tissue, gradually assuming the appearance of the surrounding mucous coat, and possessing considerable firmness and tenacity. Ulceration of the intestines—which is fully described in all its forms in the article Digestive Canal (§ 36-40)—is not satisfactorily indicated by symptoms; although a combination of phenomena may lead to a just conclusion as to its presence. A mucous-purureous or ochronous appearance of the stools, and diminution of their quantity, or shock, the presence of large quantities of blood in the stools, and symptoms of typhoid fever assuming an epidemic or chronic remittent, or hectic form, are the surest indications of ulceration. The diarrhea appearing in the course of tubercular disease is generally dependant upon, or connected with disease of the follicular glands, and, at an advanced stage, with ulceration. Whenever mucous-enteritis or follicular enteritis occurs in the course of a constitutional malady or vice—of fever, of typhoid fever, or any chronic disease, the abdominal cavity should be carefully examined for the presence of an ulcerative process. The signs and symptoms of ulceration, as the ileus, ascites, or the complication of cellulations, effusions, perforations, and the like, are all described in the article Digestive Canal.

73. b. Various organic lesions of the parietes of the intestines, similar to those about to be noticed, or more fully described in the article Digestive Canal (§ 25, et seq.), and of the mesenteric glands, may be occasioned by enteritis, the patient continuing for months or years subsequently to evince disorder of the sensibility or functions of the bowels. These lesions, particularly dilatations, contractions, thickening of the coats, &c., according as they influence the caliber, or the secretions, or the contractility, or the organic sensibility of the intestines, occasion flatulence, constipation, colic, indigestion, retching, emaciation, fecal accumulations, hypochondriasis, and various nervous complaints, and, at last, either an attack of inflammation of the bowels, or of one of the associated viscera, or some other malady, carries off the patient.

47. 2. Peritonitis, whether circumscribed or general, takes place in two ways: from ulceration, and from the extension of the inflammation to the serous coat without ulceration. It may arise from ulceration without perforation of this coat. In this case the peritonitis is usually limited. If the ulcer have perforated all the coats, general peritonitis, caused by the effusion of a portion of the contents of the intestines, commonly results. Sometimes, however, perforation takes place without effusion occurring, owing to adhesions of the opposing serous surfaces having taken place before the coats of the intestine had been entirely penetrated. This consequence of enteritis is fully illustrated in the articles on the Peritonum and Digestive Canal (§ 40-43), where numerous instances and references are adduced. The extension of the inflammation from the internal to the external surface of the bowel, whether it continue limited to a portion only of the latter, or extend to the peritoneum of the entire intestinal tract, is the consequence of enteritis, which is indicated by the symptoms already enumerated (§ 31), and by those more fully described when treating of inflammation of the Peritoneum.

75. d. Exhaustion of, or the shock sustained by the vital powers, is more frequently a termination or consequence of enteritis than space-lation or gangrene. Many of the instances of death which have been attributed to this latter consequence have depended upon the former; but, when space-lation of a portion of the intestine does take place, very nearly the same symptoms which indicate the one accompany the other. It is extremely probable, moreover, that in some of those cases where gangrene of a portion of intestine is detected after death, the gangrene had not existed at the moment of death, or had commenced either then or soon afterward; and that the symptoms were those of death or shock, leading not only to death, but also to space-lation of the most inflamed part, death occurring first, and space-lation soon afterward, or both nearly contemporaneously; an opposite course, however, taking place in rarer cases. When the pulse becomes very rapid, small, weak, irregular, or intermittent; when the breathing is hurried, laboured, irregular, and attended by increased action of the nostrils; when hicouche or regurgitation of the contents of the stomach without vomiting occurs; when the patient complains of sinking, coldness of the general surface or of the extremities, or becomes restless; when the abdomen is tympanitic without increase of pain, or the skin is cold and clammy; and when the eyes are sunk, surrounded by a dark circle, and all the features sharp and collapsed, vital exhaustion, in connexion with more or less of structural lesion, has then proceeded too far to admit of hopes of recovery.

76. c. Although gangrene of the intestine follows immediately upon the precedes dissolution, yet sometimes have its existence antecedently to this issue sufficiently demonstrated. When the inflammation is caused by strangulation, and an operation is performed at a too late period, the portion of intestines thus circumstan- ced has been occasionally found in a space-lated state, although more frequently it is a state of venous congestion, or a condition about to pass into space-lation, rather than this latter state that is observed. Moreover, in cases of enteritis caused by intus-susception, a considerable portion of intestine has been thrown off in a gangrenous state. Even portions of the villous coat of the bowel have been detached by effusion of fluids underneath it, whereby its vascular connexion being destroyed, space-lation has taken place. In all such cases, the symptoms of vital exhaustion above enumerated (§ 75) present themselves, and death ensues, with very few exceptions. These exceptions occur only when adhesions of the opposing surfaces had formed so as to admit of the
Occasionally, unconscious collapse is due to the loss of fluid, cold sweats, and coldness of the surface; constant hicough, with flatulent eruptions; unconscious or unrestrained evacuations, with a putrid or cadaverous odour; a small, weak, imperceptible or intermittent pulse; collapsed features, sunk eyes, and discoloured surface indicate the disorganization, and soon terminate in death.

77. VII. Appearances after Death. I must refer the reader to the articles on the Digestive Canal (§ 18-43), Diarrhoea (§ 13-23), and Dysentery (§ 58-80), for a detailed account of the structural changes consequent upon inflammations of the intestines, and merely state, at this place, those more generally observed. When enteritis or entero-colitis supervenes upon inflammation of the stomach or liver—the disease of these organs occasioning death, and thus furnishing an occasion of observing the earlier changes connected with enteritis—the villous coat is then more vasoconstricted and florid than usual, and more turgescent, particularly the valvulae conniventes; and in many places the mucous glands are more developed, and marked by a deeper tinge. The appearances are not uniform throughout the canal, but are most remarkable in the duodenum and upper portions of the ileum, when enteritis has been caused by a morbid state of the bile, or has been consequent upon gastritis. In these slight or incipient states, the inflammation is present only in broad patches or streaks, leaving the intermediate spaces of a nearly healthy state. The lowest portion of the ileum, the ileo-caecal valve, and cecum are oftenest found diseased, particularly in acute cases, and where enteritis or entero-colitis occurs as a complication of febrile diseases.

78. a. In the acute forms of enteritis, the villous coat is not only more vascular and turgid, but it is also softer, and sometimes thicker than natural. If the inflammation has proceeded far, it presents a brick-red tinge, and is easily detached from the subjacent coats, the connecting cellular tissue being soft, turgid, and inflamed. When this state exists in a considerable portion of the tube, the coats are apparently thickened, arising from the extension of the inflammation to the more external tissues, till the attached surface of the intestinal peritoneum is reached. The substance or parietes of the bowels may be considered as affected in these cases, even although the external surface of the mucous membrane is not affected. When this is the case, the red capillaries in the inflamed peritoneal coat are connected with the effusion of coagulable lymph, particularly in those parts where they are most numerous, the lymph or albuminous exudation existing in specks, or in considerable spots or patches, on the serous surface. When, however, these latter appearances are remarked, the interior of the inflamed intestine frequently presents more serious changes than yet noticed. The villous surface is then deeply inflamed, and seems abraded or excoriated in parts. It is sometimes, in other parts, covered by patches of lymph, or of an albumino-puriform or muco-puriform fluid, or by a sero-sanguinous matter; and it is often, also, ecchymosed in numerous points or specks, or it presents still larger marks of sanguineous infiltration. In other cases, portions of a dark, slate-coloured, or spheracelated hue are observed, with or without ulcerated specks, or even large ulcers, which have nearly penetrated as far as the external coat in adjoining parts. In rarer instances, one or more of these ulcers have made their way through the peritoneum, the contents of the bowel being partly discharged into the peritoneal cavity. Occasionally, the ulcer has become attached, at its margin, to an opposite portion of the intestines, the escape of fecal matters into this cavity being thereby prevented. In a few cases, where the peritoneal surface has been coated with coagulable lymph, in the progress of the ulcerations through the membrane, the ulcers have been covered over by the lymph, so as to prevent the passage of the intestinal contents through the perforations. In addition to disease of the follicles, and to the consequences of such disease, particularly ulceration and perforation of the intestinal parietes (see Digestive Canal, § 37, 40, et seq.), the villous surface, especially after the forms of enteritis observed in warm climates, is often excoriated or abraded in parts; and it is not infrequently spheracelated in large patches, particularly in the large bowels. These changes, however, as well as those consequent upon chronic enteritis, especially as respects the follicles and glands, are more fully described in the articles Diarrhoea (§ 12-22), Digestive Canal (§ 36), Dysentery (§ 58), and Fever (§ 519).

I shall not, therefore, allude to them farther at this place.

79. In the forms of enteritis in which the substance of the intestine or its peritoneal coat is chiefly affected, either primarily or consequentially, the whole of the coats are often very vascular, red, or of a brick-red colour, and are readily torn. Coagulable lymph is effused on the serous surface, either in distinct clots, or as a general film, of greater or less thickness, and glistening the convolutions to each other, and to the adjoining viscera and surfaces. In these cases, the omentum has sometimes participated in the disease, being either more than usually vascular, or drawn up irregularly to the arch and flexures of the colon. When the examination is made within a few hours from death, as is usual in warm climates, the vascularity of the diseased parts is very great; and, although the colour may be beginning to change, or the parts to assume a gangrenous appearance, yet complete gangrene of all the coats of the bowel is not often met with. It is, however, common to find the villous surface spheracelated in places, and the external coat of the same part either of a bluish or brownish hue, but not altogether deprived of its cohesion, although more easily lacerated than usual. In these acute cases, the inflamed intestine is generally distended with flatus; but it is sometimes constricted, and the constricted portions are occasionally so small as to give the appearance of stricture by the application of a fine ligature. Intersusceptions of portions of the ileo-
um, which had taken place subsequently to the occurrence of inflammation, or even just before, or at the period of death, are met with in rare instances.

80. b. In chronic cases, as well as in the acute, the changes are chiefly observed either in the villous surface or in the follicles, or in both. Many of the lesions observed after the acute forms of the disease are also met with after the chronic states. In the latter, however, the villi are frequently of a blackish tint; and the isolated follicles and glands are often augmented than the augmented glands, which latter are often covered by a mucous membrane. In most instances, the villous coat, the lesions consist of softening, thickening, and induration; with various changes of colour, from the lighter hues to a slate or deep-brown colour, and even to black. While softening of the internal coats is most common in the acute, hardening of these parts is most frequent in the chronic states of the disease. With the thickening of the villous and connective tissue there is sometimes a very remarkable contraction of the bowels, and many of the appearances described in the article Digestive Canal (§ 26–31, 52, et seq.). As respects the changes of the follicles and glands, I can add but little to what I have stated in this and the other places already referred to.

81. c. The ulcerations which take place in this form of the disease assume three different forms: 1st. Those which commence in the agminated, or Peyrier’s glands, and are seated longitudinally in the intestine; 2d. Those which originate in the isolated follicles and glands, and are of a rounded form; and, 3d. Those which attack the villous surface, and present a transverse direction as respects the canal of the bowel. Either of these may go on to perforation, and the production of acute or chronic peritonitis. Occasionally, tubercular matter is detected at the margins of the ulcers. The mesenteric glands are often enlarged, inflamed, or congested, softened, and even suppurated.

82. d. I have had no opportunity of observing the appearances after death in the chronic cases, where membranous or tubular exudations have been voided from the intestines, but such appearances have been observed by several authors. Dr. Monaro states, that when the villous coat of the intestines is inflamed, the diameter of the part is much diminished by the effusion of coagulable lymph upon this coat; that the quantity of lymph is very various, sometimes being as thin as a water, at other times nearly filling the affected bowel; and that occasionally it forms only a thin lining to the villous coat, or appears in the form of tattered shreds, in some cases filling the spaces between the valvulae conniventes, in others, covering these. In a case described by M. Pailloix, the villous coat was covered by a membranous layer, extending uniformly over its surface. The follicles did not seem to have any share in the production of this membrane, which he considered as differing only by its continuity and thickness from the small isolated patches secreted by the villi in aphthous affections. According to the appearances observed by MM. Billard and Lallct, these tubular exudations and false membranes are produced from the villous surface itself, and not from the mucous secreted by the follicles, or from a diseased ac-

83. c. In the acute and chronic forms of enteritis, inflammation of portions of the mesentery is sometimes observed, either with or without disease of the glands; and an edematous state of this part is occasionally met with. Other changes are more rarely remarked, both in the small and in the larger intestines; but they are merely incidental, and are described in the places above referred to. Various alterations are often, also, observed in the related visceræ; but these are mere accidental changes, which need not be adduced at this place.

84. VIII. Causes of Inflammations of the Intestines.—1. Predisposing.—The several varieties of enteritis occur at all ages, in all temperatures, and in both sexes; but they are most frequent in infants during the first dentition, and soon after weaning; and in the nervous, irritable, and sanguine temperaments. They are occasionally more prevalent in some families than in others, being, in part at least, extraneous to the constitution, and have hence assumed, in a few instances, somewhat of an hereditary character, especially in their smaller forms. Both sexes are nearly equally liable to them; males being, however, rather more frequently attacked than females, probably in consequence of their greater exposure to the exciting causes. The several forms of the disease may assume, from states of season and weather, or from the constitution of the air, a more or less epidemic character, and at particular seasons, the most common in warm and humid seasons, and when the vicissitudes of temperature are sudden and great; hence they are more frequent in autumn and summer than in other seasons, and when cold nights succeed to warm or hot days. They are also almost endemic in some countries, partly owing to the high range and high daily viscidities of the temperature, in connexion with great humidity of the atmosphere; but partly also, owing to the low and miscellaneous climates, or to the circumstances connected with the supply of water. Inflammations of the bowels of an asthenic form, often assuming the characters of dysentery, or chronic diarrhoea, or chronic ileo-colitis, or a true follicular enteritis, are very commonly caused, in hot climates, and even in numerous places without the tropics, by water preserved in tanks, or taken from marshes, or abounding with animal exuviae or annulacæ.

85. ii. The exciting cause of enteritis may be divided into, 1st. Those which operate directly on the digestive villous surface; 2d. Those which act indirectly, by arresting the secrections and excretions, and by determining the momentum of the circulation to the intestinal mucous membrane; 3d. Those which act mechanically, as strangulations, injuries, wounds, &c., and, 4th. Those which act sympathetically.—1. The cause acting directly upon the bowels are the ingesta, whether alimentary, medicinal, or poisons.—2. The food often occasions enteritis, gastro-enteritis, or entero-colitis, by its quality, quantity, variety, and incongruity. Heating, stimulating, or rich food, especially in great quantity, frequently produces mucho enteritis, and its several consequences and complications; while food which is un-
wholesome, septic, patrid, imperfectly preserved, or mouldy, or spoiled, or unwholesome, generally occasions follicular enteritis, or enterocolitis, or dysentery. Too great a quantity of food, or incongruous or indigestible food, particularly after prolonged abstinence or fasting, is a frequent cause of the more acute forms of enteritis. Thus a quantity of cheese eaten in these circumstances has, in several instances which I have observed in the course of my practice, produced this effect. Among the alimentary substances most productive of enteritis, and of long-prepared meats, pork, ham, bacon, cheese, stale fish, and high-seasoned dishes, may be particularly.

86. The inordinate use of spirituous or other intoxicating liquors is among the most common causes in the lower classes, particularly in hot climates and in warm seasons. Even a small quantity of spirits taken by persons unacustomed to them, and during disorders of irritation affecting the alimentary canal, will often already a state of inflammatory action. Urine or stale fruit; too large a quantity of fruit or of vegetables; most acid and cold fruits, and particularly pineapples, melons, and cucumbers; cold fluids or ices taken while the body is perspiring, or very soon after, or immediately upon a meal; and acidulated beverages, or cider, perry, and, often occasion either enteritis, or some one of the disorders of the digestive organs, most apt to pass into, or to be associated with this disease. The changes which the ingested undergo in the stomach and bowels, especially when excessive in quantity or variety, or otherwise incongruous, and when imperfectly changed with the gastric juice and bile, give rise to enteritis, either directly, or consecutively to indigestion, cœstiveness, colic, or diarrhoea. The influence of the secretions, particularly of the bile, when redundant or acid from the changes consequent upon interrupted excretion of it, in giving rise to ileo-colitis, has already been insisted upon.

87. The frequency of the several forms of enteritis in young children, particularly infants brought up by hand, or after weaning, is caused chiefly by the inappropriate or too abundant supply of food in these circumstances. The digestive organs cannot dispose of the food, either from its quality or quantity, and the undigested part irritates the digestive villous surface, or undergoes changes producing the same effect. In some instances, the disease, especially the follicular variety of it, is caused by the insufficient quantity of aliment obtained from the food, owing to its unsuitableness to this early period of life, this cause combining with the irritation produced by the undigested portion. The milk, also, of some nurses, owing to the state of their health, and of their digestive organs, or to their habits, especially in resorting to spirituous liquors, occasionally gives rise to enteritis, or gastro-enteritis, in the infants suckled by them.

88. The influence of an in nutritious and fluid diet in causing muco-enteritis and follicular enteritis, the latter especially, particularly when aided by cold and humidity, or by miasmata, or by foul or unwholesome water, has been too much overlooked. A starving diet and regimen not infrequently develop these forms of the disease in an asthenic form, or in the guise of chronic diarrhoea or chronic dysentery, particularly in persons previously accustomed to live fully or intemperately; and if these disorders prevail in a number of persons, either crowded together or shut up in ill-ventilated apartments, adynamic or typhoid fevers will be generated, complicated with the enteric disease. The influence of stagnant and foul water, more especially water long shut up in wooden casks, and river or canal water, containing animal matter or impurities conveyed by the sewers running from cities, are thereby producing follicular enteritis, is much greater than is generally supposed. The use of impure water favours the production of the disease, when other causes are in operation, and imparts a specific, generally an asthenic, character to the malady. It has the effect of a slow poison, and acts on the economy, not merely by impairing the tone of the organic nerves and villous surface of the bowels, but also by contaminating the circulating fluids, thereby producing inflammatory action or producing constitutional disease at the same time. In this disease, the general and local asthenia is more prominent than inflammatory action, which is limited to the intestinal glands and follicles, and is often characterized by a tendency to ulceration or disorganization rather than to reparation.

89. A. Medicinal substances, particularly acrid purgatives, stimulants, and tonics, injudiciously resorted to, are more frequently the causes of enteritis than is commonly supposed; the effects of these medicines being often mistaken for the natural course of the disease. Acrid purgatives, given with the view of removing indigestion, colic, or constipation, and injudiciously repeated, in circumstances requiring milder means, have often converted these complaints into acute enteritis, or have aggravated inflammation where it already existed. Stimulants and tonics, prescribed with the view of removing debility, and the various forms of indigestion, have likewise developed a large quantity of inflammation, or changed slight inflammatory action, giving rise to symptoms mistaken for those of debility merely, to acute enteritis, or to gastro-enteritis. I am, moreover, convinced, from personal observation, during an early part of my experience, when I had opportunities, in different climates, of observing, without interfering with the practice of medical officers in charge of hospitals, and from the perusal of the journals kept by others, that numerous cases of diarrhoea, and still more of dysentery, have been aggravated into the most acute forms of enteritis or of enterocolitis, by the repeated, continued, and extravagant exhibition of acrid or heating cathartics. I have in my possession hundreds of cases of these diseases, written by the medical men who treated them, in all of which the usual phenomena of inflammation, when seated in the villous surface of the intestines, and attended by morbid action of the unevacuated coats, were viewed as the consequences of the accumulation and retention of morbid secretions and fecal matters, and treated by large doses of cathartics, prescribed not daily only, but at intervals of a few hours, and thus persisted in until the dissolution which they either caused or accelerated took place. The fire once kindled, however slightly or weakly burning, was
thus fanned to a blaze, which soon extinguished itself in fatal disorganization. A slight diarrhoea or simple dysentery, arising from irritation or determination to the intestinal villous surface, has been converted, by a continued use of the most drastic purges, into inflammation, which, in its turn, has been urged on by the same agents to fatal sero-enteritis and peritonitis, with spacculation of the villous coat.

[We believe that the pathological conditions of the intestinal canal above described are often brought on, in this country, by the general perturbation of the nervous system, from over-drugging, or over-drugging, than by all other causes combined. It is impossible to calculate the amount of mischief thus annually produced by the use of drastic pills, patented by government, as it would seem, for the special purpose of preventing too great increase of the population. Physicians are beginning to learn that diseases are not cured by drugs, but by nature; and that harsh, perturbing treatment, especially such as irritates, and affects the intestines, is gener- ally far worse than no treatment at all. If homoeopathy had done no more than demonstrate the curability of most diseases when left to the unaided efforts of nature alone, it would be entitled to the gratitude of mankind; and this it has done beyond all controversy.]

90. c. Poisonous substances are among the most common causes of enteritis, but generally complicated with gastritis—of gastro-enteritis. Some poisons, however, pass into the bowels from the stomach, without affecting the latter in a very sensible manner. Most of the mineral poisons, and of the acid and acro-narcotic poisons, inflame the mucous surface of the intestines; and when they fail of producing fatal results by the intensity and the extent of inflammation, by their injurious impression on the organic nervous influence, and by the change they produce in the blood—by these effects, individually and conjointly—they are generally the cause of severe and prostrate symptoms of enteritis, which, however, differ materially, in its precise seat, and in its characters, according to the particular agent which excited it. (See article Poisons.)

91. B. Those causes which act indirectly, and chiefly by suppressing accustomed secretions or excretions, and by determining the momentum of the circulation upon the abdominal visera, are exposures to sudden vicissitudes of temperature, especially in connexion with im- purity and the influence of malaria; sleeping in damp beds or clothes, or in exposed places; or on the ground during campaigns; the abstraction of the animal heat from the feet, the loins, and abdomen; unusual heat applied to the back and loins; and the drying up, the suppression, or the disappearance, of accustomed discharges, evacuations, or eruptions. Enteri- tis is often caused by the suppression of an accustomed perspiration of the feet. Sleeping on the ground, or exposed to the night dew, especially after a debauch or the excessive use of spirituous liquors, is a very frequent cause of this disease, and particularly of phlegmonoid or sero-enteritis and colitis, among soldiers and sailors, especially in warm or intertropical regions. I have seen instances of the disease occasioned by sitting with the back to a warm fire at dinner; by the suppression of the cata-

mecia, and by arresting or preventing the turns of the hemorrhoidal flux, without instituting such precautionary measures as the circumstances of the case required. The repulsion of gent or of rheumatism from the extremities has, in rarer instances, a similar effect; and enteritis, appearing in these circumstances, presents certain peculiarities, especially in the gouty diathesis, or when it occurs from the retrocession of gent from the feet. It is then always very acute, is attended by intense pain, and is characterized as much by the extreme morbid reaction of the tissues, as by the severity of the inflammatory action, the former pathological condition requiring more at- tention from the physician than even the latter.

92. C. Many of the causes of enteritis are altogether mechanical, and act either internally or externally, in respect of the canal of the intestine.—a. The former consist chiefly of hard-ened feces obstructing the tube, or lodged in the cells of the colon; concretions of various kinds, and of all kinds of mixed concretions occasioned by gases or fecal accumulations. Hardened feces and concretions first irritate, and afterward inflame the parts in contact with them, if the muscular action of the coats of the bow- el fails in procuring their expulsion, and a somewhat similar effect is produced by retained or accumulated feces and morbid secretions. The over-distention occasioned by flatus weakens the coats of the intestines, overcomes their power of reaction, and favours the suppression of the natural exhalations and secretions, and the consequent development of inflammation in the over-distended part.

93. b. The mechanical causes of enteritis ex- ternal to the canal are hernial strangulations, and strictures of any kind which diminish the diameter of the canal; intus-susceptions, the pressure of tumours developed within the walls of the abdomen and pelvis, and injuries, wounds, or operations. Every patient who complains of the usual symptoms of enteritis, especially of vomiting and constipation, the patient should undergo a strict examination, in order to ascertain the existence or non-existence of the several kinds of hernia. The presence of her- nia in connexion with enteritis indicates at once both the nature and cure of the disease; but hernia or external strangulation may exist without the lesion being manifest, or its seat or cause being detected, or even admitting of detection, although suspected and carefully inquired after; and the mischief may be caused by an old hernia, or in connexion with an old protrusion, which can no longer be detected on examination. When internal strangulation ex- ist, the symptoms of ileus, or of acute enteritis, or of both in succession, are usually present. The seats and causes of strangulation are so numerous, as shown and described in the articles on Colic and Ileus (§ 37), and Di- gestive Canal (§ 56, 57), that we can but selec- tively come to a correct conclusion respecting them, unless they are subjected to our senses, as in the case of external hernia; yet we may occasionally, from a review of antecedent and concomitant circumstances, draw inferences, not only as to the existence of internal con- striction or strangulation, but also as to its source, that will approximate, although they may not be altogether the truth. Either of
the many causes which I have enumerated, in the article just referred to, as productive of ileus, may also occasion enteritis, the inflammation generally commencing at the point of stricture, or strangulating in the peritoneal coat, and extending thence usually to the dis tended portion of intestine above this point, and to the rest of the tunic.

94. c. Ileus-susceptions, produce, as shown at another place (Colic and Ileus, § 38, et seq.), either ileus or enteritis, or both, either coextensively or consecutively. Where enteritis takes place, it usually proceeds from strangulation of the intra-suscepted portion of intestine, and assumes a most acute form, the inflammation generally commencing in the serous coat, involving the rest of the coats, and sometimes terminating in gangrene, and even in the discharge of the gangrened portion of the intestine, the canal being preserved by the union of the edges of the divided intestine. But this subject is fully described in the place just referred to, and also in the article Digestive Canal (§ 54, 55).

95. d. Tumours formed in any part within the abdomen, may, from the injurious pressure, or from the irritation occasioned by them, or from the extension of inflammation from their surface to the serous coat of the intestines, give rise to enteritis. Tumours in the omentum, in the ovaria, or connected with the uterus, sometimes cause inflammation in either of these modes, particularly in the former; this effect being the more readily produced when the tumour is hard, cartilaginous, or osseous; or when it is very large, so as to interrupt, by its size and pressure, the transit of the more consistent contents of the bowels; or when an injury or blow is received upon, or in the vicinity of the tumour. The lymph diffused on the surface of an adjoining viscus will excite inflammation in whatever portion of the serous surface of the bowels with which it may come in contact; enteritis thus occasionally appears consecutively upon inflammation of adjoining organs, from the contact of a morbid secretion chiefly, and not from extension of the inflammatory process over a continuous surface. External causes are occasionally occasions of enteritis, particularly on the buccal, phlegmonoid enteritis; and gangrene of the injured and inflamed part sometimes takes place.

96. D. Mucous and follicular enteritis may occur sympathetically of some severe disease or extensive injury of external parts. Either of these varieties may be consequent upon burns or scalds, or upon erysipelas, or upon disease of some vital organ. They constitute, the latter variety especially, the most frequent complication of continued, and even of periodic fevers, and more particularly of the eruptive fevers; and they are often sequelae of these fevers. My friend, Dr. Abercrombie, of Cape Town, informed me that, when measles were lately epidemic at the Cape of Good Hope, where they were imported after an absence of upward of thirty years, the great bulk of the population being, in consequence, susceptible of their infection, enteritis sometimes occurred upon the decline of the eruption, but that it appeared much more frequently during convalescence, or a few days after the patient had apparently recovered.

97. IX. Treatment.—The indications, as well as the means of cure, necessarily vary in the several varieties of enteritis, and in the different circumstances in which they present themselves. Some reference ought also to be had to the causes which produce the disease, and to the state of vital tone or energy, especially if the complaint appeared in the course, or as a sequel of any other. I shall therefore describe the treatment most appropriate to the principal forms of the disease, and to the chief circumstances with which it is usually connected.

98. i. Mucous-enteritis and mucous-enterocolitis differ only in the extent to which the digestive canal is involved, and in the different portions of this surface, both varieties being the same in their natures and morbid relations. The means of cure are, therefore, equally suitable to both.—A. In the slighter states of the complaint, and in the less robust constitutions, local depitations, chiefly by leeches applied to the abdomen, will be generally requisite; but in strong, young, or plethoric persons, a moderate or full blood-letting from the arm should be promised. Immediately afterward, small doses of colonel, or of blue pill, or of the hydrargyrum cum creta, the last especially, should be given with ipecacuanha, or with the compound ipecacuanha powder, and repeated every four, five, or six hours. If the bowels be insufficiently evacuated, and if the stools be morbid and offensive, mild purgatives, as sweet oil, castor oil, or both, may be given, and emollient and aperient enemata administered. After these have operated satisfactorily, a warm bath or the semiclinum may be resorted to, and Dover's powders, or ipecacuanha alone, the ipecacuanha just mentioned, may be exhibited, so as to relax the external surface; and perspiration may be promoted by suitable diuretics and warm mucilaginous fluids, or by these latter containing the liquor ammoniac et castris with the spiritus aethers nitricus, and small quantities of the nitrate of potash. Or these may be taken in camphor julep, or any other suitable vehicle. When there is nausea or occasional vomiting, the medicines containing ipecacuanha may be laid aside, and the latter preparations, which may be taken in small but frequent doses, in any emollient or soothing vehicle most grateful to the patient. In such cases, the stomach and bowels should be quieted, and their functions excited as little as possible until the morbid action has subsided. In mild cases, these means, aided by a farinaceous, mucilaginous, and spare diet, will generally be sufficient; but in severer attacks, a repetition of the more active of these, and the aid of additional remedies, will be requisite.

99. B. When the disease occurs in the most acute form, particularly among Europeans in warm or intertropical countries, and as described above (§ 45), a copious blood-letting ought never to be neglected; and the antiphlogistic treatment and regimen should be strictly enforced. In this state of complaint, local depitations will often be requisite, even after blood has been taken freely from the arm, and will sometimes require to be repeated. Leeches may occasionally be applied around the anus, preferably to any other situation, more especially when any degree of congestion of the
liver is suspected. If the attack be attended by vomiting, and the large intestines seem but little affected, calomel or the hydrargyrum cum creta may be given with opium, and repeated according to circumstances; the bowels having been sufficiently evacuated, and being kept open by copious oleaginous emenata; but, if the stomach be not irritable, after having evacuated morbid secretions and fecal accumulations, ipecacuanha may be prescribed with opium and the nitrate of potass, as in the original Dover's powder, in as large and frequent doses as the severity of the case may indicate. After depletions have been sufficiently practised, the warm bath, semicupium, or hot fomentations, taking care to keep the bed-clothes perfectly dry, may be allowed. In these cases, as well as in all the other varieties of erisisis, the more acute especially, the turpentine fomentation on the abdomen, or the liniments in the Appendiz (F. 295, et seq.), employed as embrocations in this situation by means of warm flannels, will be found the most serviceable. As long as evidence is furnished of the presence of morbid secretions and fecal collections, the milder mercurealis and laxatives or aperients should be prescribed, and opiates withheld, until the obstruction is nearly removed. Of the safest laxatives or aperients are sweet oil and castor oil, if they be perfectly fresh; but if they be at all rancid, they will greatly increase the mischief. If these means, energetically pursued, do not remove the disease, it generally passes into the soro-enteric form, or into the second stage of that form, with marked exhaustion; a very different treatment being then indicated, although with little hope of success.

106. Upon the whole, the treatment of the milder forms of muco-enteritis should be nearly the same as is recommended for the more inflammatory varieties of Diarrhrea (§ 27, 28), and that of the more acute cases, particularly when the large bowels are chiefly affected, ought not materially to differ from what I have advised for the inflammatory states of Dysentery (§ 82—87); and the greater part of what I have stated in these places altogether applies to the present subject.

101. C. The Chronic forms of Muco-enteritis, especially the acute forms, require merely a modification of the above treatment, appropriately to the age, strength, and vascular states of the patient. Local depletions are sometimes necessary, also, in these forms of the disease, and should even be repeated, according to circumstances. The chronic state is often owing to the indulgence of the patient in too much or too rich and stimulating food. When this is the case, then a more rigorous diet and regimen are requisite. A diet consisting chiefly of farinaceous and gelatinous substances, of milk, sugar [we doubt much the propriety of allowing sugar, or any other form of saccharine matter, in these cases], chicken or veal broth in small quantities, with rice, &c., warm clothing, flannels worn next to the skin, warm baths, and assiduous friction of the surface of the body, aided by exercise, travelling, and change of air, will generally be found most beneficial in these cases. But the disorder may have somewhat changed its character in passing from the acute to the chronic form; a too rigorous diet, during the former state, may have favoured the development of follicular enteritis upon the subsidence of the inflammation of the villous surface. Consequently, the persistence of a chronic disorder after the acute should lead to a careful examination of the local and constitutional symptoms, and of the evacuations; and if these be marked by asthenia, or cachexia, the stools being mucous, muco-puriform, or ochreous, and the pulse weak and very quick, the means about to be recommended for the follicular variety of the disease should be prescribed.

102. D. In infants and young children—a. the acute form of muco-enteritis requires nearly similar means to those already prescribed, but with due reference to their age and their previous nourishment. For them, local depletions, the hydrargyrum cum creta, with ipecacuanha in small doses, or Dover's powder, and the warm or tepid bath or the semicupium, or stupes or fomentations, will generally be necessary. For infants, however, Dover's powder, and all other preparations containing opium, ought not to be prescribed; nor, indeed, should the alvine evacuations be suddenly arrested by these or other means in young children. When the complaint is attended by much irritability of the viscera they should be treated with oily roots and oils of service, and if the child be not very young, a small dose of opium may be given with it; and the bowels, which are usually then costive, should be moved by emollient laxative emenata. When the stomach is not irritable, and the bowels are much relaxed, the stools being morbid, I have often found small doses of the biberate of soda taken in honey, or in dill-water with paregoric elixir and mucilage, of great service, after calomel or the hydrargyrum cum creta had been prescribed. In such cases, also, the warm bath, stupes, and emollient emenata are very beneficial. In older children, when the bowels are very irritate, and the stools contain blood, small doses of the sirup of poppies, or of paregoric elixir, may be added to these or to the starch enema, or to an enema of thin gruel, or of warm water, or of strained veal or mutton broth; local depletions having been resorted to, according as they may have been indicated, and ipecacuanha or Dover's powder having been prescribed. In the chronic cases and of muco-enteritis, on the other hand, the bowels ought not to be allowed to be costive. When children will take sweet oil, it is the mildest and most suitable aperient in this disease, and it should always be employed in laxative emenata. In the more severe cases, or after local depletions, the warm bath, fomentations, and suitable medicines have been prescribed without satisfactory results, mustard poultices, or the warm turpentine fomentation may be resorted to, and be kept on the abdomen until smarting or burning heat is produced. Either of the turpentine liniments in the Appendiz (F. 296, 311) may be employed in this manner, with the addition of the tincture of opium, when the stomach or bowels be very irritable. In grown children, opium with calomel or hydrargyrum cum creta, and with ipecacuanha, or this latter with nitre and opium, in suitable doses, are the most important remedies, when employed after vascular depletions. 103. E. In the chronic cases of muco-enteritis, or of enterocolitis in children, repeated small doses of hydrargyrum cum creta with ipecac-
and the abdomen, if the foregoing means are inefficient, are generally necessary. But in this state of the complaint, diet and change of air, especially to a high and dry locality, are materially beneficial. Advantage will be obtained, also, from the warm bath, followed by frictions of the surface, and the application of a flannel roller round the abdomen. The bowels should be duly regulated by means of mild mercurials, rhubarb, magnesia, or sulphate of potash, or of sweet oil, castor oil, manna, &c., aided by enemata, according to the peculiarities of the case. In other respects, the treatment advised in the mucous and chronic states of Diarrhea (§ 30-36) should be adopted.

104. c. In both the acute and chronic states of the complaint, the utmost attention should be paid to the diet of infants and children. When there is much irritability of the stomach, indicating an extension of disorder to the duodenum and stomach, endeavour to give food, or even medicine, are more injurious than beneficial, until the severity of the attack is abated by local depletions and external means. If a full dose of calomel, with or without a little calomelated magnesia, be administered, it generally will be in such cases, nothing ought farther to be given for two or three hours, when gum-water, with equal parts of the milk of a healthy nurse or of asses' milk, or gum-water slightly sweetened, may be administered in small quantity, one or two tea-spoons full being given at a time. In these cases, no other purgative than calomel will be retained in the stomach. The bowels must, therefore, be opened by means of the enemata already mentioned. The diet and regimen must entirely depend upon the state of the bowels. If they be relaxed, the milk may be taken with lime-water. As the acute symptoms subside, more nutritious kinds of light food and farinaceous articles may be allowed. Chicken-broth, or veal or mutton broth, may be taken with rice; and mild tonics, with the alkaline sub-carbonates and small doses of ipecacuanha, should be prescribed when the digestive functions are much weakened. In chronic cases, a little fat salt pork, or bacon, broiled, with the latter: the use of the hot coffee, &c., is necessary not merely to remove the causes, but also to counteract the poisonous influence they have exerted, both locally and constitutionally. A reference to these causes (§ 18, 83) will show the necessity of thus extending our views in the treatment of these varieties. It must not be overlooked, that many of these causes are secretive or poisonous in nature; that they consist of putrid, decomposed, and decomposing substances, vegetable or animal, or both, which act as a poisonous or contaminating leaven upon the digestive mucous surface, on the intestinal glands and follicles, and upon the blood; and that this effect, although most demonstratively produced on these glands and follicles, does not always, at least in its earliest stage, consist of true or of septic inflammation. The action of these follicles is changed, but not in such a manner as to develop an excited condition of their capillary circulation; an opposite state—an asthenic congestion with impairment of their vital manifestations and vital cohesion—more probably obtains; for it is uniformly observed, that when the causes are of the above description, or when they are such as debilitate, or even such as insufficiently excite or nourish the frame, as inappropriate, unprofitable, and unwholesome food, a treatment, in lowering or debilitating kind, is always injurious. As this morbid condition of the glands and follicles of the digestive villous surface often rapidly passes into ulceration, it has been too generally viewed as being altogether of an inflammatory nature. This error has arisen from two circumstances: first, the general belief that ulceration can proceed only from antecedent inflammation; and, second, that inflammation is a state of vascular action always attended by one or the other condition of vital power, and that the tissues affected by it possess the same degree of vital cohesion on all occasions. Now I have shown, in other places, that ulceration may occur and proceed without any appreciable grade of inflammation, and more particularly of true or septic inflammatory action; and that inflammations, or, rather, that the states of local vascular action, to which the term inflammation has been too generally and often inappropriately applied, are widely different from each other in the great variety of both local and constitutional phenomena; and that these states vary, as regards the condition of the tissues and vessels, and circulating fluids and vital manifestations, not only in each of their more specific forms, but also in each of their progressive periods or stages. It may, therefore, be inferred that, when ulceration is produced in the intestinal glands by septic or contaminating ingesta, it assumes somewhat of a phlegmonic character, and that the state of vascular action preceding or giving rise to this effect is either not truly inflammatory, or is that to which I have applied the term of asthenic inflammation (see that article, § 54, et seq.), and which requires, both locally and constitutionally, a very different treatment from that appropriate to the more common inflammatory condition.

It is not improbable, however, that inflammation commencing in the villous surface itself will extend to the follicles, and even that both it and the follicles may be almost contumaciously attacked; or that the affection of the former may subside as that of the latter is de-
INTESTINES—Inflammations of—TREATMENT.

devolved; but of either of these states of disease we have no certain proofs at an early stage, although appearances after death frequently show that they must have existed. The chief difficulty is to ascertain the symptoms by which they are severally or conjointly attended and indicated, more particularly during early periods of life, when this morbid association is common; and even at much later periods, so minute a diagnosis as this can rarely be made with precision. When we have reason, from the nature of the exciting causes, from the character of the symptoms, and especially from the state of the evacuation, that disease of the follicles is associated with inflammation of the villous surface; or when the more usual phenomena of follicular enteritis cannot be connected with the septic and lowering causes mentioned above (§ 18, 85), and when the symptoms indicate more or less of vascular excitement, locally or generally, local depletions, followed by the warm bath, by the semicuprum, or by the rubefacient embrocations or fomentations already noticed (§ 296, 311), will then be requisite. The treatment in such circumstances, should not vary materially from what is advised for the more acute forms of acute diarrhea (§ 99), and for dysentery, according to the features of individual cases.

106. After the more acute symptoms have subsided, and in the more asthenic cases, more restorative, astringent, and antiseptic remedies may be employed; and more especially those recommended for the acute and chronic forms of chronic diarrhea (§ 31, et seq.) have not been removed by the natural action of the bowels, calomel with rhubarb, or the latter with sulphate of potash, or the compound jalap powder may be given, and be aided by suitable injections: afterward, frequent doses of the hydrag. eum creta, or with Döven's powder, or with ipecacuanha and rhubarb in small quantity, may be prescribed, according to the circumstances of the case; and the purgative fomentations already mentioned (§ 99) may be applied on the abdomen. In such cases, should not vary materially from what is advised for the more acute forms of acute diarrhea (§ 99), and for dysentery, the means advised in the article just referred to (§ 32, et seq.) should be resorted to. In such cases, as well as in those which have followed the ingestion of septic and contaminating substances, I have found the following of more or less service, with or without the addition of opium to either of them, as circumstances may have required.

107. B. The chronic states of follicular enteritis and entero-colitis, particularly when ulceration has commenced, can be ameliorated or cured only by strict attention to diet and regimen, as well as by the appropriate use of medicaments. Of the latter, but little can be added to what has already been stated with reference to the treatment of chronic mucous diarrhea (§ 31, et seq.) and chronic dysentery (§ 100, et seq.). The various methods and diversified means there enumerated are appropriate to the states of the disease now under consideration; and the treatment recommended for chronic mucous enteritis is also partially applicable to them. In the follicular form, however, of chronic enterocolitis, chalybeate, astrinrent and dietetical, should be even more restorative than I have advised for the other varieties of enteritis. In many cases, both medicines and diet should be prescribed almost experimentally, the effects of both being carefully watched; for it is impossible to infer correctly the effects of the several means in all, or even in the great majority of cases. In many instances, and in several circumstances in which they occur, powerfully tonic and astringent remedies are most beneficial; while in others, alterative and absorbent medicines are most useful. A spare and farinaceous diet is usually recommended, and yet abstinence may be carried too far, nutritious and digestible food being often required, especially when the disease is prevailing epidemically, or when it proceeds from the more debilitating and contaminating causes. In addition to the means already mentioned, both here and in the articles just referred to, others are variously combined, according to the ever-changing features of individual cases. Tinctures may be employed, more especially sulphate of quinine, or the nitrate of silver, with camphor and the extracts of hop and of poppy; the sulphates of quinine and of iron with these extracts, or with catechu, purified ox-gall, and capsicum; the sulphate of zinc or of copper, or the acetate of lead, with ipecacuanha and opium; the tincture of the muriate of iron, or chlorine-water, with the compound tincture of collodion, or of camphor, and various astringents, tonics, and absorbents usually employed. In this variety of the disease, the chloride of lime, or the chlorate of potash, or any of the mineral and vegetable astringents, tonics, and antiseptics, may be prescribed, according to circumstances; but those astringents which are also antiseptics should be preferred, and be conjoined with the preparations of bark, or of cascara, or of tormentilla, &c. When the follicles and glands of the large bowels, and the affected areas of the disease, has become chronic, or if ulceration be expected, many of the substances just mentioned may be employed in enemata, as the nitrate of silver, the sulphate of zinc, lime-water, chlorine-water (Pharm. Dipl.), the infusion or decoction of bark, with the compound tincture of camphor, or sirup of poppies; the chlorate of potash, or the chlorides similarly combined; and the various astringent and tonic infusions and extracts.

108. For infants and children affected by acute or chronic follicular enteritis and entero-colitis, very nearly the same means as have been advised for them when suffering under mucentero-colitis (§ 102, 103) will be found appro-
priate. As, however, the follicular variety of the disease in this class of patients is more especially caused by insufficient or unwholesome nourishment, by an unhealthy nurse, by a spoon diet, by rearing by hand or premature weaning, by cold and humidity, and particularly by living in a insalubrious atmosphere, or in low, damp, and ill-ventilated cellars and apartments, a removal of these causes, and attention to suitable diet and regimen, become most important parts of the treatment. The patient should be warmly clothed in twelve days, and always sleep in the arms of a healthy nurse, or have asses' milk warm from the animal. The diet should be regulated in other respects as already advised (§ 104). In this, and in similar states of disease of the digestive canal, the jelly prepared from the Ceylon moss is a most appropriate article of food.* In aid of these means, change of air, particularly from crowded towns, and low, close, or unhealthy localities, to open, airy, dry, and temperate quarters, or to the seaside, will always be prescribed.

109. iii. Treatment of Phlegmmon or Sero-enteritis.—When the inflammation either seizes primarily upon the substance of the intestines, or extends to it, or commences in the peritoneal coat, vascular depletion should be immediate and copious, and other remedies promptly employed. If the patient be plethoric, young, or robust, blood should be taken very largely from the arm, and leeches applied afterward upon the abdomen. A full dose of calomel and opium—from fifteen to twenty grains of the former and two to three grains of the latter, with or without a grain or two of ipecacuanha, according to the state of the stomach—ought to be taken immediately after the bleeding, and the hot turpentine fomentation applied over the whole abdomen. This last should be kept constantly applied, or should be renewed until the symptoms have abated. If the stomach be irritable, the calomel and opium taken after the bleeding, and without the ipecacuanha, will remove this symptom, and will, particularly when aided by the hot turpentine fomentation, determine the circulation to the surface, equalize the distribution of blood, and promote perspiration; and when the fomentation can be no longer endured, a warm bread-and-water poultice may replace it, and may be frequently repeated. If these means give relief, with a copious and general perspiration, the patient should not be disturbed for a considerable time, nor the stomach and bowels irritated by purgatives or cathartics taken by the mouth; and as soon as it becomes requisite to procure evacuations and to remove offending matters, the oleaginous or other mild purgative enema may be administered.

110. If the disease be very severe, or considerably advanced before this treatment is instituted, a repetition of both the general and local bleeding will often be necessary; and the calomel and opium, in the doses already stated, may be given once or twice daily, until the secretions and evacuations become free, or until the mouth is affected, or the symptoms disappear. If the stomach be not irritable, and if the bowels have been evacuated, saline med-

* [Animal jelly, as of singhiss, calf's-foot, &c., or chicken and mutton broth, given warm, will be found more generally beneficial in these chronic cases than vegetable food.]
practice; but I have found it requisite to apply leeches to the abdomen, followed by the tur- penentine fomentation and embrocation, by hot poultices, and emollient enema. A frequent use of sweet oil, both as an article of diet and as an aperient, has also been of service. A light, nutritious, and solid diet has been generally requisite; at the same time avoiding stim- ulants and irritants. The treatment, however, will necessarily vary, or even be entirely dif- ferent, in different cases, as the disease has always been variously associated or complicated in the cases which I have seen, these combi- nations often requiring as much attention as the intestinal malady.

11. v. During convalescence from any of the several forms of enteritis, the regular action of the bowels is a matter of the greatest conse- quence, and should be promoted, when defi- cient, by mild and cooling aperients and laxa- tives. At the same time, the secretions gen- erally, and particularly the biliary secretion, should be collected or promoted whenever they are deficient or morbid. For this purpose, an occasional dose of blue pill or of the hydrargy- rum cum recta, or of Plummer's pill with soap, should be taken. A warm bath, followed by active friction of the surface with hair gloves, or with a coarse towel, will also be of use. The utmost attention ought to be paid to diet. A returning appetite should be indulged with great caution. Mild broths, in small quantity, with toast, or with boiled rice &c., are very benefi- cious articles of food, as arrow-root, sage, tapioca, &c., and the jelly of the Ceylon moss, may be taken at first, and continued for some time be- fore more stimulating and solid articles are al- lowed. The patient ought to wear flannel next his skin, and be careful not to expose himself to various degrees of temperature or to moisture. He should always preserve his feet warm, and observe those articles of food which agree or disagree with his digestive organs, carefully avoiding those which have the opposite effect. In all respects, his diet and regimen should be regulated in the manner advised in the article Indigestion (§ 69, et seq.).

114. X. Of Spasm, etc., of the Intestines.

—A. The muscular coats of the intestinal tube possess a very perfect degree of muscular pow- er, and may be contracted in a very remarka- ble manner, even so as to propel quicksilver along its canal contrary to the specific gravity of this substance. The extent of spasmic con- traction of the intestines is rarely demon- strated to the sense of sight, even after death. But in dissections performed a few hours after dissolution, it has been observed so extremely as very nearly to obliterate the canal. The spasmic contraction of circular fibres, and of the muscular coats of hollow visera, is shown by the action of the urinary bladder, of the intestines, and of the sphincters; and the extent of relaxation of these structures is demon- strated by the state of these parts, both in health and disease. The healthy contractions of the intestinal canal push onward its con- tents; but this contraction is speedily followed by relaxation. The passage of substances more or less stimulating along the villous sur- face excites the action of the muscular coat, and this action ceases in one part as soon as the stimulus passes onward to a continuous

part. Where, however, the muscular coats are spasmodically contracted, there is, at least for a more or less considerable time, no consequent relaxation, as in the healthy state. It is very difficult to determine the extent to which spas-modic constriction takes place, in respect either of the amount of the obliteration of the canal it may occasion, or of the length to which it may affect the intestine, and the particular bowel affected. The spasm, there is every reason to infer—indeed, it is sometimes demon- strated in the same extent, or sometimes in the same time, more or less remote from each oth- er, the intermediate portions being remarkably dilated; and it may proceed along the intesti- nal canal, either continuously or interruptedly, from the stomach downward, or even in an op- posite direction, as in colic, hysteria, and ileus, in which it may follow either of these direc- tions. We can hardly suppose that the spasm extends, at the same moment, to the whole line of the canal, but merely to portions of it, which may be thus affected for a very varying and indefinite period. This affection may pass with rapidity from one part to another; and, as respects duration and recurrence, it may be continued, almost permanent, intermitting, re- mitting, periodical, and slight or tremulous. Some portions of the bowels are more subject to spasmodic action than others, as the duode- num, the lower portion of the ileum, and the lower parts of the large bowels.

115. B. Intestinal spasm is generally associa- ted with disorder of the secreting functions of the liver and of the digestive villous surface, and often, also, with inflammatory action in this surface. There is always more or less of irrita- tion of this tissue, or, rather, of the nervous fibrils supplying this and the muscular coats; and this irritation is attended by a more or less remarkable alteration of the sensibility of these nerves, which is roused often to the most acute pitch of sensation.
sensation of the passage of air from one part to another; the pain often, also, shifting its situation. Spasm of the duodenum has been supposed to be indicated by pain in the right side, stretching to the back, and occasionally to the right shoulder, but often changing its place upon the expulsion of air; by distention of the abdomen, slight yellowishness of the conjunctiva or countenance, and deficiency of bile in the evacuations; and by a soft, and sometimes an irregular pulse. These symptoms, however, do not furnish sufficient evidence either of the seat or of the nature of the affection, and they are attended upon it in most instances; for they also accompany other complaints, more especially torpor and other functional disorders of the biliary organs. When the pain accompanying them is eased by pressure, and when none of the signs of inflammatory action are present, then the existence of spasm is extremely probable; but its seat is not the more certainly indicated by this circumstance. Nor does pain in the right side, extending from the chest to the right hypochondrium, sufficiently prove the existence of spasmodic constriction of the commencement of the colon, although it is a sufficient reason to suspect the presence of this affection in this part. Both Sauvages and Monro admit the difficulty of the diagnosis as respects the seat of spasm. This, however, is of the less importance, as the treatment is the same, whatever may be its exact seat. But it is of the utmost moment to ascertain whether or not the spasm be caused by, or associated with, inflammatory or structural lesion; and this can be determined only by a careful examination of the previous history and present state of individual cases. The disposition, particularly in young subjects, of intestinal spasm, to be followed by intussusceptions, and by inflammation or ileus from this circumstance, should always be kept in recollection.

117. ii. The causes of spasm of the intestines are also those of spasm in other parts.—a. The nervous temperament, and the delicately or weakly constituted, owing either to original conformation or to the operation of the usual causes of debility during infancy, puerility, and puberty, are most predisposed to this affection. Dr. Gregory has very correctly and briefly stated the predisposing causes as follows: "Habitus corporis nimis sentiens, et nimis mobilis, homines spasmin opportunos reddit; lice malum feminis, infantibus, dehilibus, luridioris, desidibus, sanguine plenis, familiaris actione, praebent predisposuisse ad hanc affectionem." b. The effect of the diseases principally those which irritate the villous surface of the intestines, as all acrid, poisonous, or unwholesome ingesta; flatulency, acrid bile, retained or morbid secretions and excretions, mechanical irritants, calculi or concretions, foreign bodies, worms, biliary calculus, either passing the biliary or other ducts, or lodged in the intestines, exposure to cold, &c. Intestinal spasm is often caused by inflammation of the bowels, or by organic lesions impinging their coats; by the poison of lead, and by the numerous cases mentioned in the article on ulceration of the several forms of Colic and Ileus. It is also frequently occasioned sympathetically, by the irritation of dentition; by irritation or inflammatory action in the uterine organs, or in the urinary pas-

sages; and by affections of the mind, especially the more violent emotions. It is a frequent attendant upon hysteria, upon calculi in the kidneys or ureters, and it occasionally appears in the course of disorders of distant parts. It is also apt to occur in the gouty diathesis, either as misplaced gout, or in consequence of disorder of the biliary or intestinal secretions.

119. iii. The treatment of intestinal spasm does not differ from the treatment of colic and ileus, and it should be conducted according to the principles there detailed. The chief intentions are, i. To remove the cause or causes, whether those acting directly on the bowels, or those exerting a sympathetic effect. 2d. To remove the immediate attack. 3d. To combat associated or contingent disease, whether inflammatory or structural; and, 4th. To prevent a recurrence of the affection by such means as will prevent accumulations of morbid secretions and excretions, and promote a healthy condition of the secretions, while they restore the tone of the parts and of the system generally. If it is unnecessary to describe the modes in which these indications may be carried into effect, as they are already stated in the article just referred to, and as they necessarily differ according to the peculiarities of each ease. I may, however, remark, that the use of opiates, or of other narcotics, should not be long persisted in, with the view of accomplishing the second intention, without alternating or combining them with mild purgatives or laxatives, or with deobstructives; taking care, at the same time, to remove inflammatory action, if it be present, to any degree. Narcotics, especially opium or morphia, interrupt the biliary and intestinal secretions and excretions; and, although the latter is extremely efficacious in removing spasm, yet it counteracts the other indications. Much, however, will depend upon the modes of combining or prescribing it, and upon the other means employed. Hydrocyanic acid is often a most efficacious remedy in this affection. In the violent forms of it which sometimes occur in the gouty diathesis, opiates and the hydrocyanic acid have been most efficacious in my practice, particularly when given with camphor and an alkaline carbonate, or with the carbonate of magnesia or of ammonia, due attention being paid to the excretions, both fecal and urinary. Belladonna is frequently of service, given either internally or applied by means of a plaster over the abdomen. The administration of narcotics or analoyes in enemata is occasionally beneficial; but I have seen the effects of these medicines recommended by some writers produce very serious effects. The spirit of turpentine thus employed is an efficacious remedy, especially when much flatulent distension is associated with spasm, and particularly when its antispasmodic operation is aided by the external application of it, in the form either of eputilus, embrocation, or liniment, over the abdomen. Numerous other means may be resorted to in the different states of intestinal spasm. But they are fully noticed in the article on Colic and Ileus (§ 50. et seq.). The fact of spasm being not infrequently a consequence of congestion of blood, of local determination, and of inflammatory action, either latent or manifest, ought never to be overlooked in the treatment of these affections, more
especially in the young and plectoric, and in those who live fully and take insufficient exercise.

120. XI. A Paralytic state of the intestinal canal occurs, but only in respect of portions of it, and much more rarely than the affection just noticed. Palsy even of a portion of the intestines is seldom complete. It is rather a state of over-distension, or of inflation, during which the usual vermicular or peristaltic contractions of the bowel do not take place for a time; but this state is more rarely permanent: it generally disappears either gradually or after the use of medicine or stimulating articles of diet. In its more extreme forms, it is occasionally consequent upon permanent or spasmodic constriction, or incarceration, or stranguulation, or other obstruction of a portion of bowel, and is commonly seated above the constriction; the inordinate distention caused either by flatulence, or by fecal accumulations, or by both, as well as by the unceasing efforts to propel the contents of the distended intestine outwards, or to prevent them from over-distending the wall of the intestine, is a loss of contractile power. In addition to these sources of partial palsy of the intestines, hysterical affections, irritation of the uterus, and more particularly diseases of the spinal chord or its envelopes, causing more or less of paralysis of voluntary parts, may be mentioned.

121. A paralytic state of a portion of the intestines, particularly when consequent upon permanent contraction of a part immediately below it, is often followed by serious changes in the course of its affections. Those portions of the intesines, whose villous surface are suspended, and inflammatory action, quickly passing into ulceration, or even sphacelation, soon supervenes. Indeed, these consequent changes may take place even in those parts which are not completely paralyzed, but which, having lost much of their contractile power, continue more or less distended; this condition, in connexion with the influence of accumulated and pent-up flatus, and the secretions of the part, and favouring the occurrence of inflammatory action and its usual consequences. In cases where permanent contraction, or obstruction of a portion of bowel exists, from changes about to be noticed (§ 127, 128), the parts immediately above the contraction are generally found inordinately dilated, ulcerated, ruptured, or even sphacelated; and others still higher up the bowel are occasionally spasmodically constricted—changes resulting from the inordinate efforts made to propulse the contents of the intestines. A partially or entirely syphilitic state may likewise proceed from inflammation of the part thus affected, the muscular coats being thereby rendered incapable of contracting.

122. i. The symptoms of palsy of the intestinal canal are chiefly constipation, distension, &c.

* A very successful mode of treatment in these cases is that of gradually forcing up, by means of a large quantity of some bland fluid until it reaches the seat of obstruction, or of spasms, when a speedy evacuation and relief will generally follow. In many instances several quarts will be required before this result takes place; but in all curable cases, if reasonably applied, more speedy relief may be expected. This treatment is also applicable when obstructed parts have already recovered; it should not be attempted, however, by some mild laxative, as olive oil, in a large dose, and the diet for some time afterward be of a light and fluid nature.

† In some cases of trad colic I have found the colon so enormously distended, from flatus and loss of contractile power, that I could distinguish its form and course, in the different abdominal regions, by the eye when standing at a considerable distance; the palsy had been restored to its healthy state by repeated injections containing corrosive sublimate, or even, aided by stimulating frictions on the spine, abdomen, &c.

§ In the cases of a paralytic state of the intestinal canal, which, we believe, is a not infrequent cause of obstinate constipation, galvanic magnetism, applied by placing one button of the conducting wire over the spinous process and passing the other generally over every part of the abdomen in succession, will be found, perhaps, the most successful of all modes of treatment; for those who have been restored to a healthy peristaltic action and intestinal secretions depend. One button may occasionally be placed on the tongue, and the other in contact with a metallic bougie, introduced into the rectum or passed over the abdomen, as in the former case, or placed in a tub of water, in which the feet are immersed, with the same effect; or the body may be covered with all these modes of application, and with very gratifying success. A combination of quinine, or piperine, with some preparation of aloes, as the compound dorection, or pilis, will aid and sustain the effect of the galvanism, which, without some internal stimulant of this kind, might only be temporary.
124. XII. Rupture of the Intestines is generally a consequence of pre-existing disease of the ruptured part or its vicinity. It never takes place in the healthy bowel, unless when caused by external violence, as the kick of a horse, or the passage of a carriage-wheel over the abdomen.—A. The symptoms vary in these cases according to the amount of haemorrhage which takes place from the ruptured part. But the general powers always evince great depression from the shock and the nature of the injury; the features becoming pale and collapsed, and the pulse feeble, small, or slow, and the surface and extremities cold. There is also very acute pain in the abdomen, with vomiting or syncope, in most cases. When the rupture proceeds from softening or ulceration, there is seldom any haemorrhage, and the symptoms are nearly those which arise from perforation of the intestines; great and general delirium, prostration, feebleness, and the frequent pulse, vital depression, vomiting, constipation, decubitus on the back, with the knees drawn up, and the other symptoms of peritonitis, from effusion into the peritoneal cavity, being present.

125. The treatment in the above circumstances consists chiefly of the exhibition of full and frequent doses of opium and of perfect quiet; but it is more fully stated in the article Peritonitis.

126. XIII. Thickening and permanent contraction of a portion of intestine.—The lesions, whether consequent upon inflammation or produced by constitutional vice, and impaired organic nervous power, have been fully described in the articles Digestive Canal (§ 48, et seq.), and Colic and Ileus (§ 33). In their slighter forms and earlier stages, they are not always, or even generally attended by such symptoms as will enable the physician to form a correct idea of the nature of the affection; whether or not they are simply obstructive, or, in addition, of a malignant character. In many cases, where this latter character exists, the malady is far advanced before the symptoms marking its nature become fully manifest; and in some it is even neither supposed nor detected until disclosed by an examination after death.

127. i. Thickening and permanent contraction of the coats of a portion of intestine are usually conjoined. It is but rare that the one exists without the other. They are much more rarely observed in the small than in the large bowels. They are usually attended, in their early stages, by constiveness, or by constipation, alternating with diarrhea and colicky pains. The symptoms, however, vary according to the seat of a partial, or of a more or less complete obstruction. (See Colic and Ileus, § 32, et seq.) When they are seated in the small intestines, vomiting is generally inappetent, or of an acquiescent character, occasionally with a gurgling noise about the umbilicus, and the matters vomited are often more or less digested. When they implicate the ileo-caecal valve, or the vicinity, pain is generally felt in the caecal region; and if the obstruction be not complete, the fecal matters which have passed into the large bowels, together with the decretions and excretions from their surface, generally form scanty and cossetive evacuations. When the obstruction is more complete, the sufferings of the patient are greater, the evacuations are scantier, and the bowel above the obstruction becomes more dilated and tympanitic, ultimately inflamed, and occasionally ulcerated, or even lacertated or gangrened. In such cases, the abdominal tension, tenderness, and pain, the frequent small pulse, vomiting, &c., indicate the existence of inflammatory action; and the appearance of the vomited matter; the succeeding amelioration of the suffering, suggest the portion of intestine affected. In most cases, the abdomen is very resonant on percussion; but if the obstruction be caused by much thickening of the coats of the intestine, there is marked dulness of sound on percussion in the situation of the part thus affected. The parts most liable to thickening and constriction of the coats are the sigmoid flexure and the arch of the colon. When this change exists low in the colon, the fits of vomiting are less frequent, and the evacuations at stool much scantier and less frequent, than when it is seated either in the small intestines or at the commencement of the colon. Even when the disease is in the sigmoid flexure of the bowel, as much fecal matter may pass into the rectum, as long as the canal is at all open, although remarkably constricted, as will form a consistent stool, by its accumulation and retention at the termination of the colon and at the rectum. Thickening and permanent contraction in the small or large intestines may be distinguished, with some probability, by the seat of pain and swelling, and of the gurgling noise caused by the passage of matters through the straightened part. If the contraction be in the colon, its situation may often be detected by observing how much fluid can be thrown up, and by consulting the feelings of the patient while it is being thrown up, in addition to the other indications just noticed.

128. ii. When seirans or carcinomatous or other malignant chronic disease attacks the intestines, either primarily or consequentially (see Digestive Canal, § 48, et seq.), it is generally attended not only by great thickening or hypertrophy of the coats, particularly of the sub-villous or cellular tissue, but also by very marked constriction of the canal. Tumours of various sizes, or fungous excrescences, sometimes sprout out from the diseased or ulcerated surface, which tend still further to lessen the aperture through the diseased part. The larger intestines, and particularly the caecum, the ileo-caecal valve, the sigmoid flexure of the colon, and, still more, the upper part of the rectum, are more frequently the seat of cancerous or malignant chronic disease than the small intestines.

129. iii. The symptoms of these changes are generally obscure; for they always come on insidiously. The following modifications of the bowels: more frequent calls to stool than usual, with difficulty and pain in passing the feces; colicky pains, and stools consisting chiefly of frothy mucus, often tinged with blood, are among the earliest symptoms of the disease. The evacuations are only in small quantities at a time, are thinner than natural, and, when consistent, are much narrower, or mixed with a frothy or slimy mucus. Emaciation takes place, and the pulse becomes quick and feeble.
As the disease proceeds, very acute lancinating pain is felt in some part of the abdomen, commonly the seat of lesion. When the patient is at stool, fluxes pass through the diseased part, sometimes with a hissing sound and tremulous motion. As the contraction increases, the quantity of faces discharged is diminished, and abdominal distention, pain, and tension are increased. Occasional vomiting and eructation, and a become more and more frequent, the matters ejected being more digested, or more nearly approach the fecal appearance, as the malady advances to a fatal termination. In some cases a distinct tumour may be felt, or its seat indicated by a dull sound and pain on percussion. I was lately consulted in a case of carcinoma, seated a little above the sigmoid flexure of the colon, which occurred in a medical man aged about 40, where the seat of the disease was thus indicated. The other circumstances also, already noticed, will farther aid in forming an opinion as to the seat of mischief. The malady usually follows a slow but uninterrupted course, during which the swelling of the abdomen, pain, vomitings, and constipation increase. The countenance and general surface in this last stage commonly present the cachectic appearance usually observed in Cancer (§ 11). At first, inflammation, ulceration, or even rupture or gangrene, often takes place in the over-distended portion of bowel above the cancerous part, and the patient rapidly sinks; syncope, cold sweats, singultus, feeble, intermitting pulse, cold extremities, &c., ushering in dissolution; but the disease occasionally terminates in fatal exhaustion, without these alternations supervening, and without the symptoms of ileus taking place in a very violent form.

130. iv. Of the treatment of these changes but little can be said more than will be found in the articles Colic and Ileus (§ 71, et seq.), and Constipation (§ 21). I have seen temporary benefit derived in some cases from small, but frequent doses of Castile soap, ipecacuanha, and hyoscyamus; in others, from the purified extract of aloe, conjoined with the biberate of soda and conium. The frequent use of small quantities of sweet oil, as in the exercise of an ileus, or as in the substitution of the oil instead of butter, as an article of diet, has been of service in several instances. The injection of considerable quantities of it into the large bowels has also proved beneficial in the advanced states of the disease. A liniment consisting of the mercurial and compound camphor liniment, with opium, may be rubbed over the part of the abdomen chiefly affected, or the ammoniacal and mercurial plaster may be worn over this part. The diet should consist of such articles as are the least experimentally, or furnish the smallest proportion of fatty matters.

131. XIV. Softening of the Villous Membrane of the Intestines.—Maladie Gastro-intestinale avec Disorganisation Glandulaire, Cruveilhier.—This lesion is fully described in the article Digestive Canal (§ 31, et seq.). It occurs chiefly in infants and young children, and is distinct from the softening caused by inflammatory action. Softening, as shown in that article, may be primary and idiopathic, and, in this form, is not unfrequently seated in the villous surface of the stomach and intestines, or of either more especially. It generally proceeds from causes which greatly depress the organic nervous power, and rarely takes place in adult persons, in whom, however, M. Cruveilhier, who first correctly described the disease, met with several instances. Of 50 cases observed by Dr. Rosberg, 6 occurred from the 1st to the 3d month, inclusive; 17 from the 4th to the 6th month; 7 from the 7th to the 12th month; 14 from the 12th to the 24th month; and 6 from the 2d to the 5th year of age; the periods of weaning and teething being those during which it is most frequent.

132. i. Symptoms.—The earliest indications of this disease are frequent, watery, greenish, slimy or mucous stools, often mixed with yellowish flakes, and having a peculiar offensive, acid, or putrid odour; occasional vomitings of acid, ropy, or mucous matters, and extreme thirst; acute sensibility, perpetual restlessness and fretfulness, and screaming or crying on being touched, or upon being raised from the state of exhaustion or of lethargy into which the infant generally sinks. Fever is observed at the commencement of some cases, but it is slight, and short duration, and more commonly the skin is cool from the beginning. The surface becomes cool, or soon cold, pale, flabby, and sickly, as the disease proceeds; and the countenance is also pale, cold, sickly, and sunken. At an advanced stage there are a slight or short cough; remarkable exhaustion or sinking; a short or interrupted respiration; frequent crying and moaning; much apparent anxiety and restlessness; coldness of the extremities, with rapid emaciation and extreme debility; an irregular, languid, small, and weak pulse; a white, pale, or slimy tongue; a soft, relaxed, sometimes inflamed, but never a tender or painful state of the abdomen; and pale or whitish urine.

133. The duration of this malady varies from a few days to several weeks, or even to two or three months. When the patient is carried off more rapidly, disorder of a slighter form has existed for some time previously. When the disease proceeds unfavourably, a violent exacerbation, or a gradual exhaustion or sinking of the vital energy, usually terminates life. The symptoms of the last stage are not interrupted, but oppressed by sanguinose congestion, or by aqueous effusion, but cease in consequence of the general vital depression and the extensive lesion of the intestinal canal.

134. ii. Diagnosis.—If this disease have been ushered in with fever, it closely resembles, and, indeed, is intimately allied to, both in its symptoms and pathology, the Choleric Fever of infants. (See that article.) The greater severity of the attack, the presence of fever, and the more frequent vomiting and purging, are the chief symptoms which characterize this latter malady and distinguish it from that now under consideration. The diarrhoea, the unoppressed state of the cerebral functions, the extreme irritability, fretfulness, and restlessness, and the cerebral symptoms generally, fully distinguish this disease from inflammation of the brain or of its membranes, and from acute hydrocephalus.

135. iii. Causes.—The predisposing causes are either a weak or delicate development of the constitution, originally deficient vital energy, a poor or unhealthy state of the nurse’s milk, and
the numerous other causes lowering the powers of life in early infancy. The more common exciting causes are principally unwholesome, inappropriate, or insufficient food; weaning, or bringing up by hand, or premature weaning; and living in low, damp, or miasmatus localities, or in close, ill-ventilated, crowded apartments or cellars, or in warm, damp, and low districts. I have seen this disease prevalent in low, humid, and miasmatus places, in warm countries, and within the tropics, particularly among the children of European parents. Many of the diseases of the infants or children of white parents residing in these countries are more closely related to this malady, especially while the child is still breast-fed by frequent sippings, and never by full draughts. Asses’ milk, or milk and water, or lime-water, may be given often, but in small quantity; and if any additional food be allowed, it should be subdued to the reduced state of digestive and assimilative power, and to the age of the patient. The medicines most appropriate to the disease are the preparations of iron and of lime, and the more permanent and astrigent vegetable tonics. Of the former, the powdered common salt is most acceptable; and of the latter, the powdered Cascarells bark. At the Infirmary for the Diseases of Children, I usually gave this bark with either of these salts in the form of powder, and very generally with the best results, when the patient came under the treatment in any of the earlier periods of the disease. This practice has been adopted in this institution since my earliest connexion with it (1820); and a similar treatment has often been found successful in many by Drs. Pomer and Droste. In addition to these means, I have frequently prescribed warm salt-water bathing, and assiduous frictions, with stimulating liniments along the spine; and I have occasionally employed the iodide of potassium with advantage. An improvement in the pulse and other symptoms has often been observed on the second and third day after this course of treatment has been adopted. In this complaint, as in all others dependent on a vitally depressant influence, the symptoms are more likely when occurring in large towns, and in other unhealthy localities, change of air, particularly to the seaside, is a most important part of treatment; and, when aided by suitable diet and regimen, and by appropriate medicines, will generally remove the disease, if actual disorganization have not taken place.

IRRITABILITY—SOURCE OF.

disappearance of the power of contraction on applying irritants to the muscles. It is obvious, as Tiedemann has remarked, that both parties have used too strong arguments; if, indeed, have overstated or exaggerated the facts from which they argue. Haller and his disciples were wrong, and went counter to every idea of an organized body, in which all the manifestations of life are mutually connected, in attributing to the muscles a faculty altogether independent of the influence of the nervous system. But his opponents were equally wrong in attaching too great an importance to the part which the cerebro-spinal nervous system performs in the phenomena of muscular contraction.

4. In the year 1820, and subsequently (see Lond. Med. Repository, for May, 1822, and my Notes and Appendix to Richardson's Elements of Physiology, &c., edit. 1824, 2d ed. 1829, p. 690), I showed, as the result of my researches into this subject, that irritability is not dependent upon the cerebro-spinal nervous system, although it is excited by this system; but that it proceeds from the organic or gangliar system of nerves—that this latter system bestows on muscular or fibrous tissues the power of contraction, while the spinal nerves simply conduct or convey the stimulus to contraction. This statement, though it was opposed to the popular belief, and argued against in its favour, appeared at the time just stated; and in 1835—fifteen years subsequently—Dr. Fletcher published lectures (in Lond. Med. and Surg. Journ., vol. vii., p. 327, et seq.), in which not only the same statement, but also the identical proofs and arguments which had been urged by me in the works above referred to, were adduced by him as his own original views, and in some parts in nearly the same words as I had there employed. In the republication, of these lectures, in a slightly different form, some reference was made to the originator of these views, but in such a manner as showed that the act was one of compulsion rather than of inclination.

5. As expressed in my published notes on this subject, and on others connected with it, I have suggested that the different departments of the nervous system have been hitherto viewed in a much too restricted manner; and that, instead of considering the different orders of nerves hitherto supposed, and the large nervous masses, it would be equally, if not more correct, and consistent with the gradual rise in the scale of animal creation, and with the development of the tissues and organs in the higher animals, to view them as originating in the different structures and organs in which they have hitherto been said to terminate. The reasons which I assigned of minute and variously arranged fibrils resulting from the regular distribution of these corporicles, is the chief source of the property evinced by muscular parts of every description. On this supposition, I fail to see how either of these fibrils could not produce their specific effects on muscular fibres, owing to a nervous fibres being ramified to each muscular fibril, for this does not take place; nor do these effects proceed from the direct influence of these nerves upon the muscular fibres, for the muscular fibres have been shown to derive its property or faculty of contraction from a source different from those to which they are supposed to have been originally excited its contractions; but that these nerves seem to act directly upon the ultimate distribution or corporicles of the organ, and that the action of the nervous system in the branches of the spinal nerves, and its influence on the fibres of the sympathetic to the faculty of, or disposition to, active contraction, on the application of a stimulus; and this faculty being, I think, the true nervous origin, and is attributable only to some of those organs which are supplied with voluntary nerves, and are liable to be acted upon by cerebro-spinal influence. The mode of termination of voluntary nerves in muscular parts also favours the opinion now stated. These nerves terminate, as already noticed, in such a manner as leads me to infer that they become, in the tissues which they supply, gradually identified, as it were, or amalgamated, with the ultimate distributions of the ganglions; and the history of the embryo and the progressive development of the nervous system in the lower animals lead me to believe that the voluntary nerves originate in the tissues which they supply, that they proceed from the ganglions; and that their larger branches to the spinal marrow, and encephalon are successively formed.

As respects the more perfect manifestations of this property, by means of muscular structures, I there stated, "that, as irritability is present in parts which do not receive voluntary nerve供应s, it is not mere irritation. To what other species of organization can we refer it? We observe it, in the more perfect animals, displayed chiefly by muscular parts. Is it from this circumstance an attribute only of muscular animals, and the parts which are connected with movement? One class of physiologists answers this question in the affirmative. But irritability is manifested in the lowest forms of animal creation, as much as in its highest, by parts in which a muscular structure cannot be detected; therefore, although a property of the muscular structure, it is not restricted to it in a stricter sense than is the result of the organization of this structure, independently of some other. Consequently, this property must be referred to a conformation still more general than the muscular tissue, as respects both the entire scale of animal creation and the organization of individual species; allowing, at the same time, that a particular structure is requisite to its manifestation from itself, from its connexion with the organ, but that this structure depends upon a different source than itself for the property which it displays. It is clear, also, that irritability, although a property of muscular parts, is not the result of muscular organization merely, but is derived from a different source: the relations of all muscles to other structures, as well as to each other; and, consequently, that to no other source than this can we attribute this property.

Having inferred that the muscular fibre is only the instrument of contraction in its more perfect condition—that it performs the function in consequence of a certain conformation, which is a property inherent in the fibre, and is communicated to it by another still more generally diffused than itself—and that this property is derived from the ganglion, or soft nervous system, as we may term it, which is the source of these fibres; it is obvious that these fibres are distributed to muscular parts for specific purposes, but that these parts do not derive their innate properties from them, as the ultimate distribution of the sensory nerves do; but that the nervous system and the organs are, in this case, the contractors, or as conductors of a stimulus to properties which proceed from a different source. I have contended that these properties are innate, or the consequence of the conformation of the muscular parts, and are derived from a conformation more general, surrounding or otherwise connected with the muscular fibres, and that this more general conformation in the organic nervous system.

Considering, therefore, that this system, in its state of ultimate distribution and dissemination in the texture of a muscle, whether in the form of unarranged corporicles or
for this mode of investigation, and for adopting it in addition to the one-sided mode of viewing this subject hitherto pursued, need not be here repeated. I may, however, briefly state, that the lowest grades of animal bodies, and the earliest stage of animal formation, display merely minute granulated or nucleated globules or corpuscles, more or less abundantly disseminated throughout the cellular and other tissues; and that, as these tissues are more visibly developed, and assume a more truly cellular and fibrous conformation, from the almost abumnnous state of the earlier stage of their formation, so the gray fibres constituting these organs of nervousness become visible in connexion with these corpuscles. The fully-developed state of animal organization these granulated corpuscles are numerous and demonstrable in the tissues, particularly in the ganglia in connexion with the gray organic fibres, and in the muscular fibrils, both involuntary and voluntary. But, whether these corpuscles are formed before the large nervous masses connected with sensation, volition, &c., or contemporaneously with these masses, is of little importance. The most important question is, what is the function performed by these corpuscles? When we recollect that these bodies are found disseminated through the alburninous and otherwise almost inorganized structure of polypi, and throughout the tissues of others of the lowest animals, which manifest irritability as their most important function, and when we know that these animals are capable of being multiplied by division, and that parts cut off from them have separate existences, it seems highly probable that the vital functions they display — that irritability proceeds from this peculiar organization. Having farther observed these granulated corpuscles disseminated through other tissues, in an abundance proportionate to the amount or grade of vital function — having detected these corpuscles in great numbers within the delicate membrance investing the primitive fasciculi of voluntary muscular fibrils, and in the flattened fibrils of involuntary muscles — having seen still greater numbers of them comprised in the structure of the organic nervous fibres, and constituting the chief part of the ganglia; and having, moreover, found them giving origin to the gray and solid filaments of organic nerves, as well as comprised in or embraced by these filaments, it may be inferred that they are mainly concerned in the production of the various grades of irritability or contractility manifested by the tissues in which they are thus disseminated, and to which they are thus supplied.

6. The views which I published in 1820, 1824, and 1829, respecting the constitution, connexions, and functions of the organic or ganglial nervous system, have been more recently (from 1831 till 1840) confirmed by the researches of PETZIV, GILV, MULLER, and VALENTIN. The organic, or gray nerves, do not consist, as the motor and sensitive nerves of the spino-cerebral axis do, of parallel tubes containing a liquid matter, but are altogether homogeneous, pale, almost transparent, and peculiar in their form, distribution, and connexions. They are intimately connected with the granulated or nucleated corpuscles disseminated throughout the tissues, and they either enclose, or are otherwise associated with, these corpuscles or globules in great numbers, both in the ganglia and the thoraco-splanchnic ramifications. The gray, or ganglial nerves, thus seem to arise from the organic globules just described, especially from those contained in the ganglia. The ganglia should therefore be regarded as the central organs of the organic nervous system; and the white fibres which run to and through them, especially in the lateral chords of sympathetic ganglia, without having any intimate connexion with the granulated corpuscles, are not fibers of the nervous system, but fibers passing between these corpuscles, are the sensitive and motor fibers of the nerves derived from the cerebrum and spinal chord. The organic, or gray portions of the nervous system, and more especially of those parts of it lodged in the abdominal, thoracic, and cervical regions, preside over the organic and truly vital functions; and their connexions with the cerebro-spinal centres are such as evidently show that they are ramified thither in order to en loro these centres with the organic nervous power in common with other parts of the economy; nerves proceeding from these centres also being ramified to the ganglia to supply them with the sensitive and motor influences.

The nervous connexions or ramifications between the ganglia and cerebro-spinal axis thus consist of the solid or homogeneous gray fibres of organic nerves conveying the strictly vital or vegetative influence to the brain and spinal chord, and of the white tubular fibres having relation to and conveying nerves transmitting the influence of these organs in various degrees to the viscera engaged in the strictly vital operations. In those parts which perform complex functions, as the organs constituting the face, mouth, throat, &c., and the organs of generation, which are endowed with the functions of secretion, sensation, and motion, the nerves proceeding thither consist both of the gray fibres of organic life, and the white tubular fibres of sensitive and motor nerves.

7. From what has been here stated, from the most recent researches, and from the conformation detected by microscopic observation, the results of my own investigations many years since, as published in the works already referred to, have been fully confirmed, namely, that the organic or ganglial nervous system presides over the strictly vital functions, and that all the grades and manifestations of irritability or contractility proceed from this source. It is extremely probable that the organic or nucleated corpuscles disseminated throughout the structures, and particularly in fibrous and contractile parts, bestow a certain share or grade of contractility upon them, and that an
additional or even a principal share of this property is contributed by the ganglia and organic nerves distributed to them. Indeed, this is shown by numerous observations made by me in 1812 and 1813, when it was proved that the hearts of fishes continue to beat for a considerable time after they were removed from the animals, and from all the nervous structures external to themselves; while influence of the ganglia on the involuntary muscles was proved by the application of powerful stimuli to the coeliac ganglion having caused increased peristaltic movements of the intestines that continued for some time. (See a notice of these experiments in my "Notes," &c., already referred to.)

The organic muscles, which possess either a power of almost continued action, or a certain rhythm of action, as the heart and alimentary canal, the organic nerves are plentifully distributed, and abound with the organic corpuses above described; showing that the unexhausted irritability of these parts is chiefly owing to this organization. The facts and arguments adduced so many years since by me, in proof of the dependance of irritability upon the organic nervous system, have been very recently confirmed with the utmost precision by Fletcher, and by several German writers; but what they have advanced merely confirms what I had published, fully explained, and made even the basis of a system of general and special pathology, many years previously, in the works above stated. Among others, the subjoined remarks* of Mueller, from the able translation of his Elements of Physiology, by Dr. Baly, may be adduced in illustration of what I had stated long since respecting the functions of the organic or ganglionic nervous system, and the source of irritability. After stating the same facts as have been advanced by me, he draws the same inference, namely, "that the organic nerves distributed in the muscular substance have a principal share in the production of their automatic movements, and that the rhythmic contractions of the organic muscles are not independent of the nerves, as Haller believed." (P. 913.) The error of the most eminent physiological observers (in identifying irritations as independent of nervous influence) arose from the circumstance of their confounding the cerebral-spinal nervous influence, or sensitive and motive function, with organic nervous power, or the strictly vital manifestations. Haller, believing that there was only one species of nervous influence, and that it proceeded from the brain, considered the irritability of the muscular parts to be what it really is, independent of this part of the nervous system; but his arguments and facts left entirely unaffected, or, rather, confirmed the view, first advanced and supported by me, that this property of animal bodies proceeds from the organic nervous system, which system I showed to be altogether distinct from the cerebral-spinal nervous system, its functions being different from those of the other system, and altogether of a strictly vital character.

9. From what has been now stated, it will be inferred that irritability, according to the sense in which it has been viewed by Haller and others, is the contractility, or power of contraction, possessed by muscular parts, and displayed by them when acted upon by stimuli or irritants. In the wider sense of the word, according to Guiss and others, it is the power of sensible and insensible contraction possessed by most living tissues. The molecules of matter, composing the living organisms, are preserved in a state of cohesion, varying in grade in the different tissues. This variation in grade depends upon the organization of the tissue, and upon the state of its vital endowment. That the organization affects the cohesion of a particular structure, does not require proof; and that the state of vitality exerts a marked influence upon the cohesion of the tissues generally, is shown by the gradual loss of cohesion, as vital parts depart, and as it becomes reduced in the progress of diseases characterized by exhaustion. The state of the blood also affects the cohesion of the structures, but most probably by first reducing vital power. From this intimate dependance of structural cohesion upon vitality, the term vital cohesion of the tissues may be used with reference to some of the most important conditions presented by them in health and in disease. As the powers of life are perfect and strongly manifested, so cohesion is perfect; as vital parts are removed, so cohesion is reduced, so it also is reduced. Hence it becomes an index, in many diseases, of the degree to which this reduction has taken place, the firmness and tenacity of the tissues, and the duration of these properties for a time after death, varying with the reduction of vital energy.

10. ii. Of the Grades of Irritability.—The vital cohesion of the tissues is one of the earliest, the most generally diffused, the lowest, and the most persistent of vital phenomena. It furnishes, as it were, the basis for all the other manifestations of life; and as it becomes weakened, or ceases, these manifestations more or less completely disappear. As long as the tissues are endowed with life, vital cohesion continues, varying, however, in grade with the circumstances just stated. Of the parts possessed of vital cohesion, a very large proportion

* "It has been proved that the automatic movements of the organic muscles, like all muscular actions, are mainly on the influence of the nervous system; that the cause of the rhythm of these automatic motions is not connected with the nature of the muscular fibres, but with the peculiarity of the nervous system of the organic muscles; and that the coeliac ganglion has the property of exciting, when irritated, the peristaltic motion of the intestines. It appears, moreover, that the sympathetic nerve retains its ganglionic structure even in its more minute ramifications; and the power of the intestines to perform its peristaltic motions is found to be preserved even when these are separated from the mesentery. From these facts, then, I conclude that the minute branches of the sympathetic, which ramify in the intestinal coats, have the same power of causing peristaltic contractions as the coeliac ganglion was proved to possess. The explanation which applies to the peristaltic movements of the intestines has this application to the rhythmic motion of the heart, the first observed motion of which, in its simple tubular condition, is indeed of a peristaltic nature. Since, then, all the larger ganglia of the sympathetic, even its ultimate ramifications in the tissues of organs, seem to possess the power of giving rise to periodic motions, we can understand how the rhythmic movements of the heart, intestine, and other parts of the animal body, are enabled to continue when these parts are removed from their connections in the body."—Mueller's Physiology, Baly, p. 914.

* On this subject the reader is referred to the London Medical Repository, vol. xxii., p. 370, et seq.; and to the Author's Notes and Appendix to M. Richerand's Elements of Physiology, where will be found the same facts and opinions stated as early as 1820, 1822, and 1824, as have been exposed by Mueller, and others much more recently.
IRRITABILITY—CONDITIONS NECESSARY TO.

present certain grades and modes of contractility which have been variously denominated. Contractility is essentially a vital phenomenon, and results from changes in the vital endowment of a structure affecting the relative position or compared as being such structures. Vital contractility may be divided into grades, commencing with the lowest and the most generally diffused grade of this property of living parts—with that grade the next above simple vital cohesion, in the scale of animal manifestations.

11. 1st. Insensible organic contractility, or that state usually denominated tone or tonyricity, is, like vital cohesion, not confined to the animal kingdom; it is a property of vegetables and of animals not possessed of a heart. It is diffused throughout the tissues, and may be viewed as merely a higher grade of vital cohesion, or, rather, this latter may be considered as the lowest manifestation of life in organic structures, insensible organic contractility or tone being the next in the scale. This property, equally with the preceding, results from the vital influence with which the structures are endowed—is perfect, as this influence is perfect, is impaired as it is weakened, and altogether disappears soon after life has departed. Insensible contractility or tone is manifested by the vascular system more especially, and by the soft solids generally; and it is more or less exerted in all the vital operations—in the circulation, in secretion, in nutrition, and in absorption, the perfection of these functions depending upon its due manifestation. The organic nervous system seems to be instrumental in its production and preservation in the animal kingdom, as I have contended in the works already referred to.

12. 2ndly. Sensible organic contractility, or irritability, is that property of contraction which exists in fibrous and muscular parts. It is excited by the application of an irritant or stimulant, and depends, as I have shown above (§ 4, et seq.), upon the ultimate organization and distribution of the organic or ganglial nervous substance to these parts.

13. Both these species of organic contractility result from one species of influence with which animal bodies are endowed—they are the proximate results of vitality, and differ from each other, owing to the intimate structure of the parts in which they are seated, and to the extent to which each of the parts manifesting these properties is supplied with the organic nervous globules and ganglial ramifications.

14. 3rdly. Cerebro-spinal contractility is the contraction of the muscles which is produced by volition, and by stimulants acting upon their motive and sensitive nerves. It takes place only in such muscles as receive nerves from the spinal chord, medulla oblongata, and encephalon; and results from this conformation and connexion with these centres of volition and sensation. Although produced and directed by volition, it may also be excited by irritations acting upon, or conveyed to, the cerebro-spinal axis, or the nerves proceeding from any part of this axis.

15. The first and second species of contractility proceed from the organic nervous system and influence; the third from the super-addition of the nerves of voluntary motion and of sensation. This last form of contractility, however, may take place in voluntary muscles, independently of volition, by a "reflex sympathy," as shown by me in the places already referred to:* and independently, also, of sensation, as suddenly produced for by Dr. M. Hall, by means of what he has denominated a "reflex function," with which he supposes the spinal chord to be endowed.

16. As the various grades of contractility are dependant upon vital energy, and as the higher grades of it are influenced, moreover, by the states of the nervous systems—sensible organic contractility, by the organic nervous system; and cerebro-spinal contractility by the cerebro-spinal system—so it must necessarily follow that the states of irritability contended for by Dr. M. Hall, by means of what he has denominated a "reflex function," with which he supposes the spinal chord to be endowed.

* See, also, several articles in the first volume of this work, which were published twelve months before the appearance of Dr. M. Hall's views. In these articles (p. 322, § 29, p. 351, et seq., p. 567, et seq.), I have accounted for the occurrence of involuntary movements, convulsions, and spasms in voluntary muscles, in several diseases, by showing that they proceed from irritation propagated from the motor spino-spinal junctions to the spinal nerves, or the spinal chord itself, and thence reflected, by means of the spinal nerves, upon the voluntary muscular system. (See articles CHOLERA, CHOLERA COLICHIAN, DIABETES, and INFLA-

17. 3rdly. Conditions requisite to the healthy manifestation of the several grades of irritability.—From what has been stated, it is obvious that these manifestations will be perfect according as the vital endowment is perfect. That form of contractility with which the involuntary muscles are endowed, being altogether dependant upon the ganglial nervous system, will necessarily be influenced by the conditions of this system; and that which is displayed by voluntary muscles will vary, according to the states of the cerebro-spinal axis and nerves, chiefly in respect to the degree in which these muscles will still continue subject to the influence of volition; injury or destruction of these parts of the nervous system leaving the voluntary muscles still possessed of their contractility, although in a more or less impaired form, owing to the loss of an accustomed stimulus to contraction; and, as I have stated many years ago in my physiological notes, it is reasonable to suppose "that the voluntary nerves convey to the organic or vital nerves a natural stimulus, by which they are affected, if the voluntary nerves were deprived of this additional influence, the parts supplied with them would necessarily suffer an impairment of function."
the operation of these agents, which either exhaust or directly depress the nervous power. Galvanism, electricity, mechanical irritation, &c., exhaust this property, and narcotics destroy it, or, at least, greatly impair it. These effects are produced upon both voluntary and involuntary muscles, and whether the agents be applied to the muscular tissue directly, or to the nerves distributed to them. In the former case they affect chiefly the organic corpusescles of voluntary muscle, and the tissue of their structure; in the latter, they produce a nearly similar effect through the medium of the voluntary nerves terminating in it. Many of the exciting causes of disease, and the majority of our medicinal agents, produce these effects in a similar manner; the several manifestations of contractility being thereby impaired, exalted, or exhausted, or specifically modified, according to the natures or properties of such causes and agents. From this has been stated, as well as from obvious phenomena (to which the cognizance of every observer may be inferred) that the several grades of irritability of this property, viewed in the sense entertained by Glisson, are the most general and important of the several endowments of life, and the most requisite to the continuance of life. I have stated, and more fully attempted to show many years since, that this property results from a peculiar organization—from the distribution of the organic or vital nervous fibres, and corpusescles to the tissues displaying this property; and that the apparent dependance of it, in voluntary muscles, upon the cerebro-spinal nervous system is owing to the termination of motor nerves in these muscles, in order to bring them under the influence of volition; the high grade of irritability which they possess being, however, derived from the organic or vital nervous system; and probably, altogether, from it, by the influence proceeding from the spinal chord.

19. It follows from the foregoing, that while the several manifestations of irritability are all directly dependant upon the organic or vital nervous system—are expressions of life through the medium of this system—one form only of this property, namely, voluntary motion, is unequivocally influenced by the cerebro-spinal nervous system; this form, however, being chiefly derived from the former source, although excited and directed by the latter. Moreover, it may be inferred that these manifestations being dependant upon this source, the several changes to which they are subject chiefly proceed from changes in the condition of the organic or vital nervous energy; and that alterations of that form of this property, which is more intimately connected with volition, equally with other forms, also proceed from the same source; a healthy state of the cerebro-spinal nervous system, and of its ramifications, being requisite to the due excitement, direction, and determination of this particular manifestation of irritability. These influences, indeed, are daily illustrated by the phenomena of disease, more particularly of those diseases which implicate the vital endowments manifested through the medium of the ganglial or vital nervous system, or which affect the integrity of the cerebro-spinal system. In the former class of these diseases, the irritability of vital organs is affected; and it is equally with the voluntary muscles experienced by the ganglial system; and that of voluntary organs is also either imperfectly manifested, or incapable of being determined or directed. In the latter class, on the other hand, the organic nervous system is entirely unaffected, its functions being quite healthy, and irritability also perfect throughout the frame; yet, owing to lesion in some part of the cerebro-spinal system, the contractions of voluntary muscles are either not excited, or not directed, or uncontrolled, although the power derived from the ganglial system still continues to be possessed by them.

20. B. The influence of the blood upon the irritability of parts is demonstrable. Stenson, Arnemann, Bichat, Emmert, Segalas, and others, have proved this influence, and shown that the presence of blood in irritabile tissues is necessary to the continuance, even for a short time, of the property of contraction; and that the power of voluntary muscles is lost when blood is no longer sent to them. It is also fully proved that arterial blood is requisite to the due performance of the several grades of contractility, and that, while the continued action of this blood on irritabile parts is necessary to their functions, this blood loses something by this action, or undergoes changes in the course of it, that give this fluid the venous character. That venous blood is incapable of supporting irritability in its healthy and more permanent state, is shown by the partial destruction of this property, and by the several modes of producing asphyxia. The state of the blood in respect, also, of the presence in it of either stimulating, depressing, narcotic, or specifically alterative materials, has also a most important effect upon the several forms of irritability. Many of the causes of disease, many remedies, and many poisons, act upon the frame by passing into the circulation, and affecting, by their presence in the blood, the different grades of this property, their influence being exerted in this way, either upon the organic and cerebro-spinal nervous systems, and through them upon the irritabile structures, or upon these structures directly, or even upon these systems and structures conjointly and coextensively. The changes, also, which take place in the blood, in the course of diseases, particularly contaminating maladies and fevers, owing calker to the absorption of morbid matters into the circulation, or to interrupted elimination of effete and injurious materials from it, affect in several forms of irritability, and even the vital cohesion of the tissues, in the manner now explained; the absorption or accumulation, however, of these excrementitious matters generally having a similar effect to that produced on the frame by animal poisons. Contractility is affected by the various stimuli or irritants which may act either directly on irritabile or contractile parts, or on nerves supplying them,
or on the central nervous organs; but remarks on this part of the subject, as well as on the varying susceptibility of irritation in different persons and diseases, will find a more appropriate place in the article Irritation.

CLASSIF.—GENERAL PATHOLOGY.—SPECIAL PATHOLOGY AND THERAPEUTICS.

1. DEFINITION. An exaltation of the vital acts of a particular tissue or system relatively to the vital states of other parts.

2. PRELIMINARY REMARKS. Next to inflammation, the morbid condition which the term irritation has been applied is the most important, both to the pathologist and to the rational practitioner. Notwithstanding this, the term has been vaguely employed, and the existence of the morbid states which it has been used to designate has been as loosely inferred. This has arisen, in a great measure, from the neglect of these states, until a comparatively recent period, by most writers on general and special pathology; from the want of any precise ideas respecting the nature, extent, and morbid causes of irritation, and which the term irritation is applicable; and from the difficulty of determining the modes, grades, transitions, and consequences which these actions experience. The varying characters, also, of irritation with the tissue or part primarily or chiefly affected, and with lesions of adjoining or of functionally associated parts, and the superimposition of other morbid changes, more particularly accidental irritation, secretion, and inflammatory action, have given rise to much perplexity, in respect not only of the meaning attached to the word, but also of attempts of ascertaining its existence, seat, and extent. Hitherto irritation, as a primary morbid condition, has been inferred more frequently from the absence, during disease, of more manifest alterations than from any positive proof of its presence; and to it have been referred by many those disorders and maladies which could not be imputed to any more palpable lesion.

3. It has been shown, in the article Irritability, that irritation is the chief manifestation or expression of life in the tissues and organs of a living body. 2d. That it exists in various grades and modes, according to the organization and connexions of different textures and systems, the functions of organs being discharged in a greater measure by such agencies.

3d. That the modes and grades of this property ascend from simple vital cohesion up to that form of muscular contractility which is determined and regulated by the will. 4th. That in this, its highest grade, it interests, and is associated with conscious sensibility.† 5th. That it is variously affected by the states and changes of the nervous system, more particularly by the organic or vital nervous system, and by the conditions of the blood. 6th. And that such affections constitute the principal alterations in numerous maladies.

4. To these fundamental principles of pathology, which were fully developed by me many years ago (London Med. Repository, vol. xvii.), others may be added, having a stricter reference to the subject now under consideration. The grades and modes of irritation thus vary not only in different organs or parts, but also in different epochs of life, in different temperaments and habits of body, and under the influence of numerous physical agents and various moral influences. Depending, as it does, upon the amount or condition of vitality, so it must necessarily vary with the states of this actually and controlling principle. Where this principle is powerful or largely impeded, irritability will also be energetically evinced, and long exercised; but where life is depressed, exhausted, or feebly from the earliest endowment of it in the structures, then irritation will be feebly evinced, readily excited in its highest grades, and speedily dissipated. With weakness or vital depression, irritation becomes more easily roused—the susceptibility increased—or, in other words, the disposition to contract upon the application of irritation is greater; but the contractions are weaker, and the sooner cease altogether. Yet this increased susceptibility of parts thus weakly endowed is not general, and exists chiefly in parts which manifest the higher grades of irritability.

5. Another important circumstance which

* "The lower grades of contractility depend entirely upon the organic or ganglial nervous system and influence; the highest form only upon the super-addition of the nervous system of the organs and the mental action and sensation." —(Author’s Physiol., Notes on.)

† "Conscious Sensibility is confined chiefly to certain parts and structures, the brain, and the higher centers of the nervous system of which the cerebrum is the centre. Contractility exists throughout the whole animal structure, although in different grades, and is, with the exception of its highest grade or species, entirely independent of sensibility and volition: contractility is a general expression of life, sensibility of the higher functions only of this principle."—(Notes, &c.)
may be noticed is the increased disposition of local irritation to extend itself, in proportion to the increase of susceptibility, or, in other words, to the diminution of vital power. This augmented disposition to the extension of irritation, and to the manifestation of several of its effects in different and remote parts, evidently depends upon the same primary condition to which I have attributed increased susceptibility, namely, weakened organic nervous energy or vital power. Hence an increased disposition to be affected by irritants generally is associated also with a disposition to their effects to distant parts. The extension of irritation, or, rather, of its effects, far beyond its primary seat, evidently depends upon, or, rather, takes place through the medium of the organic or vital and the cerebro-spinal nervous systems, the former especially; but this topic will be more fully considered hereafter.

6. Illustrations of the foregoing pathological facts are daily presented in practice. We continually observe, in persons originally and organically susceptible, more particularly muscular structures, to be readily acted on by irritants, especially by such as are new; but the excited action is weak, or is soon exhausted, and rapidly sinks the principle upon which the contractility depends. In connexion, also, with this local susceptibility, an increased disposition to experience the effects of the local and primary irritation in distant parts is also developed; and these distant parts often manifest the principal amount of disorder, evincing both its nature and primary seat. In these cases, irritable parts become more susceptible of irritation, or morbidly irritable, not only locally, but generally also, as respects the nervous systems, especially the organic nervous system, upon which the several grades of irritability have been shown to depend. And here it should be recollected that the term irritable admits of two meanings, which should not be confounded with each other: some parts are naturally and healthily irritable; and these, as well as some other parts, become morbidly irritable, owing to numerous causes—to excess or deficiency of stimuli, to the operation of noxious agents, or of most of the causes of disease. A morbid state of irritability may be either more or less local or limited, or extended and constitutional; but in either case, the susceptibility of contraction is increased, while the powers and contractility are most frequently exhausted. Mr. Huxley defined morbid irritability to be "an increased disposition to act without the power to act with," with much truth, although with insufficient precision; but it will generally be found, as I have just stated, that the amount and duration of "power" will be deficient in proportion to the "increased disposition." In all cases of morbid irritability, whether local or constitutional, the intrinsic and extrinsic causes and circumstances connected with it should be considered; and this state, moreover, ought to be carefully distinguished from irritation; for the former may exist without the latter, owing to vital depression merely, or to this state associated with others; and the latter may be induced and continued by local agents, where the former can hardly be said to be present, more particularly with reference to the constitution generally. Physically as well as morally, irritation may be caused, and yet morbid irritability may not be present, although the one will favour and aggravate the other mutually. Both states are frequently associated, but they are not necessarily connected.

7. II. Of the Pathological Relations of Irritation.—If an irritant or stimulus act upon a living tissue or organ, certain changes, having reference to the nature of the functions discharged by that tissue or organ which is acted upon, and the irritant employed, are thereby produced. If the digestive canal be acted upon by one particular irritant, certain of its actions are augmented or modified; if a different irritant is employed, others of these actions are increased; and if the irritant be more powerful or in excess, the effects are locally heightened and extended to remote parts. If the external structures and organs be irritated, sensibility is excited, and all the functions of those parts are affected. If the irritant be produced, or employed, in the circulation and organization of the part upon which the irritant has acted. Seeing that the operation of irritants is thus different as respects their actions individually, and as regards the tissues chiefly affected by them, and, consequently, that irritation is various in its characters, extent, relations, and consequences, according to its cause and seat, it becomes requisite to the due investigation of this important department of pathology to analyze it more fully.

8. i. Relations of Irritation to the Nervous Systems.—A. To the Organic or Vital Nervous System.—The vital actions of a part, and contractility in particular, have been shown, both here and in the places already referred to, to depend upon this system. When a tissue is irritated, these actions are affected, and it may therefore be reasonably inferred that the cause of irritation acts chiefly upon the system by means of which these actions are produced, and that, in consequence of changes in the parts of this system distributed to the tissue or structure which is irritated, the effects of irritation are developed. If a portion of the intestinal canal be irritated, either by mechanical or chemical stimuli, its contractility is first augmented. If the irritation be continued, or the organ excited, continue for a time, the secreting functions and the circulation are affected; and if it be energetic or excessive, these are still more increased, and sensibility, so obscurely bestowed on this part, is acutely roused. In addition, also, to these changes, the irritation, which was limited, while it was slight, to the parts more immediately subjected to its causes, now extends itself, influencing different systems and parts; and, owing to the connections of the organic nervous system with the cerebro-spinal, not only is sensation acutely affected, but also the contractions of voluntary muscles are violently excited, without either the influence or the control of the will.

9. Irritation thus originating in parts endow-
ed chiefly by the organic or vital nervous influence, will either continue more or less limited in its sphere, or extend itself to various parts, according to the general susceptibility of this system, to the predisposition or susceptibility of particular organs, and to various concurring or determining causes. — a. Where the irritation is slight relatively to the amount of organic nervous power, or where the susceptibility is not increased, the limitation of it to its original seat may be long continued; but where it is more marked, organic nervous power being low, and the susceptibility, either general or local, consequently high, it will extend itself, or manifest its effects, more or less prominently, in remote situations. The limitation of irritation may be so complete that one function only of one organ is affected; but this seldom is of long duration without other functions and organs experiencing disorder. Thus, owing to mental emotion acting as an excitement to the cardiac nerves, palpitation or excessive action of the heart is produced, and as a consequence, the irritation of bile into the intestines, increased action of their coats is occasioned; but this discharge seldom is great or continued without producing augmented secretion from the intestinal mucus surfaces generally, and increased determination of blood and other changes of the vascular system, consecutively, as will be hereafter shown.

10. The extension of irritation, particularly when internal or vital part or viscera, takes place either directly, by means of the communicating ramifications of the organic or ganglial nervous system, or indirectly, and by a reflex operation of the ganglial nerves, conveying the morbid impression or action to the roots of the spinal nerves, or to the spinal cord and brain, and thereby exciting the sensations or actions of parts supplied with nerves by the cerebro-spinal system, or in both these modes, either consecutively or contemporaneously. These two distinct ways, by which irritation or impressions are transmitted to parts remote from the seat of impression, were pointed out by me many years ago, and described by the terms direct and reflex sympathy. (See Physiological Notes, &c., 1821.)

11. The direct transmission of irritation may take place either along parts or tissues similarly constituted, as mucous or serous tissues, or from one organ to another, by means of the seated in an interval nerve with which they are supplied. In this manner, irritation of one part of the intestinal mucous surface often proceeds along it; or irritation of one part of the muscular coats of the bowels frequently extends along the tube, or affects it to a greater or less extent, as in colic and hysteria. The morbid impression, also, made upon the organic or vital nerves of one tissue or viscera, is often transmitted thence to an adjoining, but different or constituted organ, through the medium of these nerves, which are supplied to both. Thus the irritants which affect the nerves of the duodenum or of the stomach primarily, extend their operation in many cases also to the liver and pancreas; and stimuli which excite the stomach raise the action of the heart and vascular system. Irritants of the kidneys frequently render the urinary bladder more irritable, or excite this latter viscera; and those of the rectum often extend their influence to both the urinary and genital organs. In cases of this description, it may be asked whether irritants or stimuli applied to an involuntary part excite the contractions and vital actions of such part by producing an impression on the organic nerves which is conveyed to their corresponding ganglia, and reflected thence by these nerves upon the muscular fibres which they activate; or whether they act directly, and without the intervention of the ganglia, independently of any reflex operation, and simply by affecting the state of the nerves themselves—by affecting the organic corpuscles and fibrils entering into the organization of the part. I would incline to this latter alternative; although I admit that the ganglia may generate an additional vital influence, re-enforcing that with which the tissues and organs are endowed. The truth of this inference is confirmed by the fact, often observed by me and others, that involuntary contractile parts, as the heart and portions of the digestive system, might be excited to contraction even when removed from their connexions with the ganglia.

12. b. As I have shown, when treating of various diseases originating in the nervous system, irritations commencing in the organic nervous system are often propagated to the cerebro-spinal system, and thence reflected upon external and distant parts, either affecting the nerves of sensation, morbid sensation or pain being felt in parts to which such nerves are distributed, or exciting those of voluntary motion, so as to remove them out of the due control of the will. In this manner I explained, in the early parts of the work (published in 1832 and 1833), the origin of several spasmodic and convulsive diseases; and insisted that the irritation thus conveyed to the roots of the spinal nerves, by means of the communicating ramifications of the gray or ganglial nerves, either might reach the spinal chord and brain, thereby exciting the voluntary parts and conscious sensation, or might affect the nerves of motion and sensation, and the parts supplied by them; the cerebro-spinal axis being only contingently implicated. *

13. B. Relations of Irritation to the Cerebro-spinal Nervous System.—That irritation of a part, as of an extremity, will excite contractions of the muscles of the same or of an adjoining part, independently of sensation or of the intervention of the brain, has been illustrated by Dr. M. Hall; but, instead of attributing this to a "reflex function," as he has done, it may be explained as I have many years ago attempted, in a work already referred to, by means of a "reflex sympathy." Dr. Hall and Mr. Gräninger, in endeavouring to establish the existence of this as a distinct function, have attempted to connect it with a particular organization of the spinal chord; and to show that there are not only voluntary and involuntary parts and conscious sensation, or might affect the nerves of motion and sensation, and the parts supplied by them; the cerebro-spinal axis being only contingently implicated. *

* The reader is referred to the articles CHOLERA, § 23, CHOLERA, § 16, and Convulsions, § 42—46, the last especially, for remarks upon reflex irritation, which were written in 1838 and 1831, and published in 1838, long before the appearance of Dr. M. Hall's views on the subject, and explained by him by means of a "reflex function."
but also a distinct class of nerves which are independent of this organ, and arise from the spinal chord. This class he has denominated the "excito-motory" and "refecto-motory" nerves. Dr. HALL limits the phenomena of reflex action to this class of nerves, and denies the cerebral nerves of special sense the power of producing them. He supposes the reflex motor actions to be in no case excited by sensation, but by a brand of the defensive nerves, the visceral fibres. He maintains the existence of spinal nerves, endowed with the "excito-motory" function; and the reflex action he supposes to be conveyed, not by the nerves of spontaneous motion, but by special fibres, which he calls "relecto-motory." This theory of excited and reflex movements being produced by nervous fibres which are distinct from those which reach the centres of sensibility and volition in the brain, has been supported by Mr. GRAINS and DR. CARPENTER. The former believes that the fibres of the roots of the spinal nerves, which pass into the chord, and are lost in the gray matter, as demonstrated by WEBER, BILLINGER, and himself, are the true excito-motory and reflecto-motory fibres. Such may or may not be the case; or the nerves which thus originate in the gray matter of the chord may be destined to transmit to the ganglial system the influence generated by this part of the chord, thereby re-enforcing, and, in certain places or ganglia, modifying the influence proceeding from the organic nervous system itself. Thus, the ganglia supplying the heart, the genital organs, and the outlets of mucous canals, are re-enforced by nerves from the spinal chord; and it seems much more probable that the gray matter of the chord gives origin to them, and generates an influence necessary to the due performance of the functions of these parts, than that it gives origin to a class of nerves, the existence of which, as well as of the imputed functions, is altogether hypothetical.

14. The chief phenomena adduced in favour of an "excito-refecto-motory" function, of its independence of sensation, and of the gray matter of the chord giving origin to nerves destined to perform this function, are: 1st. That reptiles and various others of the lower animals, when decapitated, may still evince motion of a part when its surface is irritated; 2d. That an apoplectic or paralyzed person may retract or move the paralyzed limb when it is pinched; and, 3d. That infants, when asleep, may clench their hands when the palms are irritated. The same explanation applies to these several phenomena. But as long as they admit of explanation without calling in to our aid the existence of a new and special apparatus for this purpose, the material presence of which is not demonstrated or even rendered probable, we are bound to refer them to the organization which is generally admitted, as parts of the other classes of sense-organs. In the higher orders of animals, it has not been ascertained how far sensation is extended throughout the nervous system, or how closely it is confined to the brain, or the ganglia serving the offices of the brain. The distinctions, moreover, existing between conscious and unconscious sensations have never been attempted to be drawn; unless, indeed, in the brief manner I have attempted, many years ago, in my physiological notes. That the brain is the seat of conscious sensation, in the higher animals especially, will not be denied; but that a species of sensation—a susceptibility of motion and action, particularly of such motions and actions as have become habitual, is retained and exerted under the influence of certain stimuli or irritants, when the brain is no longer conscious, even after its removal in young or in the lower animals, cannot be denied. The mere turning in bed while a person is soundly asleep is a proof of this; and the motions of a limb, upon irritation of it, in apoplexy or in paralysis, is of a similar description. In these cases, the brain is not in a condition to manifest consciousness; but, with the rest of the nervous system, it may still be so impressed by an obscure feeling of uneasiness as to give rise to motion or change of position. The explanation given of these phenomena by DR. M. HALL would have been more convincing if a different one equally, if not more conclusive, could not have been offered. For, if the facts and arguments adduced in the article Irritability, and elsewhere, be received, it will necessarily follow that the irritation of parts acted on by volition will give rise to contractions of them, as in involuntary parts; seeing that the nerves of volition are merely superadded, in the former, to the organic or ganglial nerves, which supply them in common with all other contractile parts; and that contractions will thus take place in them independently of the transmission of the irritation by means of excito-fibres to the chord, in order to be reflected back again by means of other fibres. Even granting that the irritation is conveyed by nerves of sensation, it does not follow that it shall reach the chord itself, for it may only proceed as far as the ganglia on the roots of the nerves, and there partially affect the motor parts corresponding to the sensitive fibres, without giving rise to conscious sensation.

15. Moreover, as the nerves of general and special sensation may be viewed as originating in the tissues and organs they actuate, and the parts they endow, as shown to be the case in respect of the organic or vital nerves, and as converging to the spino-cerebral axis—being, in fact, centripetal nerves—it may reasonably be expected that irritation of a part will often give rise to motions of corresponding or associated parts, without the brain, or even the spinal chord, under certain circumstances, operating in the act, or taking cognizance of it. These nerves are thus expanded in the tissues and organs, so that an impression or irritation in any one point, however minute, is transmitted from them to the central organs of perception and volition, where it gives rise to conscious sensation, if it be sufficiently strong, and if these organs be in a state capable of conveying the sensation to consciousness, as in sleep, apoplexy, &c., or when the impression is so weak as not to excite this function, still motions of voluntary muscles may follow, owing to "reflex sympathy," as explained in my Physiological Notes, already referred to. When the bronchial secretion rises to the larynx, it there irritates the nerves of sensation supplying this part,
IRRITATION—Pathological Relations of

and the irritation, if the patient be awake, generally becomes an object of consciousness, giving rise at the same time, and by a reflex sympathy, to increased or spasmodic action of the muscles of respiration: in such cases, as I have pointed out in my "Notes," the irritation is conveyed by the nerves of sensation to the cerebro-spinal axis, and thence reflected by the associated nerves of motion upon the muscular apparatus which the latter nerves supply. In many of these instances, the reflected motions, consequent upon the irritation, take place, although in a much less degree, when the brain is incapable, as in sleep, of taking due cognizance of the primary irritation; yet this is no sufficient proof, either that the brain is unnecessary to their production, or that the spinal chord alone performs them, or that a particular organization of both the chord and nervous system is destined for their performance. In the particular illustration now adduced, it is just as probable that the irritation excites the nerves of motion, independently of both brain and spinal chord, as that it acts through the intervention of one or both of them. To infer, then, that the chord contains, or is the centre of an apparatus destined to discharge certain offices, which offices may be readily performed by the agencies, and in the modes previously conceived, and which consist merely of the reception and transmission of irritation or excitement, by sensitive and organic nerves, and reflecting such irritation by means of motory nerves upon voluntary muscles—the gray matter of the chord receiving the fibres supposed to convey the irritation, and originating those transmitting or reflecting it upon the muscles—is to suppose the existence of an organization too important for the amount of function to be performed—is to assign a means of much too wide and great extent, for a contingent or an occasional office; and one, moreover, of the existence of which there is no visible, or palpable, or demonstrative proof.

16. If the apparatus argued for by Dr. M. Hall and Mr. Grainger really did exist, no reflex action could possibly occur when the spinal chord is destroyed; yet, nevertheless, the destruction of the chord could not be a satisfactory proof that reflex actions depend solely on it, seeing that the vitality of the animal receives such a shock from an injury so very extensive as this, as would prevent these actions from being manifested. Indeed, some experiments which I have made induce me to infer that reflex motion may take place independently of the spinal chord itself, and by means of the connexions subsisting between sensitive and motive nervous fibres, in the various ganglia and plexuses, and that the isolation of those and all other sympathetic actions in a single part contended for by these writers is not consistent with the connected and reciprocal functions of the different parts of the nervous system. Moreover, it should be recollected that it is not motion alone that is thus reflected from the seats of irritation. In some cases, more especially when the irritating cause affects the organic nerves, or when parts chiefly supplied with them are affected, pain or morbid sensibility, either alone or in connexion with disordered muscular action, is manifested in remote or corresponding parts. Hysteria and various spasmodic affections furnish sufficient illustrations of this.

17. In convulsive and spasmodic diseases, which have received specific and conventional appellations according to the forms they assume, we observe that irritation of sensitive and ganglial nerves gives rise to abnormal actions of the muscles, without any sufficient proof being furnished of the spinal chord being actively engaged in the circle of morbid action; and been and its membranes have presented any lesion after death from these diseases, there is every reason to infer that such lesion was merely an occasional contingency, the irritation being conveyed by these nerves to the plexuses and roots of the motory nerves, and reflected thence by the latter nerves upon the muscles, without the spinal chord being necessarily brought within the sphere of morbid action.

18. Irritation, therefore, whether of sensitive or of organic nature, gives rise, in the cerebro-spinal nervous system, owing either to the propagation of the morbid impression in a direct manner, or to the transmission of it in the first instance to the roots of the spinal nerves, or to the spinal chord itself, and the reflection of it thence, 1st. To spasmodic or convulsive actions of voluntary muscles, as shown in the articles Chorea, Cholera, Convulsions, Disease, &c.; 2d. To pain or altered sensibility of some part of the surface of the body, or of particular nerves, or of a limb. Irritation, also, of one portion of the cerebro-spinal nervous system may directly affect distant parts, or indirectly or mediatly and by a reflexed sympathy, as already mentioned. When the irritating cause is in the brain or medulla oblongata, the functions of sensation and perception may be deranged, either solely, or in connexion with morbid volition and muscular action or motion. In such cases, the irritation is central, its effect direct and immediate, and manifested chiefly in the functions performed by, or intimately connected with the tissue most seriously affected. When the irritation is seated in the spinal chord, and is unattended by effusion or other cause of pressure on the chord, muscular action only may be excited, but generally excited in such a manner, or to such an extent, as to be no longer amenable, or to be imperfectly amenable to the control of the will; or sensation only may be affected in various grades, the spinal irritation manifesting itself in the ramifications of sensitive nerves, and the morbid sensation becoming an object of consciousness through the instrumentality of the medulla oblongata and brain; or both muscular action and sensibility may be conjointly disordered. Illustrations of irritation of the central parts of the nervous system are constantly appearing in practice. When irritation is seated in portions of the gray or effective portions of the brain, the states of the mind, the sensations, and the special functions of sense are chiefly disordered. When it extends to or afflicts the fibrous structure, muscular actions are deranged. When it commences in the medulla oblongata, general sensibility, the respiratory functions, and voluntary motion are disordered, according to the extent and grade of the primary morbid condition. When it implicates the spinal chord, the consequences vary with its seat, or as the gray
IRRATION—Pathological Relations of.

or fibrous structure, or the anterior or posterior columns are solely or chiefly affected by it.

19. It has lately been supposed, as above stated, that the sympathies which I have called reflex, and those irritations which are propagated to the spinal chord, and reflected thence to remote parts of the external surface or to the extremities, with the tonic contractions of the sphincters, are essentially dependant upon the gray substance of the chord; but there is much more reason to believe that this substance is chiefly concerned in generating influences necessary to re-enforce and increase the power produced by the ganglial nervous system; and that this influence is conveyed by nervous fibres to the plexuses and ganglia of this system, and to the muscles of voluntary motion. Irritation, therefore, of the gray tissue of the spinal chord will thus affect the thoracic and abdominal viscera obscurely, indirectly, and through the medium of the ganglial system; but more directly and obviously the muscles of voluntary motion, the action of which will be thereby removed more or less from under the control of the will, and thus become involuntary or automatic. It is very probable that the continued action of the sphincters very much depends upon this part of the chord; but in this case the action is direct—is immediately dependant upon this organization, and not merely reflex; but it may be allowed that, in common with all other muscular actions admitting of being influenced by volition, irritation in the vicinity of sphincters will induce, both directly and indirectly, as above explained, increased contraction of the sphincters.

20. It has likewise been supposed that the spinal chord, and more especially the gray substance of it, is the source of irritability. I have already ascribed this very important, and, indeed, chief manifestation of life, to the organic or ganglial nervous system, whether as manifested in the voluntary or in the involuntary muscles—in hollow muscles or in sphincters—the fibres proceeding from the spinal chord unencumbered by the organic or ganglial system, and proceeding directly to this muscle; so that, although the tonic contractions of the sphincters depend upon the organic nerves, these contractions may be exalted by volition, through the instrumentality of the spinal nerves.

21. Whatever energy may thus be supplied by the spinal chord to the genital organs and sphincters is most probably generated by the gray substance of the chord, while the will merely stimulates this energy, and develops it in a more or less active and sensible manner. If we analyze the phenomena manifested by the genital organs, we shall find that the essentially vital and sensible changes and functions of these organs are dependant upon the organic nerves with which they are so abundantly supplied, and upon the connexion of these with the rest of this system; while the excitation of these functions, and the sensible changes attending such excitation, take place through the medium of the organization of the spinal chord and of the nerves proceeding from it. The former of these classes of phenomena require a more remark, rather than that they are performed with a degree of perfection proportionate to the strength and constitution of the individual. The latter phenomena are produced in one or other of two modes—either by the influence of the mind upon the nerves of these organs, through the medium of the chord, or by the local irritation of these nerves; the influence of such irritation extending not only to all these organs, but also to the spinal chord, and to the brain, whence it may be again reflected back upon them and upon other parts.

22. While thus the tone, irritability, and strength of contractile and sensitive parts are furnished by the organic nervous system, and augmented by the influence generated by the gray substance of the chord, irritation, implicating either of these parts of the nervous organization, excites and removes from under the control of the will the functions of the parts which receive nerves from the part irritated; and while irritation of the parts giving origin to nerves necessarily exalts the functions performed by these nerves, whether these be sensitive or motory, yet, if it be either carried to too high a grade, or continued too long, vital exhaustion will succeed. The vital tone and irritability of contractile parts will also be exhausted by the excitement caused by volition, when either energetic or prolonged beyond what is necessary to the healthy development of these organs.

23. All Relations of Irritation to, and Influence on, the Vascular System and Blood.

—There can be no doubt of the commencement of many of the diseases, both local and constitutional, of which the vascular system is the seer, in the nerves, more especially in the ganglial or vital nerves supplying this system, and the several tissues and secreting structures. I have attempted to show that this must necessarily be the case in respect of many maladies, both in the article on Disease generally, and in those on specific affections. At the same time, I have not only admitted, but even demonstrated, that the blood may be either primarily or consecutively altered from its healthy constitution; and that it may, moreover, present such states as, although they may not
amount to actual disease, may strongly predispose to it, and contribute much to the development of it, as soon as the nervous system is subjected to any shock, irritation, or morbid impression; or as soon as some vital, or secreting, or excreting viscera experiences any interruption of its functions; the morbid condition of the blood, in its turn, affecting the nervous systems of organic and animal life, and exasperating or perpetuating disorders primarily seats in these systems.

34. The influence of irritation on the vascular system is well demonstrated by the changes consequent upon irritating the nerves of erectile, glandular, and mucous tissues. We observe excitation of the nerves of these parts produce expansion of the capillaries, increased action of the arterials, and turgidity of the veins. The irritation is thus generally followed by what has been variously denominated turgor vitalis, vascular turgescence, vital turgescence, &c.; and this condition, especially when favoured by the tissue, as irritation of mucous surfaces, or by the temperature, constitution, or diathesis, or by states of the blood, may readily pass into active congestion or determination of blood—its common consequence; or into inflammation, or sub-inflammation; or it may give rise to hemorrhage. As respects mucous surfaces, cellular tissues, and glandular structures, the usual consequences of irritation are increased exhalation, secretion, and vascular determination or flux; which, if allowed to proceed, or if the irritating cause act violently, is followed by some state or other of inflammatory action and its various consequences.

25. A. The relations of irritation to the several states of inflammation are more intimate than have been generally admitted by pathologists. Irritation seated in any tissue, or in a secreting surface or organ, can be viewed, at its commencement, only as connected with the nerves of the part; and in this stage, as well as in those which follow, it is attended by more or less of altered sensibility. In some structures, morbid excitation may be the chief disorder throughout its course; but in parts which perform a secreting function, or which are highly vascular, augmented and otherwise altered secretion, and increased vascular determination and action, very generally supervene. In secreting surfaces and glands, an augmented flow of their natural products usually follows the commencement of irritation; and, as the irritation proceeds, or as it increases, these products are generally augmented in quantity, but also changed in quality; and the vascular determination also is increased, or it assumes an inflammatory form, or one very closely allied to the more chronic or sub-acute forms of inflammation, several of the changes usually consequent upon inflammation also appearing in the advanced progress of the disorder, thus originating in, and chiefly consisting of, irritation in its earlier stages. Diarrhoea, from irritating ingesta, or from food, and simple catarrh, or catarrhal bronchitis, often furnish illustrations of this course of morbid action; and the more simple, as well as the more complex of the glandular structures, are liable to similar changes. A disorder of function, consisting of irritation or excitation of the organic nervous endowment of the part, is gradually converted into structural disease, owing to this disorder having affected the secreting, and consequently the circulating functions, morbid capillary and arterial action ultimately passing into organic change. Many of the forms of inflammation, particularly those which are chronic and sub-acute, originate in irritation, or in a change in the state of the organic nervous influence of the part, the liability to the vascular disease, as well as the grade of action, depending upon the susceptibility of the system in connexion with the state of the blood, and with the structure or tissue or structure in which the irritation is seated.

26. B. The relations of irritation to hemorrhages and serous effusions are very similar to those just instanced in respect of inflammations. The irritation which in one constitution would produce some form of the latter will produce in others some one of the former, the particular effect being, in a great degree, influenced by the states of organic, nervous, or vital power, of the irritability of capillary tissue; the states of the blood; these states themselves being, in some measure, dependant upon those viscera chiefly engaged in the functions of assimilation and excretion; or, in other words, these several morbid conditions often acknowledging one source, namely, the state of the vital nervous influence. Hemorrhages, particularly those taking place from mucous surfaces, are often traceable to local irritation, in connexion with impaired tone of the extreme capillaries, and often with vascular plethora; but something is also to be attributed to the constitution, or individual conformation, as shown by the distinctive characters by which it is marked, and by its hereditary disposition. Many of the phenomena, also, preceding hemorrhage, as well as some of those attending it, are referable to irritation, this primary morbid condition of the organic nerves of the part influencing the states of vascular determination and action in the same manner as the irritation or excitement of the sensitive nerves of the sexual organs and of erectile tissues affects the bloodvessels of these parts. Serous effusions, although occasionally a consequence of irritation, is much less frequently so than either inflammation or hemorrhage, and is met with, as a result of this state, chiefly in leucophaemetic or lymphatic temperaments, or in persons whose assimilating and excreting functions are impaired or interrupted.

27. C. The relations of irritation to the production of such nutrition and secretion, although confounded for by Broussais, and most of the pathologists of his school, are not so manifest nor so uniform, or even general as they contend. Viewing irritation as simple exaltation of the organic nervous influence of the affected tissue, increased nutrition and secretion might be supposed to be legitimate consequences of it; and as irritation is not merely a simple, but also a morbid exaltation of this influence, so these consequences might be also inferred to be morbid. These influences are doubtless correct as regards many cases of morbidly increased nutrition and secretion, especially when the irritation is exerted chiefly upon muscular or contractile parts, and on secreting organs and surfaces. Irritation affecting the nerves of a hollow muscle will, if protracted,
ultimately cause hypertrophy of this muscle; and a similar change in the state of the nerves of the liver, or of the digestive mucous surface, will both increase and otherwise change the secretions of these parts. Morbid nutrition and secretion, however, although very frequently proceeding from irritation, do not always thus arise; for either or both these more palpable changes cannot, in many instances, be traced to any obvious grade or form of irritation, so far as irritation can be viewed as excitation of the organic nervous power: they must, therefore, be considered, as regards these instances especially, as consequences of a perversion of this power, as I have endeavoured to show in the article Disease. (See § 87, et seq.)

28. D. That irritation should affect the state of the blood, particularly when prolonged or excessive in any important organ or tissue, may readily be admitted. Changes in direction of irritation upon the vascular system, especially in producing a febrile state, and in thereby impeding the functions of digestion, assimilation, and excretion, must necessarily, more or less, change the blood from its healthy constitution. Even in cases where local irritation does not produce marked febrile excitement, or merely a remittent or intermittent form of it, the quantity, as well as the healthy condition of the blood, may be affected. Changes in direction of irritation upon a particular tissue or viscus takes place in plethoric persons, febrile excitement or reaction may be very fully manifested, and a consequent change in its constitution may take place with a rapidity co-ordinate with the grade of excitement; but, when the blood is deficient in quantity, or in the proportion of hsematosine, the febrile excitement may be of either a low, remittent, or obscure form, or be identical with hectic, and the blood may experience still further changes in its condition. But, in all cases, much of the effect produced by irritation on the blood will depend upon the temperament and circumstances of the individual, as will be shown hereafter.

29. While, however, this condition thus affects the blood, the states of the blood, in their turn, exert an equally marked effect upon the local manifestations or products of morbid secretion and nutrition depending as much upon the conditions of this fluid as upon the irritation which, existing in a particular viscus, has determined these changes to take place in it. Indeed, the materials furnished by the blood often constitute and characterize these changes, the local irritation causing either a discharge of a portion of these materials in the secretions of the part, or their deposition in its structure, thereby giving rise to various organic lesions more or less harmfully visible in the article Disease (§ 93, et seq.), and in the various articles more particularly devoted to each of these lesions.

30. iv. Of the Propagation, Reflection, Reaction, and other Consecutive and Sym pathetic Phenomena of Irritation. Irritation may act in various modes, or may have its effects limited or extended, in various grades, in different persons, in diversified circumstances, and according to the kind, nature, or degree of the irritating cause. It may thus be, 1st, Simp-
Irritation more rapidly develops its effects, other circumstances being equal, than when this power is unimpaired, the resistance exerted by the constitution to the morbid impression or irritation being weaker, and consequently the less capable of overcoming this primary affection, which increases and extends itself with a rapidity co-ordinate with the vital or the organic nervous depression or exhaustion. Morbid conditions of the blood, arising from the passage of contaminating matters into it, or from the accumulation of effete materials in it, owing to deficient or interrupted action of eliminating organs, exert an equal, if not a still more remarkable influence, in favouring and in accelerating the extension and consequences of local irritations. Puncture, external abrasions, local injuries, the acid, contaminating, and animal poisons, and numerous other causes acting locally, or even on the minutest point of the organism, produce effects of the most severe and deleterious character in these circumstances of organic nervous power, and of the circulating fluids; and, although these causes are often deleterious in the most healthy conditions of the frame, yet are they very much more so in the circumstances just now stated, by occasioning the worst forms of erysipelas, diffusive inflammations of the integuments and subjacent cellular tissue, the most violent constitutional disturbance, contamination of the blood and soft solids of the body, with effusion into shunt cavities and other lesions, and, ultimately, death.

34. B. Reflected irritation may be of three kinds; namely, (a) The irritation may occur in a purely perivisceral or a perivisceral part of a viscous, either chiefly or solely with organic or ganglial nerves, and be transmitted to the ganglion by the nervous fibres first affected, and thence reflected upon these fibres themselves, or upon others supplying different structures, or communicating with other parts of this system, or with the cerebro-spinal axis.—(b) The irritation may commence as in the preceding variety, and extend to either the roots of the spinal nerves, or through the cord itself, and thence reflected, in the form of pain or spasm, to superficial parts, or to the extremities.—(c) The irritation may commence in, or affect the nerves of sensation in these last situations, be transmitted to the spinal chord, or to the roots or ganglia of the spinal nerves, and be reflected thence by sensitive and motory nerves, occasioning altered sensation, morbid sensibility, or convulsive or irregular movements. These several modes of reflected irritation occur most frequently in nervous and irritable temperaments, and in persons neither plectoric nor robust.

35. a. The first of these often attends visceral disease, both functional and organic, hysteria, the several forms of colic, constipation, gastro-intestinal disorders, visceral neuralgia, or painful affections of the abdominal organs, and diseases of the sexual and urinary organs, but generally in irregularly or imperfectly manifested forms. Irritation of the nerves of the uterus or ovaria, or excitation of their sensibility, may be extended to the ganglia, from which these nerves depart, and be reflected thence, not only upon these organs themselves, but also upon the intestinal canal, giving rise to irregular movements of its muscular coats and to borborygmi, or to altered sensibility, or to abdominal pains, such as I have described in the article Hysteria, or to both spasm and pain, as in hysterical colic. The irritation of calculi in the pelvis of the kidney may be extended to the renal ganglion, and thence reflected upon the digestive tube in the form either of colic, or of nausea or vomiting. The irritation of calculi in the bile-ducts may, in a similar manner, be reflected upon the duodenum, stomach, or other abdominal organs.

36. b. The second variety of reflected irritation, or that extending to the cerebro-spinal nerves, and from thence expressed upon superficial or distant parts, may exist either alone or in conjunction with the foregoing variety, as in the several forms of hysteria, especially the more irregular forms of it, in chorea, in verminous complaints, in symptomatic epilepsy, cholera, &c. In these affections, as shown in the articles devoted to them, irritation affects a certain portion of the organic nervous circle, and extends to corresponding ganglia, and thence reflected upon the fibris of gray nerves supplying other viscera, or upon those communicating with the roots of the cerebro-spinal nerves, occasioning either altered sensibility or extreme pain in the extremities of the nerves of sensation, or spasmodic or uncontrolled movements of the voluntary muscles, through the medium of the nerves of motion. The convulsive affections of infants and children are frequently thus produced without any disease of the brain, although the circulation in this quarter generally is affected in the course of their illness. The nature of the convulsive nervous or respiratory processes attending it, and to the impeded passage of blood through the lungs and heart. The irritation of worms in the intestinal mucous surface gives rise not only to various painful and spasmodic states of the canal, and to palpitations of the heart or of the abdominal aorta, but also to convulsions and spasm of voluntary muscles in the manner just explained, and as I have stated in the article Cynoeca. The following is an instance of a very extraordinary case characterized by constant clonic spasm or convulsive movements of the abdominal muscles. The cause was instantly recognised; spirits of turpentine was prescribed, and immense accumulations of fecal matters and many hundreds of lumbrici were evacuated; and then the convulsions of the voluntary muscles ceased. This case was published (see Lond. Med. Repos., vol. xvi., p. 242) soon after its occurrence, and was explained as above. Other illustrations of this form of reflected irritation might here be adduced, but they are unnecessary; others will be noticed hereafter.

37. c. In the third variety, or when the irritation implicates, or is seated in, the cerebro-spinal or sensitive nerves, and is transmitted either to the plexuses of nerves, or to their roots, or through these to the spinal chord, and even to the brain itself, and is reflected thence so as to manifest its effects in the form either of spasm or convulsion, or of pain or altered sensibility of some superficial or distant part or limb, then consciousness is frequently affected, in some way or other, in the course of the process; and, consequently, the functions of the brain are co-ordinately implicated. Still,
the brain may be no farther affected than in being cognizant of either the primary affection, or of its sympathetic-unity. In this case, only one of the functions of the brain is acted upon, and all the other functions are unimpaired and unaffected. But in other instances, the irritation, owing either to its intensity and extension to the cerebro-spinal axis itself, and more especially to the brain, or to the latter organ being implicated in the course which it takes in developing its effects, may so affect the brain as completely to overpower its functions; yet this result rarely takes place without being attributed to convulsions.

38. On a careful examination of disorders characterized by convulsions, spasms, or irregular muscular actions, we shall find that they may be divided into, 1st. Those which are attended by consciousness; and, 2d. Those in which consciousness is suspended. The one, however, may pass into the other, but in comparatively rare instances. In the former of these, the brain retains the power of sensation, and is not incapable of exciting its functions during the paroxysm; in the latter, consciousness is for a time altogether overwhelmed, and is restored, more or less rapidly, after the attack has ceased. It may reasonably be inferred that, in the one, the primary irritation is propagated to the roots of the spinal nerves only, or to the spinal chord, and reflected thence, by the motor nerves, upon the voluntary muscles, the brain being still capable of discharging all its functions, excepting that of controlling the muscular movements; in the other, the irritation extends against the brain, or its circulation, in such a manner as to suspend, or to extinguish consciousness and all its modifications for a time. In many, if not all the latter class of cases, the medulla oblongata seems to be the part more immediately implicated; as soon as the affection extends to it, consciousness and the other subordinate manifestations of mind being suspended for a time. (See article Convulsions, § 42, et seq.)

39. b. Severe or neuralgic pains are often caused by irritation, the presence of which may be in the trunk of the nerve where the affections are thus affected, or in the spinal chord, or in visceral or ganglial nerves passing to the roots of the spinal nerves, or to the spinal chord itself. In this latter case, the primary irritation manifests its effects in distant parts by a reflex sympathy, as already described, and as long since insisted upon in the works already referred to. In all instances of pain from irritation, whether the irritating cause be seated in the nerve itself, or in the chord, or in other or distant nerves, the effect is produced by the latter, of course, the chord or of ganglia, it is expressed chiefly in the ultimate ramifications or smaller branches of nerves. When the pain is seated in the trunk of a nerve, it will generally be found that the sheath or neurilema of such nerve is inflamed, either in the seat of pain or near it. In a case recorded by Dr. Denmark, where extreme pain was felt in the points of the fingers and thumb, the limb was amputated, and a small portion of a ball, which had been detached from it when a small strength against the patient was found imbedded in the fibres of the median nerve. In several cases which have occurred in my practice, as well as in others recorded by authors, irritation and chronic inflammation of the spinal chord or of its membranes have been attended by pain in the members of the extremities, given off from the parts of the chord chiefly affected. Numerous illustrations of this are given in the article Neuralgic Affections. In nearly all cases where the pain is caused by irritation merely, it is intermittent or periodic, or returns only after distant intervals. But when it is produced by inflammation, or by irritation of an intense and permanent kind, it is either continued or remittent only. When it proceeds from the former cause, it is sudden in its accession, intense in grade; sudden in duration, and it generally ceases suddenly. When it arises from the latter cause, it is more gradual in its increase and subsidence, and more permanent than in other circumstances.

40. The cases of pain from irritation, expressed in distant parts by reflected sympathy, furnish some very singular phenomena, which fall more particularly under consideration in other articles. These are characterized chiefly by their seat, intermittency or remittency, and by the nature of the organs, including the vascular system, in the very great majority of instances. Thus, irritation of the stomach or bowels, by accumulated matters, or by acidity, or by flatulence, or by morbid secretions, often causes severe pain in distant and superficial parts, or even in less remote organs. A gentleman was seized suddenly with a violent pain in the heart. I was called to him, and, while I wrote a prescription, I directed him to swallow two or three small pods of Cayenne pepper, which, in a few hours, averted the danger. He instantly afterward exclaimed much flatus, and the pain as instantly ceased. Pains of short duration, but of great severity, are often experienced during disorders of the digestive organs, in various parts of the body far removed from the seat of irritation. Thus, pain at the vertex, or in the temple, or in a limb, or in other parts, is sometimes felt; but it instantly ceases upon the escape of accumulated flatus, or upon the neutralization of acid in the prima via, or after the operation of an emetic or of a brain-bath. (See article Neuralgic Affections.)

41. C. Reactive, Consecutive, and Sympathetic Irritation.—In certain circumstances of the economy, especially those which will be noticed hereafter, irritation gives rise to general vascular reaction, or to various consecutive and sympathetic effects, having a more or less obvious relation to the state and grade of the primary affection. In most instances, the first effect of irritation is displayed in the vessels of the part, in-fever and non-plethoric described above—in either inflammatory action or hemorrhage; but in some cases, the irritating cause, owing to its nature, or to the part irritated, or to the constitution and diathesis of the individual, gives rise to very severe febrile commotion, or to various consecutive phenomena of a painful, or a spasmodic or convulsive kind, without the local vascular disturbance being remarkable; and these effects may be more or less limited in extent, or may change their seats and character. Chemical irritants, and various vegetable and animal poisons, produce these effects, which usually present a very marked
IRRITATION—PATHOLOGICAL RELATIONS OF.

speciality, their characters varying with the cause which produced them, and with the circumstances in which they are developed. Thus, the irritation of the digestive mucous surface, or of some part of it, by worms, by acidity, by catarrh, by noxious ingesta, or by accumulat-
ed sordes, frequently is followed by spasmodic movements of the voluntary muscles, by painful affections of the joints, by neuralgic or rheumatic pains, by gout, and by various visceral affections of a painful or of a functional kind.

42. The presence, also, of morbid elements in the blood, or the accumulation of those materials in it which require to be eliminated, will not only occasion irritation of some portion of the organic nervous system, but more especially of that portion which is supplied to or authenticates the organs destined to the elimination of these materials, but will, at the same time, favour the rapid development of the reactive and sympathetic effects of the more local affection. Gout, erysipelas, and several other diseases, illustrate this principle; indeed, most of the disorders which are seated principally in the excreting organs furnish proofs of the truth of this view. Probably the effects of local irritation are to be traced by means, 1st, of the nervous system of organic and animal life; 2d, of the vascular system and blood; and, 3d, of the excreting viscera as influenced by the organic, nervous, and vascular systems. But the consideration of these, if farther pushed, leads to the following part of the subject, which is very intimately connected with the foregoing general views.

IV. CONSTITUTIONAL EFFECTS OF IRRITATION.—The principal and most serious effects of irritation are ascribable, 1st, to the nature of the irritating cause; 2d, to the state of organic, nervous, or vital power, especially as manifested by the irritability of contractile parts; 3d, to the state of the circulating fluids, particularly as respects the accumulation of excrementitious or noxious materials in the blood; and, 4th, to the functions of eliminating and depurating organs. Of the influence of the cause in determining the evolution, as well as the kind of constitutional conditions produced merely by irritation, sufficient notice will be taken hereafter; and I have already shown (§ 31) that the effects of irritation are, ceteris paribus, more extensively, more rapidly, and more severely propagated throughout the frame, the more the organic nervous or vital power is depressed at the time when the irritating cause is in operation.

44. A. When the circulating fluids are loaded with noxious elements or materials, in consequence either of interrupted excretion or of the absorption of injurious matters, not only is the vascular system the more readily excited thereby to increased action, but the vital power is also greatly impaired at the same time; and hence, although vascular action is augmented, power is diminished, and the sooner altogether exhausted. The impeded or interrupted action of depurating or excreting organs, in first causing a morbid state of the blood, exerts, according to the extent of this organic element, a similar influence in developing, accelerating, and aggravating the constitutional operation of local irritants; and hence the necessity of bringing our means of cure to act upon these organs in all cases of local as well as of constitutional irritation. The influence apparently arising, in connexion with irritation, from a superabundance or deficiency of blood, and from a too rich or a too poor or watery state of this fluid, has been already noticed, particularly with reference to the supervision of inflammations, hemorrhages, and various spasmodic and nervous affections; but these conditions of the vascular system seldom give rise to so rapidly developed, so severe, or so dangerous commotions of the whole economy, as when the blood is loaded with excrementitious materials, and when important emaciations are interrupted or impeded in their functions. It may be, therefore, inferred, as a pathological axiom, that other circumstances being the same, the constitutional effects of local irritants will vary with, and be proportionate to, especially in the rapidity of their development and in the severity and acuteness of their characters, the grades of vital power and of vascular purity, and the states of the several emaciations. In proportion as power is reduced, and the blood is impure or changed from its healthy state, so the brain becomes less abounded; the soft solids are contaminated, the vital cohesion of the tissues weakened, and the depurating organs impeded; effusions of serum, sero-sanguineous exudations, hemorrhages, and various structural changes ultimately supervening, with more or less rapidity. Erysipelas, local irritants giving rise to diffusive inflammation of the cellular tissue, wounds or injuries, and punctures followed by severe disturbance, and many acute affections consequent upon irritating and morbid poisons, furnish sufficient illustration of these inferences.

45. VI. OF THE CONTINUITY, PERIODICITY, DURATION, AND TERMINATIONS OF THE EFFECTS OF IRRITATION.—A. The effects of irritation are seldom continued, or of equal severity throughout, unless they be aggravated by morbid conditions of the blood, or by impeded action of the emaciations. In such cases they may be progressively acute or severe, until they terminate fatally, without any approvable intermission or even opposition of the morbid constitution. The blood may also be more or less contaminated, particularly by the absorption into it of morbid secretions, and yet the effects will still assume a periodic or remittent form, as in cases of hectic fever; but very generally the constitutional effects of irritation are continued when the blood is much contaminated either by absorbed matters or by uneliminated elements, as shown by most of the forms of erysipelas, by the consequences of punctured, poisoned, or contaminated wounds, and by numerous irritating causes acting locally in these states of the vascular system.

46. B. The effects of irritation, whether they be spasmodic, or neuralgic, or painful, or constitutional, are most commonly periodic, or recur after intervals, or become aggravated by paroxysms, if they do not cease altogether for a time. The recurrence or aggravation of these effects generally observes no regular periods, unless intermittent and remittent fevers be considered as constitutional manifestations of irritation of the organic or ganglial nervous system, in which point of view, indeed, I have chiefly contemplated them in their more sim-
Irritation—in Relation to its Causes

As long as irritation extends no farther than the nervous systems, and while the exercising organs and vascular system and blood are not greatly disturbed, it generally thus manifests itself more remarkably at one time than another. In many cases, the irritation seems to proceed or to exist in a latent form, and the irritating cause seems to have ceased to produce any results after its more immediate action, until some adventitious circumstance occurs, or some change takes place in the states of organic nervous or vital power, or of the exercising viscera, favorable to the development of its effects; and these effects may either increase progressively or recur more frequently, or they may soon cease altogether, owing either to exhaustion or to the subsidence of the primary morbid condition.

47. In cases of neuralgic pains, the effects of irritation manifested in distant parts, as above shown, by either a direct or reflex sympathy, as well as in cases of spasmodic or convulsive movements similarly produced, we observe certain phenomena or circumstances of an important and practical kind: 1st. That these attacks are immediately, severe, and continued, in proportion to the intensity of the irritation, or the grade of constitutional or vital power; 2d. That they are favoured and aggravated by whatever lowers the organic nervous energy and vital resistance, the intervals between them becoming shorter or less marked, and the seizures longer or more frequent the more this power is reduced; 3d. That these attacks are similarly affected by impaired excretion and evacuation, and by impure or morbid states of the blood; and, 4th. That they are influenced in the same way by mental depression, and by directing the mind either frequently or for a lengthened period to them.

48. C. As to the cause of the periodicity, or of the recurrence of the effects of irritation, no farther or more satisfactory information can be given than by assigning this character to a law of the animal economy, which is observed as long as these effects do not extend much beyond the nervous systems, or implicate the more important emunctories and the blood and vascular system. If we proceed further in our research, we can infer only that all causes exciting or irritating the source of irritability and the sentient system, produce their effects on sensibility and on muscular movements in a more or less remittent or paroxysmal manner, the intermissions being complete and prolonged in proportion to the slightness of the cause relatively to the susceptibility of the nervous system and state of vital power. Even the most violent of painful and morbid diseases, as neuralgia and tetanus, are characterized by exacerbations during the attack; and these exacerbations exhaust, for a time, the sensibility and irritability, which, however, are quickly restored under the influence of the causes which continue to excite them; or, in other words, irritation being once excited in any part of the source of irritability or of the sentient system, explodes itself in fits or shocks on those parts most immediately affected, and is propagated with these sources; and when the cause of irritation continues in action, or when the irritation is intense, although the cause which excited it may have been removed, the effects may continue until the vital energies are exhausted, or may even increase with the vital exhaustion, until life is extinguished, unless some powerful agent be employed capable of fortifying the nervous power and vital resistance, and thereby enabling them to overcome the most immediate impression which has been produced, or to resist the operation of the causes which are present, until the parts become accustomed to their influence.

49. D. The duration of irritation depends chiefly upon the same circumstances as have just been shown to influence the character or type of its effects (§ 45): these circumstances, however, tend more especially to render the disease more acute, and of shorter duration than it would otherwise prove. In general, irritation is prolonged in proportion to its slightness relatively to the degree of vital or constitutional power; and it may continue or recur for an indefinite period, as long as vascular action and the states of the blood, and of the emunctories, are not very materially affected by it. As these become deranged or remarkably diseased, so the duration of the resulting malady is equally short; and this is especially the case when muscular contractility is either intimately excited or very greatly impaired. Tetanus, rabies, poisoned wounds, &c., are illustrations of the short duration of the effects of irritation when its action is energetic, and when its consequences are extensive in respect of the nervous, vascular, and muscular systems.

50. E. The terminations of irritation have been partly noticed (§ 23) when remarking the effects or consequences of it upon the vascular and muscular systems, and upon the secretions and emunctories. The cases of irritation of the most advanced stage of its development and its termination; but still, irritation may arise and subsist, or terminate in health, without any of its more palpable consequences or strictly structural lesions having been produced, sensibility and contractility having been only temporarily disturbed. It may terminate in death in a very short time, owing to the intensity of its action, or to its violence, as expressed in the sensibility or on the muscular and vascular systems, and previously to any very marked effect upon the organization, although generally the secreting and excreting functions, and the changes in the blood requisite to the continuance of life, are either impaired or arrested before death is occasioned. Irritation may also produce various lesions, already alluded to (§ 27-29), these lesions either superseding, extinguishing, or merely masking the original mischief; or they may increase along both it and its effects. The irritation becomes fatal, this result is owing more to the changes, often numerous and consecutive, produced by it, than to the violence of this state, as expressed merely on the sensibility and irritability of the frame, although the changes in these latter properties may either altogether, or only partly, produce this last result.

51. III. Of the Influence of the Agents of Causes of Irritation.—I. Of predisposition to irritation.—An increased susceptibility of irritation may arise from a great variety of circumstances. The influence, however, of several of these is
IRRITATION—In Relation to its Causes.

not satisfactorily established, or, rather, hardly admits of proof. It appears very probable that the usual causes of irritation act more readily, and with greater intensity, (a) On the irritable, nervous, and sanguineous, than on the phlegmatic, bilious, or melancholic. (b) The morbidly affected, and (c) and soli-
diagnosis; (b) The serofulous and gouty diathesis, and the delicate and enfeebled consti-
tution, than on the sound and robust; (c) On the young than on the old, and more particularly
on infants and children; (d) On the female than on the male sex. Besides these causes of
predisposition, others may be enumerated, as hereditary or original constitution; unwhole-
some diet and insufficient food; modes of liv-
ing calculated to weaken and to impede the
gastro-intestinal, assimilative, and excretory functions; confinement in-doors, insufficient exercise, sed-
centary occupations, and deficient ventilation.

All the depressing passions and emotions; soli-
tary confinement, suppressed feelings, and pri-
vation of light, sunshine, and fresh air; debility and pre-existing disorder, more particularly
torpor of the bowels, and of the excreting organs
generally; the superabundance of excremental
matters in the blood, or the absorption into it
of these, and either too great fulness or intense de-
ness or extreme deficiency of the blood, or vital
depression and vascular plethora, or inanition,
or contamination, either individually or vari-
ously conjoint, favour the operation of the
more immediate causes or agents of irritation
on the frame.

52. ii. The Exciting Causes.—The operation
and nature of these, conjointly with the state
of predisposition, influence and determine the
form and character of irritation.—1. The nature
and amount of external injury, especially in and
connexion with the shock sustained by the econo-
my on the infliction of it, often produce irrita-
tion of a serious kind, both locally and constitu-
tionally; and the particular nature and relations
of this effect are often misunderstood and
unsatisfactorily treated. Among these injuries,
surgical operations may be classed. The na-
ture and character of the irritation also vary
much with the nature of the tissue or part pri-
marily disturbed; and the state of nutrition and
laceration of a tendon, or of an aponeurotic ex-
pansion, will more readily induce tume spasm
or tetanus than neuralgia; and the spasm will
more readily be produced in a person preposi-
ted by a combination of circumstances; by an
irritable or nervous temperament; by depres-
sion of organic nerves and vital power; by accu-
mulations of morbid secretions in the bow-
els; and by the depressing passions, than in a
healthy individual, or in a body, lodged either
between the fibrils of a muscle, or within its
sheath, may so alter the sensibility of its
sensitive fibrils as to occasion acute pain in
their ramifications and terminations, even with-
out affecting the motor nerves, or affecting
them only slightly and occasionally. In many
external injuries the cerebro-spinal nerves may
entirely escape, and yet the extent of mischief
and the shock to the system may be great. In
such cases, the other structures may be serious-
lly injured, and especially the nervous nerves:
these latter affect the circulation in the vessels
of the injured part, and consequentially the vas-
cular system generally; and thus extreme suf-
ferring, shock to the constitution, and vascular
reaction—unless the vital powers are entirely
overwhelmed by the amount of injury and the
attendant shock, so as to prevent reaction—
are successively produced. In perusing the
numerous instances of surgical operations de-
tailed, the physiological pathologist will readily recognise, in many of the phenomena attending these cases, the effects
of irritation caused by the operation. A man
is operated upon for axillary or subclavian an-
eriusm, and the ligature placed upon the sub-
clavian artery necessarily produces not only a
shock to the constitution, but also irritation as
the shock subsides, owing chiefly to the cir-
cumstance of the organic nerves surrounding
the vessel in a closely reticulatedplexus being
enclosed, strangled, or irritated by the liga-
ture. Hence the oppressed breathing, general
coldness, and sinking of the vital powers, fol-
lowed by febril commotion and various painful
spasmodic and sympathetic affections, accord-
ing to the peculiar circumstances of the case,
so frequently consequent upon such operations.

53. b. Numerous mechanical and chemical ir-
ritants produce not only great local, but also,
consecutively, much constitutional irritation.
These, however, are generally much more
serious than by disordering or inflaming the parts
to which they are applied, unless they are so
energetic as to disorganize the structure, as
concentrated acids, alkalis, &c. Much of the
local and constitutional irritation produced by
these, unless they are thus energetic, or are
brought in contact with an extensive surface,
is owing to the states of the system, and espe-
cially of the organic functions—deficient vital
power, impure states of the circulating fluids,
and impaired secretion and excretion, particu-
larly favouring the effects of these agents.

54. C. Many substances combine, with much
local irritation, a narcotic or alterative effect
upon the nervous and vital properties.—a.
These acro-narcotics exert a decidedly poison-
ous effect, characterized not merely by local
and general irritation, but also by a specific
condition of the vital functions. There are
both a local irritation or inflammation produced
by them, and a change in the states of vital
power, of irritability, and of secretion and excres-
tion, having a special reference to the agent or
cause. Most of these substances are derived
from the mineral and vegetable kingdoms, and
constitute, owing to their peculiar modes of
action, the principal part of our means of curing
disease, when judiciously employed.

55. b. Numerous animal substances occasion
either local or general irritation, or both, or
combine with this a contaminating or unin-
formative inflammation. These, however, are
very powerfully irritating, and when locally
acting, as a part of the cure of disease, should
be employed only under the direction of a
physician. These animal matters act principally
in the first of these modes, yet partly, also, as a local, and,
through the medium of the blood and vascular
system, as a constitutional irritant. The virus
of rabies affects chiefly the nervous systems, irritating, first, the part inoculated with it, and, consecutively, the organic nervous functions, and, lastly, the cerebro-spinal actions. The venom of serpents and insects both dissolves the vital cohesion of the tissues to which it is applied, contaminates them and the fluids, and remarkably depresses the vital manifestations.

56. Acid or excrementitious matters passed into, or accumulated in the blood, are more frequent causes of constitutional commotion or irritative fever than is generally supposed. Various secretions and excretions, when accumulated and imperfectly absorbed, render the blood impure (see art. Absorption, § 15); others, when interrupted or suppressed, are followed by a redundancy in the blood of the materials forming them, which materials are the causes of irritative fever, of excessive action and greatly depressed vital power. *Urineous* fever, or the constitutional commotion occasional by suppressed or interrupted secretion and excretion of urine, is one of the forms of irritative fever and constitutional commotion, especially excrementitious or morbid matters in the blood.

57. The passage, also, of morbid secretions into the circulation is often productive of the worst forms of constitutional irritation. If these substances pass gradually, so that their elimination from the blood is as rapid as their introduction into it, the consequent irritative fever is comparatively slight, and generally assumes a hectic or remittent form; but when it passes more abundantly and rapidly, as in cases of phlebitis and of diffusive infection of the cellular tissue, the constitutional disturbance is very much more serious and acute, and very closely resembles the worst forms of putro-adynamic fever. In lying-in hospitals, where the vital powers are reduced, first, by the shock attending parturition, and, secondly, by the impure air of the ward, and when, in consequence of these circumstances, the uterus contracts imperfectly, or allows a considerable quantity of the bloody sanguinare matter to accumulate upon the inner surface of the uterus, and by the veins to the circulation, and irritative fever or constitutional irritation of the worst and most rapidly fatal form is soon developed. In many of these cases, as I have proved by repeated observation and post-mortem research, the embolism or absorption of the matter from the cavity of the uterus, and the consequent contamination of the blood, takes place without producing uterine phlebitis, or, at least, without occasioning that form of phlebitis which is attended by the production of coagulable lymph in the veins (see *Veins, Inflamm. of*); while in others the uterine and spermatic veins are inflamed, either primarily or coetaneously, owing to the irritation of the matters retained in the uterus at the mouths of the veins or sinuses left exposed by the separation of the placenta, or as they pass along the veins, during the process of imbibition. The most adynamic and rapidly fatal cases are of the former description, the more inflammatory and prolonged instances are of the latter; but this important subject is fully discussed in the article on *Puerperal Diseases and Fevers*, where the results of long and extensive experience are given. The rapid absorption of fluid diffused into the cellular tissue, as in *pleiogamia dolens, adematous erysipelas, diffusive inflammation of the cellular tissue*, and in cases of *non-encysted abscesses*, is generally followed by constitutional irritation of a most remarkable kind, vascular action being excessive, but devoid of power or tone, and all the vital and nervous functions being remarkably depressed. In a case of *pleiogamia dolens* of both thighs, under my care in 1832, the swellings very rapidly subsided, but were soon followed by all the symptoms of adynamic or typhoid fever, requiring the free use of embolism, antiseptics, which produced a most beneficial effect and rapid recovery.

58. *All the animal poisons, and all the excretions produced from dead and living organized bodies, seem to act first as local, and more or less rapidly as constitutional irritants. The most remarkable of these is the virus or fluid sometimes inoculated when examining recently-dead bodies. This poison produces excessive irritation of the nervous systems, locally and constitutionally, with extreme terminal weakness, and rapidity of the heart's action, &c., soon followed by fatal exhaustion. But, while these animal or morbid poisons irritate the more or less the organic nervous and vascular systems, they likewise depress their vital manifestations and contaminate the blood and secretions. They act as a kind of leaven which infects the whole economy, and imparts to it the power of developing a poison, like itself in all respects, capable of producing the same effects, and thereby perpetuating itself. (See arts. Infection; Poisons, Animal, &c.)

59. Numerous substances irritate the system when received into the stomach or bowels, or passed into the circulation, each producing an effect having a strict reference to its nature or peculiar properties, and to the quantity of it taken or introduced into the blood. Indeed, the operation of a large proportion of medicines depends upon this specific influence, as when, however, by a variety of circumstances, duly considered and taken advantage of by the observer and experienced physician. In cases of irritation from these causes, the local and constitutional effects vary with the tissue or viscus upon which they individually act, with their absorption or non-absorption into the circulation, with the quantity of the substance employed, and with their specific influences on the different connectories. Substances which are absorbed, or which otherwise pass into the blood, exert, according to their nature or peculiar properties, more or less of irritation of the vascular system, and of the organs by which they are excreted from the blood, modifying, at the same time, the functions of the mucous and cutaneous surfaces, and the states of nervous influence. Owing to these circumstances, these agents produce more or less constitutional commotion, or irritative fever, unless their influence is so slight as is limited to some excretory organ or surface.

60. *The sensations, when acutely excited, are often causes of irritation, more especially of those parts of the cerebro-spinal nervous system with which they are in the most intimate correspondence. Thus, inordinate excitement or irritation of the organs of sense is often followed by inflammatory excitement of the*
IRRITATION—TREATMENT OF.

brain, or of its membranes; and of the nerves of sensation in the extremities, or in the general surface, by convulsions, convulsive sensations in occasionally exerts a similar influence, or reacts upon and augments the primary irritation producing it. Acutely excited sensation may occasion, by either a direct or reflex sympathy, morbid sensations in distant parts, or spasmodic or convulsive movements, or, by exciting the vascular system or impairing the excreting functions, constitutional disturbance of a more or less severe nature. Indeed, this cause, particularly in connection with the excitement of a pleasurable feeling, as in sexual irritation, is a much more common source of the diseases of irritation, or, at least, of those which are thus characterized at their commencement, than is generally supposed; and it is almost equally prevalent and mischievous in both sexes. Its consequences are manifested both by direct and reflex sympathy, giving rise to disordered function, morbid sensation, disordered or uncontrollable muscular movements, and ultimately to central nervous disease. For the elucidation of the mischief, we shall detect the effects, first, in the weakness of the various digestive functions, through the medium of the organic nervous system; next, in the cerebro-spinal nervous system, as evinced by morbid sensibility of the spinal nerves and weakness of the mental faculties, or by affections of the voluntary and involuntary muscles, or by convulsions: and, lastly, in the augmented disorder of all these, in disease of the vascular system, in deficiency and poverty of the blood, and in various nervous, cachectic, and even structural changes, terminating in some instances in death.

61. h. Various moral emotions and intellectual powers, when inordinately excited or exerted, and especially the malevolent passions, anxiety, and some of the depressing feelings, excite more or less of irritation, disturb the circulation in the brain, and disorder the actions of the heart. In addition to this, in a uniform and regular manner in respect of the nervous system, they may also produce violent constitutional commotion, and derange all the secreting, assimilating, and excreting functions, this latter effect increasing still farther the vascular or febril disturbance. The mental emotion may even irritate particular organs, according to its nature, as the heart, the urinary, and genital organs; and the physical effect may in its turn be a source of irritation to other parts. The mental emotion, also, may be of so violent a nature as to give rise to convulsions, or altered sensibility of remote parts, previously to vascular or other disorder of a general kind having been produced.

62. In estimating the influence of moral or physical causes in exciting local or general irritation, too great importance should never be attached to one, or even two causes only, without endeavouring to detect others, or compi-
sing local ones, to predisposing circumstances in our pathological estimate. Every influence or occasion ought to be recognised and duly weigh-
ed; for, upon the evidence we obtain of each, must a principal part of our indications of cure be founded.

63. IV. Treatment of Irritation.—The indications, as well as the means of cure, or of alleviation, of both local and general irritation, must entirely depend upon the knowledge that is obtained of the causes, of their individual and conjoint influence in producing the existing effect, and of the extent of functional or structural disease which has already resulted. It is manifest, from these and other considerations, that the indications and means of cure of irritation must, in order to be appropriate and beneficial, have strict reference to the several predisposing and exciting causes, and to the existing morbid conditions of each case. However closely observant, however experienced the writer may be, he cannot state these so as to apply them to every case or class of cases they are daily occurring in practice. He can only assign those which are the most important and the most applicable to the more usual occurrences, leaving the reader to modify them, or even to add to them, according to the emergencies or the variations presented by particular instances.

64. There is no class of diseases in which the fundamental principle in therapeutics, of avoiding the cause, is more applicable than in cases of irritation; for the causes, is so necessary to be observed, or so difficult to be practised, as in this very important and numerous class; and none which requires greater physiological knowledge, or a more sagacious recognition of healthy and morbid sympathies than this does. Thus impressed, I have been led into a fuller exposition of the pathological relations and causes of irritation than may appear necessary to many. It seems, however, that this procedure was not the less necessary that it was difficult, and either avoided by nearly all preceding writers, or treated of in a most empirical manner, or, at least, with a less strict reference to the early, the intimate, and the consecutive changes characterizing the diseased condition in question—with a less regard to the actual process of morbid phenomena than the existing state of physiological knowledge warranted. In entering, therefore, upon the consideration of the cause of mental and constitutional irritation, it is necessary that we should ascertain fully, and to estimate justly, the predisposing and exciting causes, with the view of removing or counteracting them, but also to trace the origin, the various relations, and the obvious and probable effects of this condition, and to consider them in connexion with the states of vascular action and purity, and of vital power or resistance, and with the sympathies existing between distinct organs and distant parts.

65. 1. Treatment of Irritation with reference to removing, subduing, and counteracting the Causes.—Many of the causes admit of removal, others can be counteracted merely; and where the former cannot be accomplished, the latter must be attempted. In many cases, certain only of the causes may be removed, and the others may be either counteracted or subdued—a circumstance which should not be overlooked in framing our plan of cure. The first part of this indication, requiring the predisposing circumstances to demand farther notice. In order to subdue or to counteract irritation, the means should be applied with strict reference to the nature of the causes, to the state of the economy, and to the seat and state of irritation. The means which are to be thus employed may be divided into two classes: 1st. Those which are strictly local, or topical; and, 2d Those which act more or less
IRRITATION—TREATMENT OF.

711

constititionally, or upon one or more of the general systems of the frame.

66. A. Of the means applicable to the seat of Irritation. These consist chiefly of emollients, analgesics, or sedatives, and narcotics; in some instances of refrigerants, of stimulants or irritants, and of convulsants. The former of these admit of being variously combined. It is in comparatively few cases of irritation that these means can be applied to the part primarily affected; but where this may be done, it should never be neglected.—a. Under the head emollients may be comprised all the modes of employing substances or structures of a slightly fungous, and warm with humidity; as the use of fomentations, warm vapour, and poultices.—b. Analgesics and narcotics are indicated chiefly in connexion with the former, the particular agent being suggested by the nature of the cause and the seat of affection. This combination exerts a more sedative influence on the local disorder than either would if employed singly. Thus, warm water, vapour, fomentations, or poultices, with laudanum, conium, belladonna, poppies, camphor, and aconite, are generally beneficial emollients used simply. It should not be overlooked, that protection from the action of the air aids many of these in their beneficial operation.—c. Refrigerants are much less efficacious than the foregoing in removing local irritation, although they act, like them, chiefly upon the sensibility of the part; and, in order to be useful, they should be constantly applied. Refrigerants are most beneficial when irritation is about to excite either haemorrhage or inflammation, and they may then especially be conjoined with various astringents and sedatives, as the preparations of lead, of zinc, of opium, &c.

67. d. Stimulants, or even irritants, are sometimes useful in subduing local irritation, but it is often difficult to determine the particular circumstances in which they should be resorted to. When the irritating cause is of a poisonous, septic, infections, or contaminating or specific nature, then stimulants, or even the more powerful irritants, are generally beneficial. Thus, camphor, ammonium, the chlorides, the nitrates of silver, and numerous other vegetable and mineral substances, are often of service when applied to a part irritated by any of these causes. In such cases, the artificial irritant, if sufficiently energetic, supersedes the action of the morbid one, especially if it be employed before the organization of the part and the vital powers have suffered, or before morbid sympathy has been developed; and in these circumstances they may greatly aid the constitutional means of cure. The stimulus, even of dry heat, may be useful in relieving irritation when judiciously employed, or conjoined with other agents. When heat is indicated purely as a stimulant, or even as an antisepsic modus and sedative, these will often be most useful when applied in a dry form. The combination of stimulants with narcotics is sometimes of use, even locally, in many cases of irritation, attended by pain or spasm, and it will be seen in the sequel that this combination is still more beneficial when prescribed internally, or constitutionally. In most cases of irritation manifested chiefly in the nervous systems, this combination is especially indicated, and is often not less efficacious when topically than when constitutionally employed.

69. B. The constitutional or more general treatment of irritation consists chiefly of the use, 1st, of agents calculated to lower or subdue not only the local affection, but also its sympathetic and constitutional effects, by their direct or specific operation; 2d, of such means as will excite irritation in a particular part or viscus, and thereby supersede or reduce the primary affection; 3d, of those medicines which stimulate or impart tone to the nerves and vascular systems, and thereby either subdue the local morbid condition, or enable the constitutional powers to resist it until it subsides, either naturally, or from the disuse of the irritants, or from the influence of local treatment; and, 4th, of remedies which remove injurious materials from the system, which promote the excretions, and preserve the circulating fluids in a state of purity. It is obvious that, in the more severe and intense states of irritation especially, these several means require to be variously conjoined, and to be aided by the topical measures already advised.

70. a. The means most useful in reducing local or sympathetic and constitutional irritation are the usual antiphlogistic remedies; as low diet, abstention, vascular depletions, refrigerants, sedatives, and physical and moral quietude. These are more particularly indicated when irritation affects the sanguine, the plethoric, and the robust, or when it has superinduced a state of sub-inflammation, or of active congeation, or of active haemorrhage, or of simple sanguineous determination to an important viscus. In opposite circumstances, especially in the delirious; in the nervous, melancholic, lymphatic, and irritable temperaments; in persons with a poor, or deficient, or morbid state of the blood; and for those who have long suffered, or who are suffering from depressing influences, the lowering measures now enumerated generally increase the local irritation, and even hasten and augment its sympathetic and constitutional effects. By lowering the constitutional powers, resistance to the extension of the disorder is equally weakened. In cases of this kind, the more restorative measures about to be noticed (§ 76) are required. Where the remedies comprised under this head are indicated, the choice of them must altogether depend upon the causes and nature of the case; but generally they should be cautiously prescribed, and they should
IRRITATION—TREATMENT OF.

be neither repeated nor persisted in, even when indicated, without being combined with narcotics, or with antispasmodics, according as morbid sensibility or spasm may be the consequence of irritation. In cases where want of sleep or mental irritation attends this affection, the state of circulation in the head should receive attention; and if these symptoms are clearly not referable to increased vascular action in this quarter, then narcotics or anodynes, sometimes combined with alkalies, are of great service, and reduce both the local irritation and the nervous affections consequent upon it. In cases of spasm, as well as of morbid sensation, anodynes and narcotics are nearly equally serviceable; but, in the former especially, a combination of them with those stimulants commonly called antispasmodics is productive of great benefit. When these symptoms are violent, particular determination to the brain, antisploegistic and lowering means are generally prejudicial, the opposite measures about to be noticed being the more appropriate. In the circumstances just noticed, a recourse to alkalies or their sub-carbonates, with anodynes, is often of service, particularly when the urine is thick, deposes a sediment, is acid, and when the stools are offensive, and the skin felt.

The irritation artificially produced in an organ or part remote from the primary seat of morbid irritation sometimes supersedes this latter state. The principle of counter-irritation, of vascular derivation, of artificial irritation, &c., has been long recognised in medical practice, has been variously denominated, and various means have been used in carrying the principle into effect. It is, when judiciously prescribed, more serviceable in disorders of irritation than in any other class. The agents employed with this intention may be divided into 1st. Those which irritate internal organs, and are serviceable in consequence, chiefly, of this mode of action; 2d. Those that are applied externally with this intention.—a. Of the former, (a) drastic purgatives are the most commonly used, and sometimes most beneficial. They not only give rise to an amount of irritation occasionally sufficient to supersed the original affection, but they evacuate accumulated morbid secretions or fascets to them—in some cases a frequent or otherwise contributed to cause the disorder. Their good effects may partly, also, be imputed to the vascular determination to the digestive canal, and consequent derivation from the seat of irritation produced by them. It is principally, however, when disorder is seated in parts intimately sympathizing with the intestinal canal that they are the most useful. If it is seated in the nervous centres, or if it affects sensation or muscular motion, cathartics energetically employed afford relief, as shown in the articles on NERVOUS AFFECTIONS, TETANUS, &c.—(b) Emetics are, upon the whole, less serviceable than cathartics; yet they are of much use for irritation of the respiratory organs, especially for hooping-cough, asthma, erysipelas, and for all spasmodic affections of the larynx and bronchial consequent upon irritation of the nerves of these parts. Of cathartics and emetics it may be remarked, that a cautious recourse to them—in some cases a frequent repetition of them—is often necessary to the removal of the irritation produced by morbid secretions accumulated in the gall ducts and bladder, or even in the cells of the colon, or in the e covert.—(c) The more irritative diuretics, as turpentine, caantharides, &c., are sometimes decidedly beneficial in many disorders of irritation; and, according to my experience, they are most so when the irritation gives rise to spasmodic or convulsive actions, as in trismus, convulsions, or the like. They are, however, to be thus useful, should be given so as to produce a marked operation on the urinary passages. I have frequently seen a very manifest improvement of states of these diseases as soon as the urinary organs became irritated.

—(d) Salivation may be considered as one of the modes of internal irritation and derivation, especially when maintained for a considerable period. Mercurial salivation is, however, more appropriate to inflammatory diseases than to disorders depending upon irritation, unless, indeed, the latter tend to the former character, and affect the states of vascular action either generally or locally. Irritation, also, when productive of hemorrhage, is often most successfully combated by mercurial salivation of a slight form, when it may be readily produced, and without having recourse to a too free exhibition of this mineral. In the slightest forms of irritation, especially those affecting parts about the face, mouth, &c., artificial excitement of the salivary glands by pyrethrum or other salounges may be of use.

72. B. External derivation or irritation has always been prescribed for disease; but in recent times it has been resorted to by empirics and impostors, who have employed it injudiciously, and often injuriously. It is appropriate in most cases of irritation, in some form and mod of other; yet much discrimination is necessary to these affecting parts about the face, mouth, &c., artificial excitement of the salivary glands by pyrethrum or other salounges may be of use.

73. a. Epithems of warm flannels, soaked in spirits of turpentine, produce an almost immediate redness and a burning sensation of the part on which they are applied, and are especially beneficial in irritation of internal organs, in painful or spasmodic affections, and particularly when there is risk of inflammatory action or hemorrhage being induced. They may be applied frequently in some cases, and they then usually slightly vesicate or excoriate the surface of the part, the external inflammation...
thus produced soon subsiding, and they often procure a copious perspiration. Stinging by nettles was formerly much used, and is an immediate and often very efficacious mode of external derivation, and is applicable to the cases for which mustard poultices are prescribed. Mustard *podschria*, or mustard *manulavia*, the water being as warm as it may be endured, and mustard poultices, are of service chiefly in cases of slight irritation, and before vascular excitement has been produced, or after it has been in great measure subdued. These means are seldom of much service when vascular excitement is considerable.

74. b. The external irritants which are slow in their operation are beneficial in consequence rather of their permanent influence, and the discharge they occasion, than of the amount of irritation or inflammatory action produced by them. This is especially the case with actions and issues, in all the various forms in which they are made or kept in action. One of the best modes of forming an issue is by applying the decocted bark of mezereon, previously moistened, over the part selected, and by renewed applications daily, or by placing the common issue-pace under the plaster covering the denuded or ulcerated part. When it is desirable to produce a free discharge and much artificial irritation at the same time, then open blisters, large issues, or the antimonial ointment may be prescribed. Croton oil, employed so as to occasion free pustulation, and other applications calculated to excoriate the surface and to give rise to a free discharge from it, as various combinations of concentrated acetic acid and oil of turpentine, or preparations of ammonia, are severally of use when judiciously prescribed and applied, and when aided by appropriate internal means.

75. c. Most of these modes of producing external irritation and derivation from the primary seat of disorder are indicated, either before vascular action has been excited by the primary affection, or after it has been subdued, or in a great measure subdued by suitable treatment. As long as the irrigation is not too much, or as long as the primary irritation may be greater than the amount of external irritation that can be prudently excited, but little benefit will result from the practice, unless the discharge procured by its means assist its influence, or compensate for the deficiency in the amount of irritation. In such instances the artificial irritation is seldom productive of that amount of vascular afflux or determination capable of being decidedly beneficial. When, however, a copious discharge or blisters is produced, and the internal affection will often be removed, if it does not amount to disorganization or serious structural change; but when these changes have taken place, the amount of discharge will often only hasten the unfavourable progress of the malady, and sink the patient. In all such cases it is important to watch carefully the effects of this mode of treatment. When morbid irritation has given rise to increased vascular excitement, external irritation and derivation are seldom successively procured. In these cases they only augment the morbid vascular action, and are prejudicial, or, at least, inefficacious, in proportion to the degree in which the vascular system is excited.

76. c. The remedies which stimulate the nervous energy and impart tone to the vascular system,—a, are generally of service in diseases of irritation when the vascular system is not materially disturbed, or when it is excited to increased action, with a diminution of power, and with evidence of a morbid state of the blood. When irritation has been followed by great frequency of the heart’s action, irritability and muscular power being much impaired, and the pulse soft and open, or expansive, then the more energetic stimulants or tonics, selected with reference to the circumstances of individual cases, and conjoined with means which modify or check the accelerated action of the heart, and counteract morbid changes in the circulating fluids, are generally of the greatest service. They increase the vital resistance to the extension of the sympathetic effects of irritation, and enable the vital energies to overcome the primary morbid condition, or to resist its injurious influence until it subsides under the local or other means of cure, or from other influences. The several preparations of cinchona, or of other tonic barks, quinine, camphor, ammonia, turpentine, aloes, and of the alkaline carbonates, the hydrochloric acid and ether, wine, opium, alcoholic preparations, the turpentine, Cayenne pepper, cajepit oil, &c., and the numerous remedies more particularly mentioned in the Treatment of Typhoid Fevers (§ 530), and of Diffusive Inflammations (§ 236), are more especially indicated in this state of disease.

77. b. When irritation gives rise to extreme pain, to the more violent forms of neuralgia, or to convulsions or spasmodic actions, the most energetic and permanent tonics, variously combined, according to the states of the excreting viscerâ, are also then more beneficial than a lowering treatment; but these remedies should be aided by the most active narcotics, and by suitable local means. In such cases, brisk cathartics, followed by quinine, or the preparations of iron, or of arsenic, camphor, the alkalies, or alkaline carbonates in large doses, ammonia, &c.; and, when aided by opium, or alcohol, or the barks, or the barks mixed with the alkaline carbonates, the hydrochloric acid and ether, wine, opium, alcoholic preparations, the turpentine, Cayenne pepper, cajepit oil, &c., and the numerous remedies more particularly mentioned in the Treatment of Typhoid Fevers (§ 530), and of Diffusive Inflammations (§ 236), are more especially indicated in this state of disease.
of irritation should not be too weakening and sanguineous evacuation should be cautiously practiced, even although local phlethora, or vascular determination to the nervous centres may exist. Local depletions, or small bleedings, counter-irritation and derivation, both internal and external, tonics, anti-spasmodics, narcotics, &c., are more beneficial than other measures. Some years since, a gentleman was sent to me from the country by his medical adviser on account of neuralgia of the occipital nerves; I considered it, from the history of the case, to be due to irritation on a permanent cause of irritation about the basis of the skull. The external derivation, and the other means already advised, were prescribed, and he continued to improve for two or three years. During a visit to town, he was exposed to several sources of disorder, and in the evening he was seized with violent convulsions. The surgeon called to him bled him to a very large amount; and on the following day, when I saw him, his pulse was very quick, irritable, extremely compressible, and the intensity of the proposed excitement, with defect of power. His manner and answers to questions were hurried, quick, and unusual. I expected a return of the seizure, or paralysis, or apoplexy, in the course of a few days; but he continued to improve slightly for some months, when hemiplegia, followed by apoplexy, soon terminating life, took place. Numerous other illustrations of this principle might be adduced if my limits could admit of them.

78. D. Remedies which remove Injurious Matters, promote Excretion, and correct Mortal States of the Blood.—Many of the substances that evacuate excremental irritating matters also exert a salutary derivation, as respects the vascular afflux or determination. The old doctrine, "ubi irritatio ibi fluxus," is correct in all situations, and in every sense, and particularly when the irritant is applied to mucous surfaces, and acts upon excreting glands. During many states of irritation, particularly when the irritant is excited by the intestine, the intensity of the proposed action is materially excited by it, absorption is remarkably active, and morbid secretions accumulated, either in the biliary passages or in the intestines, especially in the cells of the colon and caecum, are more rapidly than in other circumstances conveyed into the circulation, whereby either favouring the production of, or actually producing constitutional disturbance of a serious nature consequent upon the local irritation. The more stomatic, tonic, and alterative purgatives are essentially necessary in such circumstances, particularly combinations of the compound infusions of gentian and senna, with alkaline carbonates; the spirits of turpentine, with or without castor oil; and other medicines which produce a restorative, as well as an evacuant effect. In all instances of impaired excretion, or of excremental accumulations in the circulating fluids, either central or local, particularly when vascular action is excited, the exhibition of stomachic purgatives, and the alternation of the more powerful tonics, are extremely serviceable. In this state of actual disease, the chlorate of potash, chlorides, hydrochloric, or other medicaments, produce a reaction, which in itself is merely irritant, &c.; and, when vascular action is excited, the nitrate of potash, the solution of the acetate of ammonia, and other stimulants, either separately or pre-erably, in conjunction with quinine, or with tonics, infusions or decoctions, or with one another, according to their several compatibilities, will be found most beneficial, provided that the actions of the emunctories be at the same time duly promoted, and morbid accumulations evacuated. In cases where irritation is attended by accumulations of excremental matters in the blood, not only should the bowels be freely acted upon by the means just mentioned, but the kidneys ought to be excited by the more energetic diuretics, as the purgatives, and the more powerful depletories, than for hydro-chloric athers, &c. When local, or even constitutional irritation is attended by deficiency of blood, or by a deficient proportion of hemostatine, then the preparations of iron, with alkaline solutions, as the mistura ferri composta, or the ferri ammonio-chloridum, the ferri potassio-tartras, &c., will be requisite, in addition to the other means which the circumstances of individual cases will suggest.

79. Irritation of the skin and decoctions, either alone, or conjoint with gentle restoratives, or with mild tonics, or with laxatives or aperients, are of the greatest service in the more chronic and slight forms of irritation. The most useful of these are Plummer's pill, either alone or with soup and extract of taraxacum; the hydrargyrum cum creta, similarly prescribed; the liquor potassae, or Brandish's alkaline solution, with any of the concentrated preparations of sarsaparilla, or with taraxacum; and the solution of potash, with the hydroiodate of potash. The sub-borate of soda, either alone or with the bitartrate of potash, or both these with taraxacum, are of service for irritations of the biliary organs. A combination of several of the foregoing medicines with camphor, henbane, belladonna, or hemlock, or with any of the preparations of opium, according to the peculiarities of particular cases, is often beneficial, especially when irritation is attended by increased sensibility. When there is much irritation of the cutaneous surface, the alkalies and their carbonates, camphor, prussic acid, the narcotics just enumerated, with emollients, &c., employed both internally and externally, should never be overlooked.

[In nothing is the skill of the practical physician more clearly manifested than in distinguishing irritation from inflammation, and successfully combating it with appropriate remedies. Dr. B. Travers, in his able work on "Constitutional Irritation," led the way to correct views on this most important subject; and Marshall Hall, in his more recent essay, entitled "Researches on the Effects of Loss of Blood," brought forth facts and observations of the highest practical import, which have been also confirmed by the publications of Drs. Abercrombie, Godwin, and others. With these views, American physicians, who have been very generally acquainted; but yet we have so frequently witnessed erroneous treatment, from incorrect pathology—from mistaking simple irritation for active sthenic inflammation, that we deem it proper to add a few remarks on this subject, supplementary to those of our author. We have found, in a practice of many years, that it is not always easy to discriminate]
in these cases, from the fact that excessive irritability, as maintained by Bouissac, is very often dependent on inflammation, or hyperemia; it may be latent or chronic, and the irritation hence arising will accordingly be successfully combated by antiphlogistic measures, as evacuants, revulsives, and contra-irritants. We do not, however, believe that blood-letting, either general or local, is as beneficial, or as frequently applicable in the treatment of these cases as is generally supposed. We are to bear in mind that the remedy of Mr. T. is but "to influence the susceptibility, and consequent over-activity, are invariably coupled with, and most probably dependant on weak and insufficient powers of constraint and resistance. The same principle which renders a part over-irritable renders it over-active." Medicines are not anti-irritant in proportion to their antiphlogistic effects, and therefore, as Dr. Williams has remarked, where irritation predominates over inflammation, those are to be preferred which act on the nerves as well as on the vascular functions. Physicians, especially those of the younger class, are in danger of regarding pain as necessarily indicative of inflammation, and hence calling for depletory measures; whereas it often is the result of nervous derangement, and calls for soothing and anodyne remedies.

The first rule to be laid down in the management of this affection, which can scarcely be called a specific disease, is to remove the irritating cause. This will generally suffice for the perfect cure of the patient. Thus, emetics are successfully employed to remove irritating matters from the stomach; purgatives from the bowels; acidity relieved by an alkali; the irritation of dentition by lancing the gums; of worms, by anthelmintics; of a deep-seated abscess, by the escape of the purulent matter; of hernia, by a division of the stricture; of stone in the bladder, by its removal, &c. But, unfortunately, as every practitioner must have observed, irritation, when once established, propagates itself, so as to become independent of its first cause, and we here have a complication more difficult to manage. If now we are ignorant of, or cannot reach the cause, we must endeavour to diminish the irritability of the system, which is to be done by corroborating measures, as pure air, exercise, cold and shower bath; vegetable and mineral tonics, with anodynes and other soothing remedies. As irritation results from a preponderance of nervous sensibility, we must reduce those agencies, which increase the tone and strength to the muscular system will undoubtedly prove the most efficient remedies for its removal. As a late writer has observed, under the influence of tonics, disposition and power to act will go together, and within due bounds produce the harmonious balance of even health. Whether certain of them possess a specifically sedative property towards the nervous system, or whether this is their secondary effect, after their tonic and astrignent influence on the vessels, is beyond our means of decision; but the fact is not less ascertainable than important, that the continued use of nitrate of silver or sulphate of copper will cure the epileptic convulsions independent of organic causes, and often diminish them where the cause is irremovable, by lowering in the nerves their susceptibility to its impressions. Thus, likewise, bark, carbonate of iron, arsenic, sulphate of zinc, or sub-urate of bismuth sometimes remove the painful or spasmodic irritations of tic douloureux, hemiarcia, sciatica, chorea, and gasterodyne, which the most powerful anodynes, antispasmodics, and counter-irritants fail to effect. The stomach and intestinal canal, also, under the influence of a bitter tonic, will often lose various signs of irritation, which, however, they may occasionally be accompanied by slight excreta. These fancied inflammations, owe their being to weakness and want of tone. The cold shower or plunge bath, or cold ablation, is another efficacious tonic; the more eligible, often, because, without loading the system with medicine, it rouses it to the exertion of its own powers in a vigorous vascular reaction, under the habit of which nervous mobility is physically forgotten, and ceases.

It is highly necessary that practitioners should be cautioned against resorting to antiphlogistics and counter-irritants in all cases, as temporary relief sometimes follows their employment. When local pain returns after bleeding, it will often yield to fomentations and morphia, or hyoscyamus internally, when the repetition of the bleeding would entirely fail in procuring relief. We believe, with Williams, that there are frequent pseudo-inflammations arising in irrigable states of the system which are best relieved by sedatives, a judicious supply of nourishment, and an exclusion of all exciting or disturbing influences. The local irritation occasionally with diseases following excessive evacuations which put on the semblance of violent pleurisy, pericarditis, arachnitis, or hydrocephalus, and which may be completely subdued by hyoscyamus or opium, with a sustaining nourishment, such as sago, arrow-root, or jelly, with small quantities of brandy or wine. The state of the circulation, as indicated by the pulse, is here to be our guide; and the local pains, palpitations, disturbances of the bowels, we hope, will or may in the head, should be viewed as partial reactions, to be subdued by opium or hyoscyamus, rather than by the lancet and evacuants."

* * * [In illustration of some of the preceding views, we quote the following case from the New-York Journal of Medicine, vol. iv., p. 300, by Luther Ticknor, M.D., of Salisbury, Connecticut. Mrs. A., about the middle of November, 1813, in washing some small articles of dress, pierced the end of the middle finger with the head of a threaded needle, which she supposed penetrated the ball of the finger to the depth of one third to one half inch. The first sensation was that of numbness instantly following the infliction, extending up the arm to the axilla and front part of the shoulder. This was succeeded immediately by numbness concentrated on the tip of the other hand, and next with faintness and vertigo, which brought her pretty soon to her bed. Some mitigation of these symptoms was produced by handkerchiefs, so that I did not see her until severe pain and fibrillating symptoms, oppression respiration and gastric sickening, excited some alarm for her safety, about forty-eight hours after the injury. I found her in a faint, anxious breathing, having a discordant, obscure pulse, a moist surface, with temperature but little increased, almost constant chilliness, and what the patient called faintness, which extended itself to the circumscription of the shoulder; certain points on this tumescence were excessively painful and tender to the touch. These symptoms changed their location from time to time, so as to encourage the hope that some improvement was going forward."

* * * [The local treatment consisted of dry-cupping, esparations, fomentations, amodyne poultices, &c., with very little apparent benefit; and yet anodyne
80. F. The diet and regimen of diseases of irritation require much attention. While vascular action continues excited, the diet should be mucilaginous, or farinaceous, slight and cooling, and suited to the powers of digestion and assimilation. If, however, the vascular system be not materially affected, and the functions of the stomach are not much impaired, a small proportion of light animal food may be allowed. 

In the more serious states of constitutional irritation, especially where there are marked asthenia, and a disposition to changes in the state of the blood, wine, and even alcoholic stimulants are often necessary, in aid of the means above recommended, in order to limit and prevent the extension of the mischief, by exciting the several vital endowments. In these cases, the diet should consist chiefly of such articles as are desired or relished by the patient, as being the most likely to be digested without disordering the system.

81. Change of air: residence in a pure air, exercise taken regularly and short of fatigue, travelling, the use of those mineral waters, both internally and externally, that contain the alkaline salts and carbonic acid; the waters of Bath, Ems, &c., are usually beneficial; but mineral springs should be prescribed with a strict reference to the specific forms of these complaints, after a due experience of their operation, and without being influenced by prejudices, by fashion, by guide-books, or by local interests. In many diseases of irritation the factitious mineral waters prepared at Brighton have proved of great benefit, even in the range of my own experience, having been specially prescribed there since 1821. In most cases, however, such discrimination is requisite to the procuring all the benefits they are calculated to afford. In most instances, the milder waters, such as those of Ems, of Saratoga, or of Salsbrunn, should be first prescribed; and subsequently the more tonic waters of Kissengen, Marienburg, and Carlisbad, or of Eger, Pyrmont, or Spa, having recourse occasionally to the waters of Seidschutz or Pulna, when the former have been found to be beneficial, should be tried in consultation impaired or obstructed. Several of these waters also, may be procured in London; and at Brighton their effects may be aided, in the cases that require it, by warm salt-water bathing.

—G. Verzeich. De Arteriaern et Venearum Vs irritabil. easque in Vesis Excessus, et indice ornatae Saeculorum Direc- tionum ab omn. Groning, 1766. —Baldinger, De Irritabili-
common state; still it sometimes appears as a _popular eruption_, and as such Dr. Paget has arranged it. I shall here consider the disease as _commonly vesicular_, and the modifications or varieties presented by it as accidental or contingent upon the peculiarities or circumstances of individual cases.

1. **Description**—This eruption generally appears first on the hands, between the fingers, on the wrists, on the flexures of the joints, on the abdomen, and on the insides of the limbs. It is most commonly confined to a surface of no very great extent; and, in some cases, consists only of a few vesicles dispersed between the fingers and over the wrists; but it may affect, in addition to other modifications, the palms of the hands, the soles of the feet, the face, and even the hair and scalp. It is essentially a contagious disease, and is neither epidemic nor endemic.

4. 1st. _Of its common vesicular form._—The eruption generally takes place in children at the end of four or five days from the period of contagion; but this is uncertain, for in weak or delicate children it may be delayed beyond this period, while, in the plerotic and sanguine, it appears even earlier. It seldom occurs in adults before eight or ten days have elapsed, in spring and summer, or before fourteen or twenty days in winter. It is longer in appearing in the aged than in the young or middle-aged, and it attacks in preference the situations where the skin is most delicate.

5. The eruption commences with itching, at first slight, of the parts which have been exposed to contagion. The itching is increased through the night by the warmth of the bed, by indulgence in stimulating food, beverages, and spices, and by whatever heats or determines the blood to the surface. A number of small points or spots, very slightly elevated above the surface, now appear, and present a pale rosy colour, with small acuminated vesicles on each point or spot. If the vesicles be few, they occasion but little pruritus, and preserve longer their primitive form; but if they be numerous, the skin between each participates in the irritation, and the itching becomes urgent. The vesicles are then usually torn by the nails, and allow their viscid serous contents to escape, which irritated, a little by the small, thin, orcaes, slightly adherent to the skin. If the scratching has been violent, the scabs are black, and resemble those of prurigo.

6. ii. **Varieties or Modifications**—Owing to peculiarity of constitution, to the amount of inflammatory action attending the eruption, to the depth to which it extends in the tissues composing the skin, and to the existing state of health of the patient, itch presents certain modifications which have been arranged into species by Willan and Bateman.—A. The variety denominated by them the _Scabes Papulariformis_, or _rank itch_, is that in which the eruption is more popular and inflamed at the base, but still presents a transparent apex, indicating its vesicular character. When much irritated, a 3rd or 4th day, the fluid contained in them changing to a purulent matter.

7. B. The _Scabes Lymphatica_, or _watery itch_, differs from the foregoing chiefly in the absence of the popular character and of inflammatory redness, and in the larger size of the vesicles. When the vesicles are ruptured by scratching them, most excoriations often form, and, after a time, dark scabs. This variety usually presents three stages, viz., the entire vesicle, the excoriation consequent on its rupture, and the scab covering the excoriated part. It is not so frequently observed as the former variety on the trunk, but is most commonly found collected on the lower parts of the extremities, as the fingers, wrists, backs of the hands, and sometimes on the feet and toes.

8. C. _Scabes Cauteris_, is a modification which appears more distinct than the other varieties. The round pustules into which scabies, in a few instances, forms itself, resemble the pustules of smallpox. They occur chiefly in children and young persons who have been living on a heating diet, and who have been inattentive to cleanliness. These pustules are distinct, with an inflamed base, and considerably elevated; they maturate and break after a few days, having then often attained a diameter of two or three lines. The itching occasioned by them is attended by more tension and smarting than that of the other varieties. After they break they often leave a cracked excoriation or ulceration behind, or small fissures between the scabs, the stiffness and heat of which cause considerable uneasiness. The pustules rarely appear on the trunk, but usually on the hands, between the fingers, or near their flexures, more rarely on the feet and at the bends of the arms. They are largest on the hands and between the knuckles, especially between the index finger and thumb; they often coalesce, and in these situations more especially, slight fissures or cracks form in the concretions covering the excoriations or scabs of pustulation. This variety, in pleritic children, is sometimes attended by slight febrile commotion.

9. D. The _Scabes Cachectica_, or _ecbymatous itch_ of Willan, is not, strictly, a variety, but merely an imprese modification, produced by debility and general cachectis, in consequence of intermencence, poor living, and unhealthy food, the skin and vesicles assume a dark, almost scabby, and urinizing character. As may be expected, from the circumstances in which it occurs, it is the most aggravated state of the eruption: and is more frequently than the true varieties, either form of which it may assume, complicated with other eruptions, particularly with _lichen, prurigo, ecbyma_, and _impetigo_. When itch occurs in the dark races, it generally presents this state, and is severe and obstinate—is rank and extensive, spreading rapidly over the body. As thus met with. it has been noticed by Bossy, and by Sauvages, who called it _Scabes Indica_.

10. E. The complications of itch often render the diagnosis difficult. _Ecbyma_ is sometimes associated with it, and more rarely _eczema_; but is chiefly cured by the use of stimulating washes or ointments. Scabies is most frequently complicated with _papular eruptions_, particularly with _lichen_ in the young, and when the vesicles are generally or abundantly disseminated. _Prurigo_ is often associated with it in the more prolonged cases. _Boils_ occasionally appear in the more severe instances. These com-
lications, as well as a pustular state of the eruption, are favoured by living on salt, acidic, and fat meats, and by acidic applications to the surface. Disorders of the digestive organs sometimes prevent the full evolution of itch; or persons subject to these disorders, who have caught this affection, often readily recover from it, for such disorders are aggravated by errors of diet. *Scrophula* does not materially modify scabies. In very unhealthy or cachectic subjects it sometimes assumes a livid hue; and, when its vesicles are crowded in any part, they are occasionally associated with *echyma caecuticum*.

11. *F.* The duration of this eruption depends upon treatment. If left to itself it never gets well, and may even continue through life when thus neglected. In southern climates, and in spring and summer, and in young plethoric, and robust persons, the vesicles of itch run rapidly through their successive changes, when not broken by scratching; but their progress is much slower in the north, in winter and autumn, and in the bilious, melancholic, and cachectic, and in the aged and infirm—in whom, also, it is longer in appearing after infection. When it is judiciously treated, and with strict attention to cleanliness, and to the state of the linen and clothes, it may be cured, in very recent cases, in five or six days, and in the worst cases in from ten to fourteen days to three weeks; but it may be protracted beyond this period in the old, infirm, and cachectic, or when it has been long in appearing. In some rare instances, it disappears on an attack of an internal inflammatory disease, and returns again when that disease is removed. This circumstance, however, has been doubted, some other eruption having been mistaken for the itch. In general, this eruption excites no influence upon internal complaints, nor do they produce any effect on it; although an opposite opinion has been long held by pathologists, and is still entertained by a few.

12. *H.* Diagnosis.—It is of importance, not only as respects the reputation of the practitioner, but as regards the speedy recovery of the patient, and the protection of the other members of the family to which he belongs, that a correct diagnosis between this eruption and those which so closely resemble it should be made. *A. Prurigo* is most frequently confounded with the itch; but, independently of the former being papular, while the latter is vesicular, prurigo is usually scathed on the back, shoulders, and on the outside of the limbs, or on the surfaces of extension; while the itch is observed chiefly on those of flexion, on the wrists, and between the fingers. Prurigo, also, occurs more frequently in adults, and elderly persons than it; its papulae are flat, and when afraid, the black spots of the lice are directed on their centres. The itching attending prurigo is more vehement than that of scabies, more stinging or smarting, and less plasmas. The former, also, is not contagious.

13. *B.* Lichen *simplex* most closely resembles the papular variety of itch. In the former no vesicles can be detected in the summits of the papulae, which pass away in a seury exfoliation, and do not give rise to dark scabs. Lichen appears on the backs of the hands and on the external surface of the limbs, and hardly ever between the fingers. The itching attending it is not severe, and the papulae preserve the tint of the skin, while the vesicles of scabies are of a pale pink; the former being generally crowded together, the latter being much more distinct. Lichen is commonly accompanied with some constitutional disturbance; but it is never contagious. *Ticada arcticatus* is more acute, and sometimes presents a few vesicles among the papulae; but its inflamed, wheal-like papulae, and the deep tingling, rather than itching, sufficiently distinguish it.

14. *C.* Eczema, particularly *C. Simplex*, may be confounded with itch; but in the former the vesicles are flattened and agglomerated in greater or lesser numbers, while in the latter they are acuminate and generally distinct. The itching of eczema is a kind of general smarting, or stinging, very different from those exacerbations characterizing itch. The former is usually produced by exciting or irritating causes, the latter by contagion only.

15. The association of scabies with other eruptions is of importance in the diagnosis. Such complications may be merely accidental, but they occasionally arise from the irritation of scratching, and of applications to the eruption. Vesicles of itch, pustules of impetigo or of *eczema*, and furunculi are sometimes met with on the same part; in some cases of lichen, also, may be either contemporaneous with itch, or consequent upon it. Scabies may even coexist with syphilis, without having its characters thereby modified, farther than has been noticed when mentioning the variety called cachectica. These combinations generally retard the cure, as well as often increase the difficulty of diagnosis.

16. *II.* Causation.—The great, and, perhaps, only cause of itch, is contagion. The only questions are, whether it does, in any circumstances, arise spontaneously, and what is the nature of the infecting substance, or body. These will be answered in the sequel, as far as the state of our knowledge admits of answers. Scabies is one of the most universally disseminated contagious diseases, the momentary contact of the fluid secreted by its vesicles being sufficient to communicate the infection. It occurs in every climate, in every season, in all ranks and ages; but is most common in the poor and wretched, in persons negligent of cleanliness; in sailors, soldiers, in workpeople, dealers in old clothes, in tailor's; and especially in those crowded in jails, hulks, barracks, workhouses, and factories. It rarely is observed in tanners, in dyers, and blacksmiths, or in the families of the affluent. It always spreads in consequence of contact, immediate or mediately; and of want of cleanliness.

17. Several instances of itch transmitted from animals to the human species have been cited; but most of the diseases thus named are inaccurately described, and are of a very doubtful character. M. Mouronval addsuces cases of the communication of itch from the dog to man; but M. Rayé states that M. Leblanc showed MM. Sabatier, Lettre, and himself dogs labouring under a disease called itch, consisting of a number of small acuminated vesicles, resembling those of scabies in the human subject; and stated that the man who attended them had not been infected by them, although
they communicated the disease to their own species. This, however, is no satisfactory proof of the non-communicability of the affection from the dog to man. Mr. Youatt, whose authority in this matter is the best possible, informed the author that the itch may be communicated to the dog, and by the dog to man and other animals, but that it is never sporadic in the canine race.

18. Avenzoar, and, long subsequently, Brasimias and Jorbert, hinted at the existence of an insect in the vesicles of itch; but Mörffer first mentioned it in his Theatrum Insectorum. In a particular manner. Several recent authors have described it under the name of Acarus scabei. TONi, rum, ORASSiAs their blinging their likeness their spinning their spinning their spinning, their spinning its spinning; and, having examined numbers of them, having removed them from the vesicles. Dr. Bonomo gave the following description of it: This insect moves with great vivacity; has six legs, and a pointed head, armed with two small horns, or antennae, at the extremity of the mouth. It is, he remarks, difficult to distinguish these insects on the surface of the body, owing to their minuteness, and to their colour resembling that of the skin. They first insinuate their pointed heads, and then move about, gnawing and pushing, until they have buried themselves under the cuticle, where they form a kind of covered way of communication between one point and another, so that the same insect generally causes several watery pustules. The above physicians also discovered the eggs of these insects, and even observed their extrusion from the hinder part of the animal. The eggs are white, nearly quite transparent, and hardly visible. These insects, they remark, pass readily from one person to another, by mere contact, for, being very active, and often on the surface of the skin, they readily attach themselves to whatever they touch.

19. Morgagni, Linneus, De Geer, Wichmann, Waltz, and others confirm the above description; but, nevertheless, the existence of these insects having been called in question, M. Gras took up the subject, and his investigations, which were witnessed by many members of the Institute, farther confirmed the above statement. The circumstance of Galeotti, Chirurg, Biett, Legol, and Mouchonval having failed in finding these insects occasioned fresh doubts of their existence; but their failure arose from having sought for them in the vesicles. Mörffer had long before stated that they are not found in the pustules, but by their sides; Casal had made nearly a similar observation; and Dr. Adams remarks, that they are not found in the vesicles, but in a reddish line going off from one of its sides, and in the reddish and firm elevation at the extremity of this line, and at a little distance from the vesicle. Mr. Plumber supposes that the insect is unable to live in the fluid of the vesicle, which is the result of the irritation it causes, and therefore escapes from it. Finally, M. Renucci, a medical student from Corsica, showed, in 1824, the physicists of Paris the mode of discovering this insect, which is the same as that formerly stated by Dr. Adams. Since this time, M. Rayer remarks, the existence of the acarus of the itch has been placed beyond a doubt. MM. Lemery, Gras, and Renucci had each shown him the mode of detecting it, and he had himself extracted several. M. Raspail has given an excellent description and figures of it; and M. A. Gras has entered into researches as to the share it has in producing this eruption. Although it has been proved that, in almost all who are affected with scabies, and who have not been subjected to treatment, a certain number of sub-epidermic furrows, containing acari, are to be discovered, it is also undoubted that the number of these furrows and of these insects bears no proportion to that of the vesicles. It is, farther, rare to discover these insects on the abdomen and groins, where the eruption is, nevertheless, very common and apparent; and, moreover, scabies is known to continue where no more acari are to be found. The experiments made to ascertain whether or not the acarus be the cause of the itch, or a parasitic produced by it, are not altogether conclusive.

[Dr. Watson remarks (Pract. of Physic), that "there is good reason for believing that the parasitic animal is not merely a casual companion, but the veritable cause of scabies. Various attempts have been made, and made in vain, to produce the disease by inoculation of the fluid from the vesicles. On the other hand, transportation of the acarus has always excited the eruption. These facts explain how it is that the itch, though readily communicable by direct contact or by fomites, is not communicable through the medium of the air; that fomites long retain the contagious property; and that the disease is curable by whatever destroys the acarus."

20. IV. Treatment.—As the itch is never spontaneously cured, but may continue even for many years, the treatment should be decided and unremitting. The experiments lately made by M. Gras have thrown much light upon this subject. They prove that a concentrated solution of the hydrate of potash kills the acarus of scabies in the shortest time—in from four to six minutes; and he considers that an ointment, consisting of half a drachm of this substance to an ounce of Glycerinum nitricum, is efficacious. I have prescribed this ointment in several instances, and have found it the most speedily efficacious. This physician states that the itch insect lives sixteen hours in the vapour of burned sulphur, three hours in water, two hours in olive oil, one hour in the acetate of lead, one hour in pulverized brimstone, three quarters of an hour in lime-water, twenty minutes in vinegar and spirits of wine, and twelve minutes in a solution of sulphur of potash.

21. Where scabies is uncomplicated and recent, its cure is readily accomplished by local applications, and without any preparatory or constitutional means; but where it is of old standing, and associated with other eruptions, or with an inflammatory state of the skin, and particularly if the patient be young and plethoric, a bleeding from the arm, soothing lotions, and simple baths may be premised. Prickings with the sulphur ointment (sulph. sublina, asio, etc.; with prop. Bz.), and with the compound sulphur ointments (sulph. subl., sij.; pasteau subcarb., sg; adipis, sf; or sulphuris calcis, sf.; adipis, sf.), usually cure scabies in ten or
fourteen days. The compound sulphur ointment is the next to the ointment with hydroiodate of potassa in efficacy. M. Raver advises the compound sulphur ointment in the quantity of two ounces daily, to be rubbed over all the parts affected, the patient's skin having been well cleansed with soap and water. The rubbing should be continued diligently for about half an hour, morning, midday, and at night. If this be continued unremittingly, the eruption may be cured in six or seven days. Helmerick prescribed four ounces of the compound sulphur ointment to be assiduously rubbed on the parts affected, in twenty-four hours. An ointment, consisting of sulph. sublim. lat., 3ij.; ammon. hydro-chlor., 3ij.; adipsis prepar. 8xiiij., is also an efficacious application. M. Derhem has found the solution of chloride of lime, 5j., in water Oj., and used twice or thrice daily, very efficient.

22. The plan of M. Pyrheur, to add half a drachm of the sulphur of lime to a little olive oil, and with this to rub the palms of the hands during a quarter of an hour night and morning, has been often in use, with good success, as the ointment, composed of potassa sulphuret., aqua baij., of which an ounce is to be added to four ounces of warm water, and applied to the affected parts, also speedily effect a cure. These washes do not soil the clothes like ointments, but they often cause vesicular and popular eruptions. Should these eruptions appear, or complicate the itch, irritating frictions and applications must be suspended, and tepid emollient baths prescribed. In all cases of scabies, a few tepid baths should follow the removal of the eruption.

23. Alcoholic sapo7iaccous washes, acid ointments and washes, artificial sulphureous baths, sulphureous fumigations, &c., and various other means, have been recommended for the cure of itch; but they are less certain than the above, require a longer period, and are more expensive. Washes and ointments, the basis of which are nitric acid and mercury, have occasionally produced salivation and disturbance of the internal economy of sulphur, or this conjoined with its external application, has been long employed in this country, and is efficacious and well suited to the purulent form of scabies, as met with in children. Hellchore and tobacco have also been recommended for the cure of itch, and are doubtless efficacious; but they are hazardous substances, particularly where there is much excoration, and when prescribed for children.

[We have never found any difficulty in eradicating the itch, however severe, by sulphur ointment. We mix it with a small quantity of oil of bergamot, to disguise the smell, and a little vermillion, to conceal the colour, and then direct the patient to be rubbed all over carefully at bedtime, especially over the parts affected, and to sleep in a flannel dress. A repetition of this practice, night and morning, for three days will suffice for a cure. The patient is then to be thoroughly washed with warm water and soap, and the treatment is completed.]

24. Where itch is associated with general cachexia, and is modified by this circumstance, a judicious internal treatment should be conjoined with external applications, and with warm or tepid baths. In these cases the liquor potassae may be taken with sarsaparilla, or the alkaline carbonates may be given with mild tonics; and an alternative dose of a mild mercurial may be administered occasionally at bedtime. This treatment, in addition to the specific external measures already mentioned, is also requisite when itch attacks the dark races, among whom it generally proves a much more severe and obstinate affection than in the white races.

25. During the treatment, the diet should be digestible and in moderate quantity. All acid, heating, and fat articles, as well as stimulating beverages, should be avoided. In order to prevent attacks of the itch in the family or household, and to prevent an itching eruption from taking place in a family, the body and bed-clothes of the patient ought to be subjected to disinfecting processes, as the fumes of sulphurous acid gas. The linen should be changed frequently, and the greatest attention paid to cleanliness.

[There is need of caution on one point: mercurial preparations of every kind should be laid aside in the treatment of scabies, as they often produce very dangerous consequences. Besides the accidental eruptions to which they give rise, they generally have a tendency to complicate the application, engorgement of the salivary glands, or even inflammation of the tongue. Cazenave regards the sulphuret of lime to be the most generally beneficial application in these cases: 8ss., mixed with a little olive oil, and rubbed twice a day over the part affected. The mean duration of the treatment with this remedy is fifteen days; but it is only useful where the eruption is limited and recent. We have known Doctor Rayer's lotion prove very successful: this is composed of sulphuret of potassa, 3iv.; sulphuric acid, 5ss.; water, Qjss.: mix. The affected parts to be washed with the lotion twice a day. The hellchore ointment, in the proportion of one part to eight of lard, will usually accomplish a cure in about two weeks. Helmeric's ointment will, in a large majority of cases, cure in about ten days. This is the favourite remedy of M. Biett, composed as follows: Sulphurized sulphur, 5j.; sub-carb. potass., 5i.; hellebore, 3ij., and the internal use of sulphur, or this conjoined with its external application, has been long employed in this country, and is efficacious and well suited to the purulent form of scabies, as met with in children. Children, soap water and artificial sulphur baths are very appropriate remedies; also sulphur fumigations, especially as auxiliaries. Where the itching is very troublesome, alkaline baths usually afford very decided relief.

Dr. Buckley states (Am. ed. of Cazenave and Schenkel p. 108), that the combination of sulphur with soap, of a kind and quality to suit the taste and the means of the patient, forms a convenient and efficacious mode of applying that remedy; and that he has combined it with the common soft soap in dispensary practice with good effect.

Emery gives the following recipe for an ointment used at the St. Louis Hospital: R Brown soap, 5i.; table salt, 5ss.; alcohol, 5i.; eringuer, 5ij.; chloride of lime, 5oss.; M. He says that it causes no irritation, does not soil the clothes, has no unpleasant smell, cures in a short time, and is cheap. (Bull. Gen. de Ther., apothecaries, May, 1836.)

Extensive experiments have recently been made in the Berlin hospitals (Brit. and For. Med. Rev., July, 1841), by which it is found that a slight modification of the ordinary sulphur treatment accomplishes a cure with more speed, certainty, and economy than any other.
One part of the flowers of sulphur was mixed with two parts of soap, and sufficient warm water to make into an ointment. The patients, after a warm bath of soap and water had been applied, were placed, undressed, in a chamber kept constantly at a temperature of 95° Fahr., and well rubbed with the ointment over all the parts affected, three times a day, and then made to sweat profusely by putting them into warm beds. The dressing was renewed twice a day, nights and days; on the morning of the fourth, each patient had a warm bath, and then, if not cured, was provided with clean bed and body linen, and put in a ward of ordinary temperature, in which the suspicious parts were still rubbed with the ointment, and a warm bath taken every day. In general, no internal medicines were given; but the diet allowed was reduced to a fourth portion, and water only given. The treatment of one case resulted in a relapse, with an obstinate refusal to adopt all necessary treatment. In the whole 15 months there occurred only 8 cases of relapse; less than ½ of 1 per cent. of the cases treated, and in most of these there was reason to suspect a fresh infection. In no case did the treatment give rise to any general disorder, or to the inflammations or congestions which some have described as resulting from it.

K I D N E Y S.—The Diseases of—1. Our knowledge of the diseases of the kidneys has been recently very much advanced and rendered more precise by the researches of Drs. BRIGHT, PROCT, CHRISTISON, GREGORY, WILLIS, OSBORNE, RAYNER, and others. In the present article will be discussed the diseases of which these organs are the only or principal seat; and, in that devoted to the consideration of the urinæ, those disorders in which the kidneys and other urinæry organs are functionally disturbed. The great importance of an early attention to the disorders, and more especially to the actual diseases of these organs, especially in relation to several consecutive maladies, and to various pre-existing changes of the digestive and assimilative functions and of the circulating fluids, has become very apparent since the appearance of Dr. Bauné's discloses to us some of the most interesting, most common, and most fatal of the lesions to which the kidneys are liable.

2. The causes of diseases of these organs do not, for the most part, act immediately upon them. Intimately associated with the digestive and assimilative visceræ, through the medium of the ganglial or organic nerves, with the circulating organs by the states of the blood, and with the cerebro-spinous nervous system, by which means the kidneys may be disturbed directly, and the renal ganglia and plexuses, the kidneys are liable to be deranged sympathetically, or indirectly, during the progress of the various disordered and maladies by which these important parts of the human frame are affected. As the chief emmetures of effectual and harmful materials, the ultimate product of assimilation, that are liable to accumulate in and, require to be carried out of the circulating fluids, the kidneys are disturbed by the superabundance and peculiarities of these materials. Eliminating these various elements and substances existing in the blood circulating through them, by means of the nerves influence conferred on them, chiefly by the ganglia and plexuses which supply and endow them; and combining these elements into new forms, frequently of an irritating and hurtful nature, they are liable to disorder from causes which may diminish, excite, or otherwise modify this influence, or interrupt the operation of the arterial and venous functions that are destined to accomplish. Intimately associated, moreover, with the other organs eliminating from the circulating mass, materials of an irritating or otherwise hurtful tendency, they are liable to disorder from causes which may diminish, excite, or otherwise modify this influence, or interrupt the operation of the arterial and venous functions that are destined to accomplish. Intimately associated, moreover, with the other organs eliminating from the circulating mass, materials of an irritating or otherwise hurtful tendency, they are liable to disorder from causes which may diminish, excite, or otherwise modify this influence, or interrupt the operation of the arterial and venous functions that are destined to accomplish. Intimately associated, moreover, with the other organs eliminating from the circulating mass, materials of an irritating or otherwise hurtful tendency, they are liable to disorder from causes which may diminish, excite, or otherwise modify this influence, or interrupt the operation of the arterial and venous functions that are destined to accomplish. Intimately associated, moreover, with the other organs eliminating from the circulating mass, materials of an irritating or otherwise hurtful tendency, they are liable to disorder from causes which may diminish, excite, or otherwise modify this influence, or interrupt the operation of the arterial and venous functions that are destined to accomplish.
the skin, lungs, liver, digestive canal, and generative organs; by diseases affecting the functions and organization of those several viscera; and by morbid conditions of the system in general, or of the nervous and vascular systems in particular.

3. These are circumstances calculated to increase the difficulty of the study of the diseases of the kidneys; and it should not be concealed, that these are causes which add to this difficulty. Among these, the low degree of sensibility with which the internal structure of these organs is endowed: their situation—protected in one direction by a firm and unyielding mass of muscles, &c., and surrounded in all the rest by various viscera; and the changes which their secretion undergoes in the parts through which it passes or accumulates, deserve due consideration, and should impress the mind of the physician. With the investigation of the phenomena, and of caution in forming his opinion as to the nature of the affections referrible to these organs, as the only guides by which the indications and the means of cure can be safely directed.

4. It is, perhaps, owing to these causes of difficulty that the disorders and morbid changes to which the kidneys are liable, the signs and symptoms by which they are indicated, and the means more efficacious than the others, have made so little progress until recently, and still require, notwithstanding the advantages which have been lately made, so much farther elucidation. In the present consideration of the diseases of the kidneys, I shall first describe the inflammatory diseases, and their pathological and therapeutical relations, and afterward notice the changes, chiefly structural, consequent upon these and upon other disorderred states.

5. Defin.—Pain in the lumbar region, often extending anteriorly through the abdomen, or descending to the groin and testes, with retraction of the latter, disordered state of the urinary secretion and excretion, febrile disturbance, sometimes numbness of the thigh, and nausea or vomiting.

6. These symptoms are the most characteristic of inflammations of the kidneys; yet they are not all present, unless in some of the more acute cases, or when the inflammation extends to a greater part of the tissues composing the organ; and they may be attended by various contingent and much less constant phenomena. In the slighter and more partial cases, particularly when the disease commences insidiously and proceeds slowly, any one, or more than one, of these symptoms may be absent; a disordered state of the urinary secretion and excretion being the most constant.

7. Until very recently, all the inflammatory and partial affections of the kidneys, whatever may have been the particular tissue affected, were comprised and confounded under the term nephritis. Late investigations have, however, shown that inflammations differ, both as respects their seats in the particular tissues composing these organs, and as regards their nature, in relation to the states of the constitution, and the causes which produced them. I shall therefore describe, 1st. The inflammations scarificating the cortical or vascular, and in the tubular structures of the organ, with the modifications, and complications, and lesions usually presented by them; 2d. The inflammations seated in the calices and pelvis of the viscus, in connexion with their modifications and complications; and, 3d. Inflammation of the investing structures of the organ.

8. 1. Inflammation of the Vascular and Tubular Structure of the Kidneys.—Syno. Nephritis propria. Author. Nephrite simple, Fr. Nierentzündung, the kidney.

9. A. Causes.—a. The predisposing causes of nephritis are, chiefly, hereditary constitution; the middle, advanced, and matured periods of life; the male sex, sanguine temperament, and plethoric habit of body; indulgence, long at a time, in soft, warm beds; the use of much animal food, and of highly seasoned or spiced dishes, of too much food, and fermented liquors; addiction to venereal pleasures; riding much on horseback, or in carriages, often; readers of the digestive organs; sedentary occupations, indolence, and a neglect of due exercise; and the superabundance of excrementitious matters in the blood, more particularly of urea and its combinations. The calculous, gouty, rheumatic, and scrofulous diatheses, and diseases of the bladder, prostate gland, and urethra, whether these depend upon hereditary descent or upon acquired disposition and advanced age, especially predispose to nephritis, and more, urinary diseases, the characters and course of the disease, the varieties and complications which result from their influence requiring a particular notice.

10. b. The exciting and concurrent causes of nephritis are injuries, blows, contusions, ecchymoses, or wounds of the region, or in the vicinity of the kidneys, or of the spine; sudden jerks experienced on horseback, or in a carriage, or occasioned by missing a step on descending stairs; falls on the back or thighs; too long retention of the urine; the improper use of irritating diuretics, of emmenagogues, or of aphrodisiacs; too long a course, or too large doses of the preparations of iodine, of nitre, &c.; indulgence in spirituous liquors; venereal or other excesses; the presence of calculi in the kidneys, or in the ureters; calculi in, or inflammations of, the urinary bladder; the sudden suppression of the perspiration, especially when inordinate increased; sleeping in the open air, or on the ground; sleeping in damp beds or sheets; cold and moisture applied to the loins or lower extremities; cool and humid states of the air; currents of cold air striking against the loins; sitting with the back to a hot fire; the sudden interruption of accustomed discharges, as the hemorrhoids, catamenia, fluor albus, sudor pelum, &c.; the retropulsion and drying up of chronic eruptions; and old ulcers by external treatment; the sudden transfer of morbid action from the urinary bladder, genital and sexual organs, from
the psoas muscles, or from the organs of digestion and respiration, or interruptions to the healthy functions of those organs; retrogression or misplacement of gout, metastasis of rheumatism; paralytic affections, diseases and injuries of the spine or spinal column, and especially paraplegia; fevers characterized by a low state of the vital energies, and oppression of the nervous functions, with coma, &c.; the presence of animal poisons, purulent or sanious matters, or other hurtful excrementitious substances in the circulation, however introduced there, whether by absorption, or from morbid changes in the chyle or blood during the progress of other diseases.

11. From the above enumeration of the causes of nephritis, it will be manifest that this disease, in some one or other of its forms, will appear, 1st. As a primary and simple affection, the result of causes influencing the vascular state of the kidney or kidneys, without any very manifest pre-existing lesion of this or any other organ, either communicable or hereditary; 2. As consequentially upon some other malady, affecting either this particular organ, or some other, or even the constitution generally; as upon the formation of calculi in the kidney itself; upon inflammation of the bladder or testis, upon gout, or upon disease of the prostate gland or urethra, or during the progress of fevers; 3. When appearing secondarily, it may either form the chief or only lesion, or constitute one of a complicated state of disease, as when the nephritis is complicated with gout, rheumatism, or with other diseases of the urinary organs.

4. Whether occurring primarily or secondarily, it presents various grades of activity, from the most acute to the most chronic, and gives rise to changes which have some relation to the severity and duration of the attack; the circumstance of one or both kidneys being affected; the constitution and diathesis of the patient; the nature of the predisposing and exciting causes, and of the disorders which have proceeded, or become associated with nephritis; such relation may not be obvious, nor admit of being traced with case and certainty, numerous circumstances occurring and modifying the march and consequences of the disease.

12. B. Description.—The symptoms of nephritis vary extremely, according to the severity of the attack and the particular part of the organ inflamed; to the circumstance of one only, or of both kidneys being affected, and to the mode of attack. Inflammation seizes on either one or both organs, according to the predisposition of the patient and the nature of the exciting causes; but in either case it may appear with great severity and suddenness, or in a mild, slight, and insidious manner; or it may commence in this latter manner, and quickly pass into an acute and very severe form. On the other hand, a sudden and an acute attack may degenerate into a very obstinate and chronic form, notwithstanding the best efforts of the physician.

13. Not only may inflammation of the vascular and tubular structures of the kidneys assume any grade of intensity, and hence be acute, subacute, or chronic, but it may also be modified in character by the nature and combinations of its causes; by the diathesis, constitution, and age of the patient; and by the states of the circulatory fluids. I shall therefore consider, firstly, its simple form, and as usually observed in a previously healthy constitution; and, secondly, the modifications arising from those circumstances.

14. a. The symptoms of simple nephritis, of primary or idiopathic nephritis, of inflammations of the vascular and tubular structure of the kidneys, which are independent of diathesis, of constitutional vice, or of animal poisons, vary with the severity of the attack, and with the age and irritability of the patient. — a. The acute form of the disease is generally attended, at its invasion, with chills, hoppitations, or distinct rigours, and one or other of them occasionally, sometimes daily, appear during its course. A sense of heat, which augments rapidly, is at first felt in one or both lumbar regions. This soon is accompanied with pain, at first sensitive, afterward lancinating and pulsating; in the same situation. The pain is at first not aggravated by pressure thereon, but is more, unless it be applied firmly; but it is generally increased, upon a full inspiration, and on coughing or sneezing, particularly when pressure is made upon the abdomen at the same time. The pain is also momentarily aggravated by efforts to pass a passive stool, or to expel the urine, and at the time of turning suddenly around, or from side to side, and upon sitting down, especially upon a low seat. A very warm bed increases it, and a chill of the surface has generally a similar effect. The pain extends anteriorly through the abdomen, stretching, in the course of the ureters and spermatic vessels and nerves, to the hypogastric region, often with extreme violence, to the testes, which are drawn closely to the abdominal ring, and descends to the extremity of the penis, which is small and retracted. Numbness is frequently felt in one or both thighs, according as one or both kidneys are affected; and this feeling is sometimes accompanied with painful lancinations in the thighs, descending from the knee.

The pain, posteriorly, ascends as high as the shoulder-blades; it is increased in the region of the kidneys, and is attended by an augmented sense of heat and pain after lying for some time on the affected side, when one kidney only is inflamed, or on the back when both are affected, although these positions give at first slight ease.

15. The urine is generally passed frequently, and with aggravation of the pain. It is at first limpid and colorless, but is much diminished in quantity, becomes deeper in colour, and is voided more frequently and with more pain as the disease increases in severity. In the most acute cases, particularly when both kidneys are affected, the urine is in very small quantity, is voided with the most painful efforts, sometimes only in drops, is of a reddish or sanguineous, or brown colour, or with small brownish fleeces; and it is often nearly, if not altogether suppressed, so that the bladder is found empty upon the introduction of the catheter. The chief changes presented by the urine in simple nephritis are: 1st. It contains some blood or albumen; 2d. It is but slightly acid, or neutral, or alkaline; 3d. It sometimes contains a little purulent matter, or muco-puriform matter, particularly when the inflammation ex-
tends to the calices or pelvis of the kidneys, or when the disease is associated with inflammation of the mucous surface of the bladder, or of other parts of the urinary passages. Where nephritis is caused by cantharides, turpentine, or cold, the urine very commonly contains blood. In the simple form of nephritis, the presence of albumen in the urine is not constant, as is the case in the granular disease of the kidneys, or albinous nephritis, as it is called by M. Rayer.

16. Soon after the accession of rigours, at the inception of the disease, nausea and vomiting are often present. In the most acute states, retching continues throughout, although nothing may be rejected, and is renewed after taking fluids, so that the patient refuses everything. He often complains, also, of severe colicky pains in the abdomen, which is sore upon firm pressure; particularly towards the lateral and epigastric regions. There is generally constipation, frequently with repeated desires to go to stool, and occasionally with tenesmus; all these symptoms being dependent upon intestinal consent of parts. The pulse is hard and frequent, and full during the remissions of pain; but in the paroxysms or accessions of pain it is smaller and contracted. The skin is at first hot, dry, or burning; but, as the disease advances, it becomes more moist, is partially and irregularly covered by a disagreeable perspiration, and, in cases characterized by a partial or total suppression of urine, the perspiration has a rancid odour.

17. When the disease extends to the investing membrane of the kidneys, the symptoms are then very acute, the pain severe, the pulse hard and contracted, and the urine is less changed from the natural state, relatively to the severity of the pain and constitutional symptoms, than when the secreting structure is chiefly affected. But the disease is more rarely limited to one or other structure, although either may be its principal seat. When it commences in the secreting and more internal textures, or in the calices or pelvis of the organ, the urine contains much mucous or muco-puriform matter, and is very scanty; and the pulse is softer, the symptoms are milder, and the course of the disease slower than that above described, which is seldom prolonged beyond a fortnight, frequently not beyond six or seven days, without giving rise to some one of the changes or lesions which will be noticed in the sequel. When the attack is occasioned by the irritation of calculi in the kidney, there are commonly more numbness of the thigh and painful retraction of the testes, and severe pains, shooting at intervals to the hypogastrum or in the course of the ureters, than in the more primary and simple states of the disease, which states are of less frequent occurrence than this, and of shorter duration; this particular cause, and the complication produced by it, being generally a chronic disease, liable, however, to assume an acute or sub-acute form, as will be noticed hereafter.

18. Acute and sub-acute nephritis most commonly implicates one kidney, both organs being more rarely affected, especially in the same degree, at the same time. While total suppression of urine may be considered as distinctive of severe disease of both kidneys, yet both may be inflamed, and a scanty secretion take place, for a portion of either organ may be still enabled to perform its functions. These states of nephritis commonly present themselves as follows: 1st. MILD ACUTE or sub-acute: the pain in the loins slight; little diminution or change of the urine; slight symptomatic fever, and speedy subsidence of the disease under treatment.

2d. Simple acute and sthenic nephritis: greater severity of the pain and of the other symptoms; inflammatory fever, preceded by rigours; marked diminution of the urine, with the morbid appearances and disorder attending the discharge of it (p. 15). 3d. Acute nephritis, with ischaemia, and disturbance of the cerebral functions: suppression of urine altogether or nearly complete; vomitings or retchings from the commencement; pain in the loins, in some cases severe, in others obscure; lethargy, sopor, or coma, supervening in the worst attacks.

4th. Asthenic or malignant acute nephritis: inflammation of the structure of the kidneys occurring during states of cachexia, or coincident with morbid states of the blood and depression of vital power, or apparently dependent upon intermittent, or low fever or scarlatina, attended by a livid, dusky, and offensive odour of the surface of the body; little or no pain in the back or loins, unless firm pressure be made; the supine posture in a state of stupor, or sopor, the patient answering questions with difficulty and imperfectly; suppressed, scanty, or involuntary excretion of urine; frequent occurrence of slight rigours; the tongue dry, loaded, and brown; little or no thirst; stupor, coma, and an offensive and nauseous odour from the surface.

19. 3. Sub-acute Nephritis.—When inflammation of the secreting structure of the kidney takes place slowly in a mild and sub-acute form, the patient complains of dull or shooting pains in the lumbar region, occurring at longer or shorter intervals, with disorder of the secretion and excretion of urine, aggravated by errors of diet and regimen. These symptoms are connected with more or less disturbance of the system generally, and of the functions of the digestive organs; periods of aggravation and amelioration, and occasionally assuming suddenly, especially after the operation of one or more of the causes above enumerated (p. 10), a very acute form.

20. This state of the disease is of very uncertain duration. Sometimes it continues, with intermissions, for several weeks, or even months, when it may assume a very acute or hyper-acute form, or may subside into a less severe and more chronic state.

21. When sub-acute nephritis passes into a hyper-acute state, the disease may reach its utmost severity in two or three days, and if circumstances favour its continuance, or insufficient means are adopted to subdue it, the symptoms assume, in one, two, three, or four days more, the most dangerous character. The pain becomes sometimes insupportable; the pulse small, contracted, unequal, or intermittent, frequently slow; the extremities become cold, or are kept warm with difficulty; the countenance assumes a leaden or murky hue, and the features are otherwise much changed; hiccup supervenes, and a cold, fistul, or urinous perspiration covers the surface of the body. The urine, if any be voided, is usually now very dark-coloured, filamentous, passed drop by drop,
KIDNEYS—Chronic Inflammation of the.

The existence of pain in the lumbar region extending to the abdomen, and shooting towards the bladder and groin, with numbness of the thigh and disorder of the secretion and excretion of the urine, are, however, sufficient to prove the existence of nephritis in this class of patients. Two cases of the disease in females have come before me which had been mistaken for disease of the colon, and one for inflammation of the bowels. This want of knowledge of so very important a disease has evidently arisen from the very slight attention paid to diseases of the kidneys by systematic writers, and to the careless way in which the urinary secretion is examined by too many practitioners. Nephritis is not infrequent among females recently married, but is then commonly associated with inflammation of the veins of the uterus and ovaria, or with peritonitis.

25. C. Terminations, &c.—a. When resolution takes place, the severe symptoms abate from about the fourth to the ninth day, in the more acute cases; and, in the sub-acute, frequently not until the twelfth or fifteenth of the attack. When this change occurs, the urine becomes more abundant, paler, is voided with less uneasiness and denotes a sediment, the pulse becomes more natural; occasionally fuller, softer, and even quicker than previously, especially if it have been slower during the acute state; a general perspiration breaks out, and critical discharges, particularly the hemorrhoidal and catamential, sometimes appear, especially when the disease has arisen from suppression of these evacuations. In some cases, particularly in persons advancing in age, resolution is imperfect, the urine containing scanty and albuminous, other symptoms remaining in a slight form. In these there is reason to suspect that slight depositions of coagulable lymph have taken place, during the acute state of the disease, in the tissues composed of the body of the organ, and are giving rise to granular degeneration.

26. b. Suppuration or abscess does not so often occur during inflammation of the vascular and tubular structure of the kidney as is generally supposed.richter (therapeia specialis, t. i. p. 531) says that the left kidney is more frequently inflamed than the right; and a similar opinion has been stated by other pathologists; but this is not satisfactorily proved.

24. b. Nephritis in the female is a less frequent and less dangerous disease than in the male, because often more difficult of detection, in its chronic forms especially; it is liable to be mistaken for affections of the uterine organs, with which, also, it is occasionally complicated.

and of a cadaverous odour. The muscular force sinks rapidly: fainting delirium, convulsions, stupor, and coma supervene, and the patient dies.

22. y. Chronic Nephritis.—Inflammation of the substance of the kidney may exist in either the acute or sub-acute form, and gradually lapse into the chronic state. Or, in many instances, the inflammatory action may commence in a slight and mild form, proceed gradually and insidiously, and he so obscure as not to awaken the fears of the patient, and as to escape the observation or detection of the physician. In these cases, pain, if at all present, is often slight or obscure; disorder of the quantity and states of the urine; a diminution of acidity, and a neutral or alkaline state of it; disorder connected with the evacuation of it; a feeling of weakness or of slight numbness in one or both lower extremities, are the symptoms most commonly observed. The urine is generally turbid, occasionally only albuminous, generally abounding with the phosphatic salts and with mucus, and often depositing sediments, or containing more or less of gravelly matters. It is always voided frequently, but in very small quantity at a time. Pain in the loins is often not felt unless on firm pressure, and on taking a full inspiration. It sometimes extends in the course of the ureters, but seldom to the testes. When it is not associated with disease of the bladder or prostate, there generally is little or no fever, unless at night, or when the patient is heated by a warm bed. This state of nephritis is often excited or perpetuated by disease of the urethra, or prostate gland, or urinary bladder. In some cases this form of the disease approaches a succession of slight attacks of acute or subacute inflammation, of short duration, and in some instances extends in the course of the ureters, but seldom to the testes. When it is not associated with disease of the bladder or prostate, there generally is little or no fever, unless at night, or when the patient is heated by a warm bed. This state of nephritis is often excited or perpetuated by disease of the urethra, or prostate gland, or urinary bladder. In some cases this form of the disease approaches a succession of slight attacks of acute or subacute inflammation, of short duration, and in some instances extends in the course of the ureters, but seldom to the testes. When it is not associated with disease of the bladder or prostate, there generally is little or no fever, unless at night, or when the patient is heated by a warm bed. This state of nephritis is often excited or perpetuated by disease of the urethra, or prostate gland, or urinary bladder.
KIDNEYS—INFLAMMATION OF THE—Terminations.

ours occur irregularly or at different hours of the day; and when perspirations become frequent and copious, the pulse small, weak, and soft, the symptomatic fever assuming an adynamic, and subsequently a typhoid character, cerebral symptoms supervening, we may then conclude that an abscess has formed in the structure of the kidney.

Either chronic or sub-acute cases terminating in abscess, an edematous fulness or swelling, without change of colour, is sometimes observed. In several instances, firm pressure of the lumbar region occasions acute pain, extending to the groin; and the urine contains either blood or gravelly matter, or a whitish purulent matter more or less intimately mixed with it, and rendering it thick and turbid. In these more chronic states, the constitutional symptoms are nearly those of hectic fever. The symptoms may terminate in the existence of abscess, and yet no pus be seen in the urine, which may even remain clear. But, after a considerable time, the matter finds its way into the pelvis of the kidney, and a large quantity of pus, with some blood, is evacuated with the urine, often occasioning, by its aerymony, much irritation of the bladder and urethra. In other cases, little or no pus is evacuated in the urine, owing to the passage along the ductus being obstructed, either at the pelvis of the kidney, or in some part of the ureter, by a large calculus, which most probably induced the inflammatory action giving rise to abscess, and which now prevents the passage, not only of the matter, but also of the urine to the bladder. In some of these cases, the abscess points externally in the back or loins, or even in the side or above the groin, the patient either sinking under the affection, or partially or altogether recovering. The abscess may burst internally into the renal cavity, and it then proves quickly fatal; or it may open into the colon, and the patient either recover or sink. Of these occurrences, numerous instances are recorded in the works contained in the Bibliography to this article.

28. In the greater number of cases of abscess, the ureter remains more or less pervious, and the patient continues at intervals to discharge pus, and sometimes small calculi, blood, &c., with the urine for a long time (Prout). When the abscess opens externally, the aperture continues for a considerable time to evacuate purulent matter of an urinous odour, or pus mixed with urine, and sometimes urine only. When the abscess discharges pus merely without any urinous odour, or without any intermixture of urine at any period of the discharge, it is then very doubtful whether the abscess is connected with the kidney or not. It may proceed from ulcers of the walls of the vertebræ, from which it is necessary to distinguish the abscess now under consideration.

29. When the fatalous opening, leading from an abscess of the kidney, becomes obstructed, either by granulations or by a calculus, the discharge ceases, and a pulsatory pain generally returns in the lumbar region, followed by increased heat of skin, accelerated pulse, or even delirium, which continue or increase until the obstruction is opened or the abscess evacuated. When at last the external opening heals up, without the immediate return of the previous dangerous symptoms, a relapse may take place at a more remote period, owing to the return of the inflammation, probably again induced by a calculus formed in the kidney. In the majority of cases, especially in the earlier stages of abscess, one kidney is only affected; but this may be altogether destroyed by it. In protracted cases, particularly in aged persons, it is a kidney generally to inflammation in the disease, to a greater or less extent, before the one first attacked is altogether disorganized. Although suppuration is a consequence of inflammation, whether unconnected or complicated with calculus in the kidney, yet the origin of the calculus is a matter of importance. It is very probable that they may be a result of slow inflammatory action of the tubular structure, and that, when they are formed, they heighten this action, and give rise to suppuration.

30. When the chronic states of nephritis occur in serofulous persons, abscess often results, even independently of calculi, with which, however, the abscess may be associated. When abscess takes place in the strumous diathesis, the symptoms attending its formation and maturation are much more obscure than in other constitutions, and the disorganization of the kidney generally is more complete. In the latter stages of this disease, Dr. Howship has remarked that the patient refers his complaints more to the neck of the bladder than to the region of the kidney; but in recent cases this is not so generally observed. Dr. Prout has met with instances where the pain referred to the lumbar region, as in ordinary cases, and the urine was acid, and, abstracting the pus, not very unnatural. I agree with Dr. Prout in imputing the sufferings in the bladder, in the more chronic cases of this form of abscess, to the exceedingly fetid, acid, and unnatural state of the urine, which is usually alkaline, and evidently of so irritating a nature as probably not to be retained in a healthy bladder for a moment, without producing great pain. Mr. Howship, however, mentions instances of this form of the disease where the urine appeared natural, and yet the pain was referred to the bladder, nevertheless. But there was very probably, in these cases, disease of the prostate gland, or inflammation of the parts in its vicinity, or of those adjoining the openings of the ureters, complicated with the disease of the kidney; for I have observed such complications in cases which occurred in my practice, where the symptoms were chiefly referred to the bladder, and yet the urine seemed nearly natural. Dr. Prout remarks, that the cases of this serofulous affection of the kidneys that he has seen have also been attended with indolent fever and abscess of the inguinal gland, produced by occasional pain and swelling in the testicles. They were accompanied by great extermination of the body, and derangement of the general health; and in all instances ultimately proved fatal. (On Diseases of the Urinary Organs, p. 216.)

31. c. The termination of nephritis in gangrene is very rare; the change actually taking place, and often mistaken for gangrene, as sometimes proceeding from this state, is softening, more or less marked, of portions of the internal tissues, with purulent infiltration, in a greater or
less number of points. If gangrene take place, it is indicated by the symptoms usually attending it in other organs, especially by sudden sinking of the vital powers, and cessation of pain; singultus, vomitings, anxiety, restlessness, coldness of the surface and extremities; small, thready, and weak pulse; wanderings of the intellects, and delirium. The urine also becomes altogether suppressed, or remarkably scanty and foetid.

32. a. Some degree of either induration or softness follow acute nephritis, particularly the former; and the patient may either apparently recover, or the disease may assume a chronic form. Some degree of induration of the surface of the organ consequent on the acute state of the disease may not be inconsistent with the discharge, to some extent, of its functions; and when one organ only is affected, the urine may not be materially altered, or even not at all diminished. In these cases, the quantity secreted by the indurated organ cannot be maintained, as the function of the healthy kidney is increased. The albuminous state of the urine in these cases seems to indicate that the indurated kidney still performs some part of its functions.

33. D. Changes observed after death from inflammation of the vascular and tubular structure of the Kidney.—a. At an early stage of the acute form of the disease, the volume of a part, or of the whole of the organ, according as the affection is general or partial, is more or less increased. In a few cases the kidney may be increased to twice, or even thrice its natural bulk. At this period, and before the parts inflamed become infiltrated with pus, they present a morbidly red tint, generally a deep or dark red, and sometimes a brownish echymosed appearance. The vessels of the cortical structure, and the more superficial veins, are enlarged and more than usually distinct. Besides these, M. Raynier remarks, that a number of small points of a lively red tint, not elevated above the surface, may be seen with the unassisted eye in the exterior of the organ. These small red points are also found in the first stage of gangular disease, or inflammation of the kidney—of the nephrite albuminosa of this writer—and are often intermingled with black points and with small vesicles. These latter points are often surrounded by a very delicate network of vessels. On division, the vascular or cortical tissue of the inflamed kidney presents a similar copiousness of red points, distinct from the orifices of divided vessels; these points are disposed in lines or seriers, very rarely in groups, and are the glандules of Malpighi—the corpora Malpighiana—highly injected. Sometimes these glandules, especially at the exterior of the organ, assume the appearance of dark or black spots, either isolated and distinct, or approaching each other in a series, or in groups. The surface of the organ, also, presents an irregularly red tint, with scattered spots of a livider red than that of the surrounding tissue. The substance inflamed is, moreover, dotted with true echymoses, disposed either in lines or in bands, which probably become the bases of the purulent infiltrations observed at a farther advanced stage.

34. When the acutely infected kidney is augmented in volume and weight, it often, also, presents a red induration of the vascular and tubular tissues. This induration and redness are commonly general as respects both these tissues; and the glandules of Malpighi are also highly injected and very apparent. Upon pressing the divided parts of an indurated, reddish brown kidney between the fingers, a larger quantity of blood escapes than in the healthy state; but not with that facility observed in the passive congestions of the organ consequent upon intercepted circulation through the right side of the heart.

35. In some states of simple acute nephritis, M. Raynier has observed portions of the organ in a state of anemia interspersed between other parts which are morbidly red, and echymosed, or infiltrated with pus. This association of anemia of some portions of the kidney with inflammatory injection, &c., of other portions, is also often found in cases of chronic nephritis which have passed into the acute form previously to death.

36. Purulent infiltration is more frequently remarked in the vascular than in the tubular tissue of the organ; the former portion being more commonly and severely inflamed than the other. The infiltrated pus appears in the form of grains of white sand, or of minute deposits of the size of pins’ heads, surrounded by a brownish red tissue. In some cases, the purulent formations are much larger, although less numerous, being of the size of pustules, or of small pebbles, in rare instances, as large as nuts. It is comparatively rare to find abscesses, or purulent collections, in the substance of the kidney larger than these, most of the cases of large abscesses in this organ being purulent collections of the calices and pelvis consequent upon inflammation of these parts, and obstruction of the ureter. These collections are surrounded by a deeper redness than that of the adjoining parts, even when the whole of the organ is inflamed. The small abscesses, seen on the surface of the kidney, penetrate more or less deeply into its substance, and often infiltrate the tissue immediately around them, so that drops of pus may be squeezed from it by the point of the scalpel. Some parts of the organ are softened and infiltrated with pus, and are of a yellowish white colour, drops of pus being squeezed from them when divided; these have not yet proceeded to the state just described, or are merely in the course of passing into that of small abscesses; they are met with in the vascular as well as in the tubular structure. Gangrenous softening is very rarely observed in these structures, and is characterized by its brownish hue, by their tomentose aspect when they are plunged in water, and by the colour exhaled by them.

37. b. The chronic forms of nephritis present various changes, some of which are very opposite in their natures. When the whole of the organ has been chronically inflamed, or of it is much more frequently observed than hypertrophy, which also occurs. In some instances, the vascular tissue of the organ presents a species of hypertrophy occasioned by a deposition on it of lymph, which has assumed subsequently a fibril-cellular character. In others, patches of a yellowish colour are seen exteriorly, and are found to consist of a somewhat similar substance, manifestly produced from coagulable lymph long previously thrown out. Al-
KIDNEYS—INFLAMMATION OF THE—DIAGNOSIS.

The chronic states of inflammation, the substance of the organ is more or less indurated, denser, and specifically heavier than natural. The external surface is often granulated, or rough, or it presents a variously-coloured, or marbled appearance. Deep redness is seldom observed, unless an acute state of inflammation has supervened on the chronic shortly before death, and then it is seen both on the surface and more or less through the substance of the organ. An anæmic condition, either partial or general, and commonly associated with a lessened density of texture, is one of the most frequent leisons produced by chronic simple nephritis; and is generally further associated with a granulated and marbled state of the surface, and with atrophy. This anæmic state commences in the vascular tissue, and extends to the tubular texture, both of which may become ultimately pale, indurated, atrophied in a very remarkable manner. When atrophy takes place in several distinct parts or parts of the organ, the external surface often presents an irregular, rugous, or mammulated appearance. The papillae of the cones or tubular structure undergo various changes consequent upon their induration. Sometimes the cones are very acute, and of a whitish yellow colour. The papillae are occasionally eroded or infiltrated with pus, more rarely are they ulcerated.

38. e. The membranes external to the organ often participate in the inflammation of the more internal textures, and present the usual consequences of this participation, especially vascular injection, exudation of coagulable lymph, and, in the chronic cases, thickening of the membranes and increased adhesions of them over the parts inflamed. In some cases they also experience various changes of colour, chiefly of a brownish or blackish hue; and occasionally they are changed, in places, to fibrous, fibro-cartilaginous, or even to a cartilaginous or bony nature. Besides the changes hereafter to be described take place as a consequence of inflammation, and various inflammatory changes are also observed in the calices and pelvis of the organ. The veins of the kidneys are sometimes inflamed, but independently of this form of nephritis. Renal phlebitis is more frequently associated with granular degeneration of the kidneys or albuminous nephritis.

39. E. DIAGNOSIS OF THE SIMPLE STATES OF NEPHRITIS. The distinctions between these and the other forms of nephritis will be made more manifest when the latter come under consideration. I shall, therefore, merely remark very briefly that, in the gouty variety of nephritis, the urine deposits crystals of uric acid, which are never observed in the simple form of the disease; and that the granular degeneration of the kidney is always either accompanied or followed by dropsy, and characterized by a constant and marked albuminous state of the urine, this latter change being only accidental and evanescent, although sometimes recurring in the simple forms of nephritis. The inflammation of the substance of the kidneys, occurring in the course of low and exanthematus fevers, arises from the morbid poison in the blood, or, rather, from the accumulation of excremential matters, and the consequent alterations in this fluid in connexion with the state of organic nervous powers; and, from being thus a consecutive disease, and attended by certain features hereafter to be noticed, cannot be confounded with the primary and simple nephritis just described.

40. b. It is often impossible to distinguish the acute form of simple nephritis from inflammation of the investing membranes of the kidneys, on the one hand, or from inflammation of the pelvis and calices of these organs, on the other; because the disease is seldom limited to either of these parts, although it be seated in one or other chiefly. When the urine contains much mucus, or a muco-puriform matter, the urethra and urinary bladder being sound, then the morbid secretion can proceed only from the pelvis and ureters. But, in these cases, it is almost impossible to say that the bladder is healthy. However, when inflammation of the pelvis and calices is so severe as to produce an abundant secretion of mucus, or to obstruct the kidney, the kidney does not participate in the inflammation. When, in addition to this secretion, there is severe pain felt in the loins, attended by vomiting and other acute symptoms, it may be inferred that the disease extends to both the substance and the pelvis of the organ. It is much more difficult to distinguish the chronic states of inflammation of the substance from those of the pelvis of the kidney, even although the morbid action be confined to either structure; but such limitation often does not exist, both parts being implicated, although one or other is more especially affected. Still, in the simple chronic nephritis, the quantity of muco-puriform matter in the urine is much less than when the calices and pelvis are chronically inflamed, and the phosphates are more frequently found in suspension. Most of the cases usually denominated abscess of the kidney are nothing more than accumulations of pus in the pelvis, owing to the morbid affection being situated in the pelvis and the surrounding parts, and transforming the organ into a large multilocular tumour containing puriform matter. When the inflammation is seated chiefly in the calices and pelvis of the organ, and especially when it is caused and perpetuated by calculi, then more irritation is felt in the bladder, especially about its neck, and more pain in the course of the urethra, than in other cases. The irritability of the bladder is sometimes so great in these cases as to almost amount to incontinence of urine.

41. c. Inflammation of the surrounding cellular tissue, or of the investing membranes of the kidneys, very closely resemble acute nephritis; but there are not such remarkable changes in the quantity and character of the urine, or such disorder connected with the excretion of it, correspondent with the acuteness of the local and constitutional symptoms, and observed in chronic nephritis. When the membranes especially are inflamed, the sense of heat and the pain are very great, while the diminution of urine and the difficulty of excreting are not so remarkable. When the surrounding cellular tissue suppurates, and a considerable abscess is formed, the lumbar region becomes full and distinctly edematous, and ultimately even fluctuation may be detected. Inflammation of the
cellular tissue surrounding the psoas muscle—para-
tis, or the commencement of lumbar abcess—
may be mistaken for nephritis; but in the for-
mer disease the pain is much increased upon
flexure of the thigh upon the trunk, while the
secretion and evacuation of urine are either not
disordered or but slightly disturbed.

42. d. Nephritis is distinguished from the
simple irritation consequent upon the passage
of a calculus along the ureter, chiefly by the fever
which accompanies the pain of nephritis from
its commencement, and after a time, ass, besides
being acute, is present, although it is generally
characterized by remissions and exacerbations.
Nephritis can hardly be confounded with nep-
hralgia: this latter affection is very rare; the
pains constituting it are much more violent
than those of nephritis, are sudden in their ac-
cession and disappearance, and are unattended
by fever or heat of skin.

43. e. From acute rheumatism nephritis will
be readily distinguished by the nausea, vomit-
ing, from inflammation of the psoas muscles,flexure
ness of the thigh, the extension of the pain to
the hypogastrium and groins, and to the testes,
with retraction of them to the abdominal ring,
and the disorder of the secretion and excretion
of urine which characterize the latter disease,
but which do not attend the former unless rheumatism
attacks or extends to the investing
membranes of the kidneys, as will be more
particularly noticed hereafter. Lumbago can
hardly be mistaken for nephritis, as, besides
the absence of the above symptoms in the for-
mer disease, it is seldom attended by any febrile
action; and the pain on bending the back,
upon rising from a seat, or exerting the dorsal
muscles, is distinctive of the rheumatic nature
of the affection.

44. f. In females, nephritis is often distin-
guished with difficulty from colic, from inflam-
mation of the psoas muscles, from enteritis,
from obstruction and inflammation of the colon,
and, from the urinary region and abdomen;
the manner in which the patient will be
affected, the dulness of the thigh, the extension of
the pain to the hypogastrium and groins, and to the testes,
with retraction of them to the abdominal ring,
and the disorder of the secretion and excretion
of urine which characterize the latter disease,
but which do not attend the former unless rheumatism
attacks or extends to the investing
membranes of the kidneys, as will be more
particularly noticed hereafter. Lumbago can
hardly be mistaken for nephritis, as, besides
the absence of the above symptoms in the for-
mer disease, it is seldom attended by any febrile
action; and the pain on bending the back,
upon rising from a seat, or exerting the dorsal
muscles, is distinctive of the rheumatic nature
of the affection.

45. g. It is often more difficult to distinguish
nephritis from urethritis than is generally sup-
posed. It should, however, be recollected that
both diseases are often associated: and that
both simple nephritis and inflammation of the
pelvis of the organ, caused by the irritation of
uric acid, may be attended by more severe
symptoms referred to the bladder and urethra
than those felt in the lumbar region; while ure-
ritis may be attended by pain in the loins,
and various other symptoms of nephritis.
The great irritability of the bladder, the appearance
of the urine, the pain behind the pubes, and the
absence of calmness of the thigh, or of pain
and retraction of the testes, unless when
the kidneys are also affected, will generally indi-
cate the seat of the disease. But this subject
will be noticed more particularly hereafter.

46. i. Modified States of Nephritis.—In-
flammation of the kidneys presents various
modifications or varieties proceeding from the
diathesis of the patient, and the nature of the
exciting causes.

47. A. Of Gouty Nephritis.—of Nephritis in the
Gouty Diathesis. The fact of gout attacking
the kidneys was first remarked by Artucus,
and more particularly by Wepfer, Speeht,
Svedem, Bonet, F. Hoffmann, Moriagni,
De Haen, Stoll, Van Swieten, Chopart, and
by other practical writers of the last century.
Modern authors, especially Bailliez, Home,
Gelbert, Sedgmore, Brodie, Raver, and others,
have farther shown that manifesta-
tions of the kidneys, either with or without
gravelly and calculous formations, but most
frequently in connexion with them, are very
liable to occur in gouty constitutions, or in
connexion with gouty attacks, and to assume
peculiar features.

48. a. Symptoms.—These vary remarkably,
according as the inflammation is associated
with uric acid gravel in the vascular and tubu-
lar structures of the absorbing gland, or in the
other parts of the organ, or with disease of the
bladder or prostate gland. Gravel or some calculi
may exist long in the substance of the
kidney, without any of the symptoms of disease
of the organ being felt, or, at least, felt so as to
attract particular notice. It is only when these
produce irritation, or when various circum-
stances occasion vascular determinations or
congestion of the kidneys, or when a calculus
is arrested in the ureter, the bladder, or urethra,
and a dis-
KIDNEYS—INFLAMMATION OF THE—MODIFIED STATES OF.

quently neutral or alkaline, deposits an amorphous sediment, usually composed of the phosphate of lime, or of the urates, or of the ammoniacal-magnesian phosphate. In proportion to the acuteness of the attack, to the diminution and other changes of the urine, and to the predominance of the symptoms more strictly referable to the kidneys and bladder, is the constitutional or febrile disturbance usually great. When the urine is suppressed or nearly so, bloody, remarkably scanty, or very dark-coloured, and the pains in the loins, &c., and the attendant fever severe, either inflammation, or acute congestions of the veins, of the vessels, or of the tubal structure, or obstruction of the pelvis at the commencement of the ureters of both kidneys, has taken place. When this attack occurs somewhat suddenly, or upon the premature disappearance of gout from the lower extremities, or after the usual premonitory indications of gout, if it appear either as suppressed, or metastatic, or misplaced gout, then acute inflammation, or very active congestion of the kidneys might be induced to exist. I have lately treated a case of gouty nephritis, in which the urine was of a black, inky tint, and remarkably scanty; this colour having arisen from the action of the acid in the urine upon the blood exhaled from the inflamed organ.

49. b. On dissection of fatal cases of gouty nephritis, numerous particles of crystallized uric acid may be detected at the surface, or in the substance of the vascular structure of the kidney. This structure becomes divided into inflamed parts, and altered in structure, as already described when stating the lessons produced by simple chronic nephritis (§ 36). Gravel or small calculi are also found in the papillary structures, in the calices, and in the pelvis of the organ; those in the latter situations being commonly larger than those found in the tubuli. The investing membranes of the kidneys are rarely materially altered.

50. B. Of Rheumatic Nephritis—\textit{a}. The occurrence of nephritis in connexion with rheumatism in different parts of the body has been noticed by several writers; and, in very recent times, also in connexion with rheumatic periarteritis or endocarditis, or antecedently or subsequently to these diseases. I have seen nephritis supervene upon rheumatism of the lower extremities, and upon rheumatism of the testes after sleeping in a damp bed; and I have observed in a female rheumatism of the limbs, of the ovaria, and of the kidneys, nearly contemporaneous, owing to the same cause, the affection, however, of the former parts subsiding as that of the latter became more prominently developed. This variety of nephritis is generally very obscure. Pains in one or both loins, in the limb of the same side, and in the testes, are very equivocal symptoms, particularly in a rheumatic subject, as they may be either simply rheumatic, or symptomatic of inflammation of the kidneys; but when they are attended by ischuria, or by a very marked diminution of the urine, while there is not a very copious perspiration, and by an albuminous and acid state of the urine, which is voided frequently, and in small quantity, with increase of pain, and which is either very deep coloured, or deposits a rose-coloured sediment, it becomes probable that the kidneys are actively congested or inflamed.

51. b. It is not infrequent to find extensive organic changes in the kidneys of persons who have died of diseases of the heart, consequent upon rheumatism; and who have recently, or at no very remote period, complained of disorder of the urinary functions or organs. These lesions have consisted chiefly of the infiltration of coagulable lymph, at several points of the vascular structure of the kidneys. These nearly solid deposits have given rise to marked, unequal prominences on the external surface of the organ, where they appear as yellowish patches. These deposits of lymph are of various sizes; sometimes sinking deeply into the vascular structure, and approaching nearly the size of a nut or bean. Their limits are distinctly marked by a dark reddish tint of the surrounding tissue. The membranes external to the kidneys, particularly the portions of them corresponding with the deposits of lymph, are generally injected; the calices and pelves are also enlarged or materially narrowed by vascular arborizations and red points. Small collections of pus are sometimes observed in the vascular and tubular structures; and the organ is generally increased in weight and volume, and occasionally, also, more or less indurated. In the more chronic cases of this variety of nephritis, or when the nephritic disorder has preceded dissolution a considerable time, eminences and irregularities of the external surface of the organ are observed; and what had manifestly been the bases of deposits of coagulable lymph are changed into a firm yellowish substance, of the consistence of condensed cellular tissue. In the pits or depressions on the external surface, the fibrous and cellular membranes of the kidneys are so firmly united with each other, and with the subjacent cortical substance, as not to be separated unless with the greatest difficulty. These membranes are sometimes thickened throughout, but much more frequently only in patches where they are also much more opaque. Simple serous cysts are occasionally found in the vascular and cartilaginous bodies in the tubular structure.

52. C. Consecutive Nephritis—\textit{Symptomatic or Secondary Nephritis—Asthenic Nephritis}.—Inflammation principally of the vascular and tubular structures of the kidneys often arise in the course of febrile and exanthematic maladies, especially those which assume an asthenic or malignant form, or in which the blood becomes more or less contaminated. In many of these cases, it is a state of active congestion of the organ rather than that of inflammatory action which takes place; or if it be the latter, it is inflammation of the asthenic kind, described in the article \textit{Inflammation} (§ 54, \textit{et seq.}), and is produced by the morbid state of the blood, or by the superabundance in it of those injurious elements which are usually excreted by the kidneys. M. Raver has described these consecutive diseases of the kidneys under the head of nephritis from morbid poisons; but the affection of these organs is merely an accident or contingency occasionally occurring in the course of certain contaminating maladies, or rarely only in the course of others, and as fre-
quently takes place during paraplectic diseases or after injuries of the spine, as during the progress of those maladies.

53. During the continuance of *adynamic* or *typhoid fevers*, and particularly when the nervous manifestations are prostrated or depressed, and where the blood becomes altered either by the inflammatory process in it of excrementitious matters, or from the insufficient supply of salutary elements, congestion, or asthenic inflammation, not infrequently occurs in the kidneys. In these circumstances both organs are generally affected. The pain in the loins commonly complained of during fevers, and attributed to other causes than to inflammation, or to congestion of the kidneys, often misleads the physician, and, when really proceeding from the vascular condition of these organs, is not generally ascribed to it. In other cases the sensibility is so much impaired before this affection supervenes, that the state of the urine itself, and the phenomena attending its evacuation, are the chief indications of its existence. In these especially, the *suppression* of the urine may be the first indication of it; and then it may be difficult to determine whether or not the suppression be the cause or the consequence of the inflammation; for it may be either. The circumstances in the urine of such cases, is very decided, and by the physician will generally enable him to infer correctly the alternative; if the suppression of urine has been preceded or attended by sopor or coma, or by the supine posture and partial loss of sensibility, the inflammation of the kidneys probably has been consequent upon or aggravated by it; the suppression being the consequence of *congestion*, which may pass into asthenic inflammation; but if this state of the urinary function has preceded sopor or insensibility, or is independent of this state of the nervous manifestations, then is it the consequence of inflammation of the kidneys, and not the cause. It is extremely rare, however, for the suppression or the non-secretion of urine to precede those states of disease; more generally the urine is secreted, its *retention* or *accumulation* in its existing morbid condition being the cause of the affection of the kidneys. In all cases of fever, when the urine is retained in the bladder for some time, or when this viscus becomes distended by it, the superintendence of nephritis should be suspected. Whenever, in the course of low fevers, the urine is remarkably scanty, or of a dark-brown colour; when it ceases or nearly ceases to be acid, or becomes alkaline; when it contains mucus, or blood globules, or albumen; and when the patient complains of pain or difficulty in voiding it, or of pain or of tenderness on firm pressure of the lumbar region, then disease of the kidneys may be inferred; and this interence will be the more likely to be correct, if suppression or retention of urine follow its alkaline character, and it soon ceases to flow. These and the more malignant symptoms become more fully pronounced than previously.

54. *After death* from this consecutive disease, or complication, both kidneys are found congested or inflamed, but one is often more affected than the other. They are always more vascular, redder, and larger than natural. At the surface and in the vascular structure, numerous red points, intermingled with purulent specks, are sometimes observed; and the substance of the organ is of a deeper or darker hue than usual, and softened in parts, or torn with greater facility.

55. *Consecutive nephritis* often proceeds from the absorption of purulent, or sanious, or other morbid matters into the circulation. When these matters pass into the blood, and more especially when they are imbied by the veins, they contaminate this fluid, and the kidneys, being the most active organs in eliminating or excreting them from the system, are especially exposed to their injurious influence. Hence *asthenic nephritis* often occurs in the course of *phlebitis*, especially of *uterine* and *traumatic phlebitis*, of the more acute forms of *tuberculous consumption*, of *diffuse inflations* of the cellular substance, and of *diffuse abscesses*; and, after the rapid absorption of purulent matter from the more chronic abscesses, especially from abscesses of the liver. In these cases, various changes in the urine have been observed. It has been generally alkaline, often puriform, or mucous-puriform, thick, scanty, and ultimately suppressed; a morbid state of the perspiration, *adynamic* fever, sopor, and coma, with other typhoid and malignant symptoms, appearing towards the close of life. In some cases, a large quantity of pus, with some mucus, has been noted in the urine, the affection of the kidneys supervenes; but as it becomes fully developed, so pain in the loins, scanty, painful, and frequent micturition, with the other symptoms of nephritis, is observed, and precede the sopor and other typhoid symptoms, which are the consequence chiefly of the partial or total suppression of urine caused by the consecutive nephritis. On dissection the kidneys generally are found containing, in their vesical and tubular structure, small collections of pus; the structure immediately surrounding these being softened, of a dark or brownish hue, or paler, especially in patches, and infiltrated with purulent matter. Occasionally the tubular structure seems filled with pus, and, in rarer instances, the renal veins have been found inflamed.

56. *Nephritis is often consequent upon the eruptive fevers*, more particularly upon *scarlatina* and *smallpox*. Its connexion with *scarlatina* is of two kinds: 1st. It may appear in the course of this fever; and, 2d. It may not take place until after the rapid subsided, or until the advanced progress of convalescence from it. (a) When it occurs in the course of scarlatina, it generally assumes very nearly the same features as have been noticed in connexion with *typhoid fevers* (§ 7), and is extremely acute, the urine being either suppressed or very scanty, dark-coloured, bloody, or abounding in blood-globules, albuminous, and passed frequently, in drops merely, or in very small quantity and with much pain. These attacks of nephritis are either consequent upon a premature disappearance of the eruption, or on an imperfectly developed state of it; or it complicates the more malignant states of scarlatina, and causes its rapid termination in coma, &c. — (b) Where nephritis appears during convalescence from scarlet fever, it is more frequent of that particular kind which has been called *abdominal nephritis*, or *granular degeneration* of the kidneys, and which I have viewed, since it was first described by Dr. Broun, as a form of in
flammation of these organs; and as such it has also been recently considered by M. Raver. When this state of disease is discussed, then its connexion with scarlatina will be fully noticed.

57. (c) Asthenic nephritis also occurs during small-pox, particularly its confluent and malignant forms. In these cases the urine is very scanty, alkaline, mucous-puriform, or bloody, and sometimes nearly black; or it is altogether suppressed. When this complication of small-pox takes place, all the characters of the disease assume an aggravated or more malignant character, coma and other typhoid symptoms supervening. After death the kidneys are found congested, ecchymosed, partially softened, of a dark hue, and, in rare instances, infiltrated with purulent matter.

58. e. Nephritis, or often consequent of paraplegia; and the influence of this state of palsy in causing it is remarkable, whether the paraplegia proceed from injuries or from diseases of the spine or spinal chord. Nephritis may also be consequent upon coma, especially in low fevers, as above mentioned; while in these maladies, it more commonly produces or aggravates this and other adynamic symptoms than is supposed. When nephritis appears in these cases, it usually proceeds from retention of urine, and the changes caused by this retention; for it rarely takes place when accumulations of urine are prevented. Probably, however, the loss of that portion of nervous power supplied to the urinogenous organs by the spinal chord has some influence in predisposing to inflammation of the kidneys; and in imparting an asthenic character to the disease, which, in these circumstances, is attended not only by retention of the secretion, but also by a very alkaline state of the urine, indicating the existence of disease of the bladder. Indeed, the alkaline, or ammoniacal, or offensive odour of the urine in these cases, arises from the partial decomposition of the mucous and other animal matters in it, while the urine is retained in the pelvis of the kidney and in the bladder. In these cases the structural changes in the kidneys are nearly the same as are met with after other consecutive inflammations of these organs, as already described.

59. f. Nephritis is often consequent of the prolonged disease seated in the urethra, or the prostate gland, or urethra. The frequent and continued irritation of the urinary bladder from inflammatory action of its mucous membranes or of its mucous follicles, may occasion congestion or inflammatory action of the kidneys, owing to the intimate connexion depending on function, and nervous communication. Disease of the prostate gland, when of long duration, or when it interrupts the discharge of urine, is also apt to be followed by inflammation of the kidneys, either with or without cælous formations or gravel, these latter more frequently occurring in the gouty diathesis in connexion with the prostate disease. The pressure, also, of stone in the bladder, by the irritation it occasions in this viscus, and in the neck of the organ and prostate, in connexion with the interruptions it produces to the free discharge of urine, often gives rise to inflammation of the substance, as well as of the cause by the kidney. In some of these diseases, the morbid action seems to extend from the bladder along the ureters to the kidney, as shown by the inflammatory action and its consequences observed in one or both these ducts. Structures of the urethra, more especially where they produce retention of urine, are not infrequently followed by acute or chronic nephritis. As regards all circumstances, in which the disease appears consequent of disorder or structural change of some other portion of the urinary passages, it should be recollected that it is often chronic, sub-acute, slow, and insidious in its progress; that it requires close and careful examination of the physiological symptoms, and of the appearances and states of the urine, to detect it; and that its progress, as well as its accession, is often masked by the symptoms referred to the bladder, urethra, and perinaenum, where they are most severely felt as well as by those attending the excretion of urine.

When nephritis is thus superinduced, its indications are to be found chiefly in connexion with the seats of primary disorder, with the powers of retaining the urine, with the frequency of passing it and the quantity passed, with appearances and characters, and with its partial or total suppression or retention.

60. iii. Of the influence of inflammation of the substance of the kidneys in producing the consequences of the disease, it is necessary to be perfectly noticed, until Dr. Basset directed attention to it in his researches in the granular degeneration of these organs. The consequences which arise from this particular state of disease will be stated hereafter. I shall confine myself chiefly at this place to the consideration of those which more immediately proceed from the states of nephritis already brought under consideration. It must be manifest that, where inflammation is a most severe character, and especially concerned in the performance of the functions of the organ, the discharge of these functions must be remarkably disturbed. It is well known that, like other glands, when the kidneys become inflamed, they experience a remarkable impairment of their functions. The membranes which surround them and support them have the effect of compressing them, especially when their vessels are injected, congested, and inflamed, thereby the urine suffering insensible excreta from the inflammatory state, of performing their usual offices. The deposition, also, of coagulable lymph, either in considerable patches, or as an infiltration of the textures, farther increases the pressure on the vascular and tubular structures, and otherwise interrupts the eliminating action of these organs. Whether, however, impairment, or interruption, or suppression of the functions of the kidneys be thus or otherwise produced, there is no doubt of either the one or the other of these being the consequence of developed inflammation of the proper structures of these organs. Owing to this change—to this interruption—the fluid and saline matters requiring elimination from the blood accumulate in it, and the vascular system experiences a state of excremental pletora, giving rise to impairment of vital energy, to congestions of other viscera, and to effusions into shut cavities and cellular parts. During the course of this disturbance, the blood, by order, and before the blood becomes so impure and so watery as to overpower the tone and
reactive energy of the vessels, and hence to occasion congestion and loss of function of vital organs, a vicarious elimination of a portion of the injurious materials accumulated in the blood takes place by means of the skin and digestive mucous surface, and in the form of aqueous vapour from the surface of the bronchi and air cells. At last, however, if the functions of the inflamed kidneys are not restored, the brain becomes congested or oppressed, and such is the condition of the venous system and the membranes. Hence the suppurative coma which occurs in the last stage of unfavourable cases of nephritis, and which supervenes more rapidly the more abundant and the more impure the blood has been previously to the occurrence of nephritis, as in the consecutive forms of the disease just considered.

61. Even when a vicarious action is exerted by the skin and mucous surfaces during inflammation of the kidneys, yet these are incapable of evacuating several or all of the elements or materials requiring excretion from the blood, and of combining them into those forms which facilitate their discharge. The blood, therefore, must become, not merely loaded with these materials, but farther changed, and even rendered morbid or noxious by the influence they exert upon the hematonic or principal constituents of this fluid. Hence a state of actual cachexia, of a most acute and malignant nature, particularly in respect of its consequences, is developed, the soft solids are ultimately universally contaminated, and the body experiences a rapid dissolution as soon as life departs. During the progress of these changes in the blood, produced by the accumulation in it of aqueous and effete matters, various local diseases may appear as consequences of this excrementitious plethora, and contribute to hasten a fatal result, or concur with others in producing it; or these consecutive maladies may arise if they do not arise upon the removal of the inflammation, and restoration of the functions of the kidneys. Thus, diseases of the digestive organs, particularly of the liver, asthenic inflammation of the lungs, of the brain, of the endocardium, and of the veins or arteries, and effusive effusions, may appear as results of the action of the impure and morbid blood on these organs. Dropy, however, unless the more acute states of it and sudden effusions of serum, does not appear as a consequence so frequently of the inflammations of the kidney already considered, as of the more chronic and peculiar form of disease first described by Dr. Bright.

62. Various other important consequences follow nephritis, and arise rather from the intimate connexion subsisting between the kidneys and the parts consequentially affected, through the medium of nervous association and relations, continuity of surface, and intimate consent and connexion of function. Many other diseases of the urinary and sexual organs proceed from the primary disorder of the kidneys, more especially when such disorder is connected with the formation of gravelly and calculous substances, and with inflammatory irritation of the calices and pelvis of the organ; but to these a stricter reference will be made in the sequel. As to the part performed by slight or partial inflammatory action in the substance of the organ, in giving rise to the formation of gravel and calculi in the kidney, it is difficult to decide. It is not improbable that it may favour these deposits by obstructing the free passage of the urine along the tubuli; but there is much more reason to infer that these deposits take place, independently of pre-existing inflammatory action, from the superabundance in the blood of the elements or materials constituting them; and that when inflammation does occur, it is rather a consequence than a cause of their formation—that they proceed, in the first place, from impaired power of the digestive functions, in connexion with an excessive supply of the articles of food abounding in the chief elements of which they consist, and consecutively of impaired action of the kidneys, probably sometimes in connexion with partial congestions or inflammations.

63. iv. Complications of Nephritis.—It is obvious, even from what has already been advanced, that inflammations of the vascular and tubular structures of the kidneys will both supervene in the course of other maladies, being thus consecutive, and give rise, when it is primary, to various important changes in the economy, both of a local and of a constitutional kind. Owing to these circumstances, nephritis will often present itself in practice as an associated or complicated malady—most frequently, 1st. With inflammation of the mucous membrane lining the calices and pelvis of the kidneys; 2d. With gravel or calculi in the substance or pelvis of the organ; 3d. With inflammation of a portion, or of most of the investing membranes; 4th. With disease of the ureters; 5th. With disease of the bladder and prostate gland; 6th. With stone in the urinary bladder; 7th. With stricture in the urethra; and, 8th. With any two or more of these. As already shown, the disease may be farther complicated with one or other of the diseases, upon which it occasionally supervenes, or which it sometimes produces or develops. It is obvious that these associations of nephritis cannot receive a more particular notice at this place. To several of them attention will be paid hereafter; and others of them are fully treated of in the articles Urine, Urinary Bladder, and Urinary Calculi.

64. v. Prognosis.—The prognosis entirely depends upon the progress that nephritis has made, upon the nature of the predisposing and exciting causes, upon its severity, upon the age of the patient, and upon the circumstances of its being a primary and uncomplicated malady, or consequent of, or complicated with some other disease, either of the urinary organs or of some other viscera. The simple states of nephritis, particularly when occasioned by cold and humidity, or by purgation or emetics, generally yield to judicious treatment; but when the disease is consequent upon other affections of the urinary organs, or upon operations on any of these organs, or supervenes upon some other reason, or when it is so severe as to be attended by suppression of urine, or by incontinence of it, the prognosis should be unfavourable, or, at least, be given with caution and reservation. The prognosis ought, also, to be extremely unfavourable, when the disease occurs in the course of low, aymetric, and exanthematous fevers, or when it is productive of supur or...
KIDNEYS—Inflammation of the—Treatment.

coma, or waen any of the more important changes, either in the blood or in other organs, which it has been shown occasionally to cause, is unequivocally manifested. The occurrence of retention, or of suppression of urine in aged persons, who have been the subject of incontinence of it, or of the more chronic symptoms of urinary disease, or the suppression of the acute attack, upon a slight or chronic state of the malady, is always most dangerous. In every instance, when the symptoms indicate the accession or the presence of suppuration, abscess, or of any other unfavourable consequence of nephritis, are manifested, or even when the disease has not yielded to a judicious treatment within the period assigned to the acute form of the malady; when the urine becomes alkaline, offensive, and purulent, as well as scanty, and the perspirations are urinous and copious, the constitutional symptoms indicating depression of the powers of life, obscuration or oppression of the cerebral functions, and contaminaion of the circulating fluids; and when a severe attack of nephritis occurs in the advanced progress of disease of some other organ, or of low or exanhematous fevers, then a most unfavourable prognosis of the result should be given.

65. When disease, also, of the bladder supervenes on a chronic affection of the kidney, owing to the morbid state of the urine; and more especially if suppuration occur about the neck of the bladder, in consequence of irritation, inflammation, or other lesion of the kidney, a very dangerous state of disease is present, more particularly when it occurs in aged persons, or in those who have been subject previously to disorder of the digestive or urinary organs. In these cases, the disease of the one organ reacts upon the other, and thus both are aggravated to a most dangerous extent.

66. vi. Treatment.—The treatment of nephritis is subordinate to the causes, particular form of taking in, and state of the disease, to the progress it has made, and to the age and constitution and previous ailments of the patient.

67. A. Treatment of primary and simple Nephritis.—(a) When the disease proceeds from a concussion, sudden jerk, contusion, injury, or wound, early and even repeated blood-letting ought to be then especially prescribed, and the patient should be restricted to an antiphlogistic regimen; diluents and demulcents being allowed in small or moderate quantity. Of these, instead tea, but better, the mucilages, the usual emulsions, &c., are the most appropriate. Anodyne or opiate fomentations or poultices may be placed upon the loins; and the patient may have recourse to a tepid, emollient, or slightly warm bath, on the following day. If the pain and other symptoms continue notwithstanding this treatment, or if they be only partially removed, or if symptomatic fever is still considerable, more blood should be taken away; and if sufficient blood be not thus obtained by cupping or by leeches, the former being the preferable method, but the quantity should be preserved without reserve, for too copious vascular depletion is less injurious in this disease than in most others, and much less so than a too sparing recourse to this measure. The smallness or contraction of the pulse should not deter from copious blood-letting, especially if the local and symptomatic pains are severe, and if retching or vomiting is frequent. In these cases, the pulse will become fuller and more developed by depletion.

68. (b) M. Raver remarks, that, if the inflammation is caused by a wound of the kidneys, and the fever has been subdued, and the pain is inconsiderable, and if the discharge of some pus in the urine indicate the supputation of suppuration, blood-letting should be abstained from, and a severe regimen and regular dressings of the wound prescribed. If the suppuration is prolonged, the diet ought to be more generous, as a certain degree of power is favourable to recovery; while too great severity of regimen may retard recovery, and is only applicable when the injury or wound has extended to the peritoneum, or has complicated the nephritis with enteritis or peritonitis.

69. (c) When nephritis is caused by cantharides, by turpentine, by iodine, or by acid diuretics, in too large doses, or too long employed, and the disease is slight, a moderate blood-letting, demulcents, and tepid baths soon remove the disease. If the symptoms, however, persist, these means should be carried still farther, according to the circumstances of the case. Camphor has been recommended when the disease has been caused by cantharides; but it should not supersede blood-letting. It is an excellent adjutant of other means, particularly when conjoined with oleaginous, mucilaginous, or demulcent substances, and given in small or moderate doses wound prescribed. It be more generous, as a certain degree of power is favourable to recovery; while too great severity of regimen may retard recovery, and is only applicable when the injury or wound has extended to the peritoneum, or has complicated the nephritis with enteritis or peritonitis.

70. (d) Nephritis, caused chiefly by cold and humidity, in strong, young, and plethoric persons, requires an active recourse to general and local blood-letting, and the antiphlogistic and emollient means above advised. If the symptoms are merely abated, cupping, or a repetition of it, over the loins, must be prescribed, and demulcents taken by the mouth and administered in enemata. For nephritis from this cause, tepid or gently warm baths, and fomentations, emollient fomentations, and anodynes, are especially indicated. In this, as well as in other states of the disease, the bowels should be kept in an open state; and for this purpose, castor oil, or sweet oil, or both, may be prescribed and administered in demulcent vehicles. In some cases, after the disease has been even for some days apparently subdued, chills or rigours return, followed by pain in the loins, febrile reaction, and other symptoms of a recurrence of inflammation. When this is the case, a large blood-letting ought to be prescribed, unless the patient be far advanced in life; and, in this case, cupping on the loins, and the abstraction of eight, ten, or twelve ounces of blood may be sufficient. When the symptoms lead to the inference that the investing membranes are chiefly affected, then the depletions should be copious, and calomel, with antimonials, or with other diaphoretic, ought to be freely prescribed.

71. (e) Nephritis caused by injury, whether a contusion or a wound, requires a similar treatment to that above advised; but vascular depletions need not, in general, be carried so far as in the acute form. One large cupping over the loins may be sufficient; but it will often be necessary to repeat it; and, although this state of nephritis may not be so severe, it may be more obstinate than that already considered; and when both kidneys are affected,
the treatment should be more energetic. The other means just mentioned are also appropriate in this state of the disease; or the diet and regimen should not be materially different from that directed for the acute form. The use of animal food, and of renunced and spirituous liquors, ought to be especially avoided.

72. \(f\). Chronic nephritis is often removed with much more difficulty than the acute attack; for, as it often has proceeded far before it has come under treatment, and is frequently caused and perpetuated by calculi in the kidney, the most judicious means may produce only temporary benefit. It is generallyrendered more obstinate by the continuance of the habit of its producing usually pursued by the patient during the treatment, notwithstanding the injunctions of the physician to the contrary. Generally one or two cuppings on the loins, with the antiphlogistic regimen, aided by a strict avoidance of animal food and of exciting beverages, will remove the disease, or very remarkably ameliorate it, even when calculi have produced it; but farther measures are often necessary, particularly when it proceeds from this cause. Having, in such cases, carried vascular treatment and other antiphlogistic means as far as may seem prudent, some permanent external derivative will be requisite, in order to supersede the irritation still existing in the kidneys. Issues or setons in the loins, or in the sides of the thighs, kept freely discharging for a considerable time, and the internal use of the preparations of the Diosma, or of the Nea Urs, with demulcents, with alkalies, or with acids, especially the muriatic or nitro-muriatic, according to the state of the urine, which ought always to be carefully and even chemically examined, are often the most beneficial means which can then be advised, particularly if they be aided by a suitable diet and regimen.

73. If either the sub-acute or chronic states of the disease suddenly assume an acute or hyper-acute form (§ 14-17)—a circumstance by no means uncommon—the means advised for acute nephritis (§ 67-70) ought to be most promptly and energetically employed. The treatment of the modified and consequent nephritis (§ 46, et seq.) necessarily varies with the diathesis of the patient, and with the disorders or maladies occasioning it.—A. Nephritis in the gouty diathesis (§ 47) is generally removed by cupping on the loins, and abstracting blood, according to the age, strength, and habit of body of the patient; by derivatives applied to the lower extremities, and by diluents and demulcents containing some one of the alkalies or alkaline earths, and anthrones. Magnesia or soda, with colchicum, or these with cathartics or purgatives, a vegetable or bland diet, attention to the digestive functions, and avoidance of heating and exciting ingesta, are also of great service.

75. In robust and plethoric persons, general blood-letting is often necessary at the commencement of the treatment; and when the inflammatory action is perpetuated by the irritation of calculi or of gravelly matter, local depletion should be repeated, and demulcents, combined as above, should be assiduously employed. When the disease passes into a chronic form, the treatment recommended for chronic nephritis (§ 72) ought to be prescribed, and the infusion of Paracurra Brava, or of the Diosma Crenata (or the Nea Urs), aided by the alkaline mineral waters and external rubefacients, freely employed. When gravelly or crystallized substances are aided, or when their presence in the tubuli uriniferi is interfered, these remedies and the means already advised should be persisted in for a considerable time. This form of nephritis is not readily removed when it assumes a chronic form in old, gouty subjects, or when it has been neglected in an early stage, or in previous attacks. In these cases more especially, much attention is requisite to diet and regimen, and to the state of the evacuations. The biliary secretions should be promoted, and then the constitutional purgatives and potent rubefacients, and the diaphoretics and tonics, are to be instituted, and it is requisite that the most energetic and powerful rubefacients are employed. When the disease has occurred in persons suffering from the disorder under consideration, it is to be treated as a chronic inflammation; and the treatment recommended for chronic nephritis (§ 72) is to be employed.
utive states of nephritis, the secretion of urine altogether suppressed, and both organs affected, particularly when occurring in the course of continued or eruptive fevers, or after the absorption of morbid secretions into the blood, or after injuries of the spine. When this is the case, but little benefit results from cupping on the loins, for other modes of vascular depletion, unless means be used at the same time to rouse the action of these organs. The choice and application of these means are, however, among the most difficult things in practical medicine. Indeed, the practice, in these circumstances, can only be experimental, endeavouring, however, to suit the remedies to the pathological states inferred to exist at the time of prescribing them, and to the sensible qualities of the urine. In most of these cases, especially when the disease is consecutive of paraplegia (§ 58) or coma, the urine is more or less alkaline, and is probably secreted in this state, although the partial decomposition or change of the mucus secreted by the urinary mucous passages may farther increase it. The mineral acids, particularly the hydrochloric, conjoined with hydrochloric ether, and given in tonic, antiseptic, and restorative vehicles, seem to be the most appropriate medicines to these cases. Camphor may also be tried in conjunction with nitre or the chloride of potash; and embrocations containing this substance and the spirits of turpentine may be applied to the loins; or, this latter may also be given internally, in small doses, with the view of exciting the nervous energy of the kidneys and the action of the congested vessels. When, however, the patient is plethoric or robust, and vascular action and tone are not remarkably reduced, the abstraction of blood from the loins by cupping should precede the use of the above remedies, and should be carried as far as the states of vital power and of the circulation may permit. When vascular deplletion cannot be farther prescribed, dry cupping on the loins may still be had recourse to.

79. For the form of asthenic nephritis which sometimes occurs in the course of low fevers, or in consequence of the absorption of morbid secretions into the blood (§ 53–57), the remedies now recommended may be tried, particularly dry cupping, camphor, the chloride of potash, the chlorides, hydrochloric acid and ether, nitre and the spirits of nitre ether, stimulant and rubefacient embrocations and blisters on the loins, or other derivatives; but little dependance can be placed on medicines when this state of the disease is attended by a total suppression of the urine, as observed in the worst cases of it, and more especially if coma or convulsions have taken place.

80. Defin.—Un easiness or pain in the loins, pulsed or cachetic appearance of the countenance, disorder of the digestive functions, more frequent calls to void urine than natural, this fluid contain- ing albumen, and being of less specific gravity than usual, owing to a diminution of its solutes and of urea, droppy or some visceral disease appearing in connexion with the morbid state of the kidney, of its vascular influence, and of its digestive, excitatory, and secretory action on the body. When the urine, after cupping, is still scanty, and contains albumen, with a more cold, or a more weak pulse, the patient may be considered cachetique, a disease frequent in children; it is not uncommon in young persons, and often associated with the morbid state of the intestines, or of the digestive organs.

81. Pathol. Charact.—A morbid state of the blood, characterized chiefly by the presence of urea and deficiency of albumen, and of hematosis, in connexion with lesion of the circulation, minute glandular bodies, and [altered] structure of the kid- neys, with various organic changes in other viscera, and generally with severe effusion into the cellular tissue and sub cutaneous scabs.

82. A general idea may be formed from the above definition of the view I intend to take of this disease, which has attracted much attention since it was discovered by Dr. Bazin but not more attention than its real importance deserves. Although medical writers of high authority have fully investigated this malady, still certain topics connected with both its patho- logy and its treatment, the particular tissue of the kidneys primarily affected in it, require further elucidation. Indeed, the connexions subsisting between it and morbid states of the blood, and between it and many visceral maladies, still require a full exposition, and to these topics farther notice will be directed in the sequel.

83. i. Description.—Cachetic nephritis assumes two forms, the Acute and the Chronic, the one gradually passing into the other, although sometimes sufficiently distinct, in respect of the course of individual cases, to warrant this distinction, which has been made by both Dr. Christison and M. Rayer. The acute form is frequently febrile, or attended by marked vascular reaction; the chronic is non-febrile, and although the pulse may be accelerated, it is usually compressible or soft, or even small and weak. The symptoms may be acute at the commencement, but pass into those of the chronic in the course of the disease; and after having thus assumed the chronic state, exacerbations of febrile states may occasionally take place; but in either form, especially in the chronic, it may present a variety of aspects—numerous modifications—according to the previous circumstances, disorders, or predisposition of the patient, and to the various affections either associated with it at its commencement, or appearing in its progress.

81. A. Symptoms of Acute Cachetic Nephritis. —This form of the disease is frequent among children after scarlatina, especially during cer- tain epidemics, and also in adults, after exposure to cold and humidity, and to sudden changes of temperature; but is much less common than the chronic. It often is ushered in by shivering or chills, followed by the usual symptoms of fever, particularly a hard pulse, heat and dryness of the skin, and restlessness. A dull aching, or pain, or a sense of un easiness or of weight, or of constriction, is always felt in the loins, sometimes more in one side than in the other; but M. Rayer believes that these feelings are never so severe as in simple nephritis; nor are they attended by retraction of the testes, nor by pains darting in the direction of the ureters. Dr. Christison, however, has
observed, in some cases, pain extending down the inside of the thighs and to the genitals. At the same time with the occurrence of these symptoms, the urine quickly becomes scanty, occasionally nearly suppressed, highly albuminous, and occasionally even bloody, or of a red-dish colour, resembling the washings of fresh meat. It is always acid; and its specific gravity is often above, seldom below; that of healthy urine, the proportion of urea and of the saline ingredient not being materially altered, according to M. Raver; but such is the case only at the commencement of the disease. When allowed to rest, the urine deposits a filamentous substance, apparently of a fibrinous nature. The odour of the urine is feebly urinous; but at the end of twenty-four hours it resembles that of beef-soup. When the albuminous and sanguinolent urine is first voided, it may be seen by aid of the microscope, suspending a number of blood-globules, also the globules of mucus and minute lamellae of epithelium; all which, with the fibrinous substance, forms a sediment when it is left some time at rest. There is frequently distress, or even pain, in voiding the urine, occasioned by sympathetic irritation of the bladder and urethra, increased by the difficult passage, in some cases, of the fibrinous substance along the urethra; and the calls to pass it are more frequent than usual. The quantity of urine is much less than that of fluids taken. There is always more or less fever. The tongue is furred or loaded, and the bowels constipated. Nausea and vomiting often occur, sometimes with pain across the epigastrium, and cough is occasionally present.

85. Very soon after these symptoms have been developed—generally within twenty-four or forty-eight hours—signs of drooping effusion appear, and proceed with great rapidity, affecting first the eyelids and whole face, or the limbs, and extending to the other parts of the body. The skin is hot, and does not put, unless after very firm pressure. If blood be drawn at this time, it is always straw-coloured, very remarkably so, and the serum is occasionally milky. At the commencement of the disease the serum coagulates nearly as in health, but in a very few days the coagulum furnished by the serum is much less firm, and this fluid becomes specifically lighter. The greater the quantity of albumen in the urine, the lower is the specific gravity of the serum; and as the albumen becomes less abundant in the urine, so the density of the serum increases. According to the researches of Dr. Christison, urea may be detected at an early stage of the disease in the blood.

86. The terminations of the acute form of the malady are, 1st. In restoration to health; 2d. In the chronic state; 3d. In coma, or convulsions, or both; 4th. In pleurisy, or in inflammation of some other serous surface; and in death, usually preceded by one or other of these more acute affections.—a. Recovery often takes place rapidly under judicious treatment, especially after scarlatina or during pregnancy; and is commonly indicated by profuse and general perspiration, by a copious discharge occurring, sometimes by a diminution of the albumen, and increase of the urea and salts in the urine, and by a subsidence of the febrile symptoms and of the anæmous swellings.—b. The chronic state is generally shown by the subsidence of the febrile and acute symptoms, and often of the anæmæ; the urine, however, still containing albuminous.—c. The occurrence of coma, or convulsions, or both, is generally a fatal indication.—d. The appearance of pleurisy, pneumonia, or pericarditis, or of any other visceral inflammation, or of effusions into shut cavities, is always a dangerous circumstance, and even in their milder states renders recovery protracted, or even doubtful, especially if the urine still continue albuminous.

87. B. Symptoms of Chronic Cachetic Nephritis.—This form of the disease is sometimes consequent upon the acute, but it is incomparably more frequent without any febrile or active stage—latent and obscure in its origin; and it is a very much more common malady than the acute. It generally occurs in persons of an original or an acquired constitutional taint, or in those whose vital powers have been depressed or exhausted by some injurious function and circulating fluids deteriorated by previous disorder (§ 141), or by exhausting, depressing, or other injurious circumstances, as exposure to cold and humidity, insufficient or unwholesome nourishment, &c. For a long period, there is no disorder sufficiently severe to withdraw the patient from his usual occupations, or even to attract particular notice, until gradually increasing debility, or an unhealthy or pallid countenance, alarms him or his friends; and then, if the medical adviser is alive to the nature and extent of the malady, the urine is found specifically lighter, and more or less albuminous, its solid ingredients being deficient. Not infrequently, almost contumaciously with, or rapidly consequent upon debility, pallor of countenance, or still more manifest cachexia, some serious visceral disorder or disease is developed, and proceeds pari passu with, or even outstrips the renal malady and the symptoms by which it is indicated. Dr. Christie remarks, that, in cases apparently the most obscure in their origin, the urine has been very long scanty; or, on the other hand, too abundant, or occasionally of a cherry-red colour from a little blood, or that it was passed frequently, and with difficulty or with pain, or that there were frequent gnawing pains in the loins or flanks, extending at times to the thighs or groins. He further remarks, that no symptom is so invariable, or indicates so truly the commencement of the disease, as the patient being regularly awakened once or oftener in the night by the call to pass water.

88. The disease may thus advance in obscurity, particularly in serofulous persons, for months, or even for years, until either the state of the urine attracts attention, or some incidental cause aggravates the disease, or renders it more acute, or develops a partial or general anæmæ, or some associated or secondary malady. It is, however, generally indicated by reduction of strength, slight emaciation, by pallor or sallowness of the countenance, by a dry state of the skin, and want of perspiration during exercise, a frequent tendency to drowsiness, various dyspepsias, a languid state of digestion, and occasionally sickness, or even vomiting in the morning or when first awakening from sleep, slight thirst, and the other symptoms above mentioned (§ 87). The counte-
KIDNEYS—CAELECTIC INFLAMMATION OF THE.

...

93. A. The urine, when first passed, is generally slightly acid, but in a few cases it is neutral, or even alkaline. It is always pale in the advanced or chronic stage, sometimes more or less opaque, or like whey, suspending small, whitish flocculi. Its odor is faint, and very different from that of the healthy secretion; its specific gravity is generally below, sometimes very considerably below, that of the urine in health. The want of transparency is occasionally owing to fatty matter held in suspension, which may be removed by means of sulphuric ether, when the urine becomes clear. Examined by the microscope, albuminous urine generally exhibits numerous small, thin lamelle of a whitish color, often blended with mucous matter, which is either amorphous or in the form of globules. A vessel containing this urine usually presents on its sides or on the surface of the fluid a number of bubbles; and when air is blown through a tube into it, a multitude of large bubbles are formed. The application of heat forms it in an albuminous coagulum, or small coagula, which are remarkable in proportion to the quantity of albumen. Nitric and other strong acids, and a solution of the bichloride of mercury, produce a similar effect. The yellow excreta of potassium and iron also coagulates albuminous urine, if it has been previously acidulated with acetic acid. A sediment sometimes forms after it has been passed, which is commonly lithic acid or the lithate of ammonia, and which is redissolved at a gentle heat, lower than what is required for the coagulum containing albumen. The urine deviates from the healthy standard in containing an unusually small quantity of its solid ingredients. This urine is also more prone than healthy urine to decay, a decidedly ammoniacal odor being occasionally soon developed after it has been discharged.

90. Dr. CHRISTISON remarks, that this urine at the boiling point sometimes forms a gelatinous mass; more frequently it becomes a soft pulp like thin custard; often, too, when the quantity of albumen is less, there are distinct flakes in a separable fluid. The earlier the stage of the disease, the more is the urine loaded with these flakes, and the more does it form of a pulp or gelatinous mass. Nitric acid acts in like manner; but it separates the albumen always in the form of flakes or pulp. It is advisable to use the tests both of heat and of nitric acid; for, if the urine be ammoniacal, heat may fail of coagulating the albumen, although the quantities of albumen are considerable; and alone may occasion a flaky precipitate where there is no albumen, owing to the superabundance and consequent separation of earthy phosphates—a deposition which nitric acid will both prevent and remove. Also, nitric acid alone may occasion a flaky precipitate of lactic acid, which, however, is redissolved by an elevation of temperature, while albumen remains insoluble. To avoid all sources of error, the urine should be tested before it decays or becomes ammoniacal. In the early stage of chronic caelectic nephritis, the chief characters of the urine are, a moderate reduction of its specific gravity, a strong, albuminous impregnation, and a material diminution of the daily discharge of solid ingredients—of the urea and saline substances.

91. As the disease proceeds, the albumen often is diminished in the urine; and even suddenly and for a time disappears. When it has made considerable progress, the quantity of urine is often but little reduced; frequently it exceeds rather than falls short of the healthy ratio; and in some cases, the amount has continued for weeks as much as double or treble that of health. But the quantity may be diminished either when the exciting causes develop an acute state of the disease in the course of the chronic, or when coma, stupor, or intermission of albumen is evident. When the granular degeneration has reached a certain or great extent. As disorganization advances, the density of the urine sinks from about 1021 to 1026, which it usually presents at an early stage, to 1016, 1014, or 1012; and when it has proceeded far, the density is generally as low as 1010 to 1007, even although the quantity be rather under than over the natural standard. The lowest density which Dr. Cresson has ever noted, where the quantity was not in excess, was 1004. A low density, he remarks, is an essential character of the urine in the middle and final stages, whether the quantity be great or small; and the density goes on diminishing as the disease advances. When disorganization of the kidneys has proceeded very far, the albumen very frequently, if not generally, disappears altogether, and may not reappear unless acute symptoms occur. In this stage the chief characters of the urine are, a great reduction of its specific gravity, and an equal reduction of the daily discharge of solids—of urea, lactic acid, and salts, frequently associated with the presence of albumen in small quantity.

[M. Raspail discovered that the genito-urinary epithelium, as well as that of other mucous membranes, undergoes continual desquamation in the natural state, and that in certain diseased conditions, as that of the disease under consideration, this physiological process acquires morbid activity, the scales that are thrown off appearing under the microscope of extreme delicacy, and transparent, except in occasional instances. With respect to the presence of albumen in urine, the combination of the two following tests would seem to be necessary to establish it: 1st. Coagulability by heat and nitric acid; 2d. Non-precipitation by acetic acid. Thus, urine containing milk or caseine would coagulate by heat and nitric acid, although it contained no albumen; but it would not coagulate by acetic acid on the addition of acetic acid. Again, if albuminous urine is alkaline, it will not ordinarily lose its transparency by the action of heat, unless the quantity of albumen be very great, but it will instantly coagulate on the addition of a small quantity of nitric acid. A quantity of acid, however, barely sufficient to neutralize the alkali present, will not always suffice to render albuminous urine coagulable by heat:
the quantity of acid should be considerably in excess. Where alkaline urine is rendered turbid by heat, Mr. Kass has shown that the loss of transparency is usually due to the precipitation of phosphates, as is proved by its complete restoration on the addition of nitric acid. Dr. Christie states, that where the urine is muddy, from the deposition of lithic acid and the lithate of ammonia, heat will remove the turbidity, by dissolving those compounds: as nucius causes muddiness, and will not disappear under the action of heat, it should be removed before the test is employed. It should also be borne in mind, on the other hand, that precipitation by nitric acid alone will not prove the matter thrown down to consist of albumen. Such precipitate may be composed of lithic acid and lithate of ammonia; the matter thrown down by nitric acid may consist of albumen, uric acid, and urate of ammonia; but microscopic inspection (with which every physician should make himself familiar) will, in such cases, prevent error, by disclosing the lamellar, corrugated, and peculiar appearance of albumen, crystals of lithic acid, and an amorphous powder, convertible into similar crystals by nitric acid (lithate of ammonia); we can ascertain the excesses of albumen by precipitation by acetic acid and evaporation. If albuminous urine be red-coloured from the presence of hæmatosine and the globules of the blood, nitric acid, in a great measure, discolours it, by precipitating all the foreign principles together: the microscope will detect the globules, either in the urine, or imprisoned in the flakes of albumen.

The quantity of albumen present in the urine in this disease varies exceedingly in different cases, causing, of course, different appearances in the coagulum. In some instances, its presence is barely perceptible; in others it amounts at least 1/30 of a part of the whole fluid; in 2. Strongly coagulable—where a precipitate distinctly separates by heat, and yet occupies, in twenty-four hours, the whole; or nearly the whole fluid; 3. Strongly coagulable—where the precipitate, in twenty-four hours, occupies half the volume of the fluid; 4. Moderately coagulable—where it occupies a fourth of the fluid; 5. Slightly coagulable—where it occupies an eighth of the fluid; 6. Pinkly coagulable—where it occupies less than an eighth of the fluid; 7. Hazy by heat—where the urine becomes cloudy, but does not form visible flakes a few seconds after being boiled" (p. 44). There are other tests for albumen, such as tannin, ercasote, alcohol, ferrocyanate of potassa and acetic acid, bichloride of mercury and acetic acid; but they are inferior in accuracy to those already mentioned. We would urge upon practitioners the importance of microscopic inspection of the urine, as it is indispensable for the recognition of the globules of pus, mucus, or blood, and of the particles of lithic acid and lithate of ammonia, which are often thrown down in union with the coagulum. It is now generally admitted by chemists that healthy urine contains no albumen, but that it is found to be present, in greater or less amount, in a considerable variety of local or general derangements of the system, either owing to a morbid state of the blood, or to a defective exercise of its secretory function, or, perhaps, subsequent adixture. We find albuminous urine, for example (see Brit. and For. Med. Rev., July, 1839), in—1. An abnormal condition of the blood, dependent on scurvy, purpura, hemorhagic eruptive fevers, and perhaps absorption of peculiar albuminous matter; 2. Dropsical effusions. II. In lesions of the genito-urinary apparatus, either, 1. of a functional kind, as idiopathic hæmaturia, diabetes, secretory excitement of the urinary organs and passages, produced by articles of food, or by medicinal agents, and active renal hyperaemia; or, 2. of an organic nature, which cause albumen to be formed subsequently to the act of secretion, as in blood thrown out in cases of contusions, wounds, calculous lithiasis, cancer of kidney, ureter, renal syphilis, fungous tumours, acute cystitis, papillary dropsy, urothelial cystitis, uric acid stones, and albumous diathesis.

The chemical changes which take place in the urine during the diseases of the kidneys are, as a general rule, in the same direction as the morbid changes in the blood, which the disease causes. Hence the urine in healthy kidneys is the same in chemical composition as the blood, but when albumen is thrown out in the urine, the blood contains less quantities of albumen, and other morbid changes also take place. Inflammation of the kidneys is attended with a great increase of uric acid, and a diminution of the proportion of uric acid to albumen; also, the albumen is more coagulable, and the urine contains a greater quantity of the albuminous matter. The albumen is increased in the urine, and sometimes culture proves that the urine is diabetical, and that the urine was secreted by the kidneys. This albumen is increased in the urine, and sometimes proves that there was no serious organic change. Temporary albuminuria, Dr. W. supposed, may be produced by congestion of the kidneys brought on by cold, intense heat, or cold, and often complicated with other affections, and disappearing with them, sometimes, however.
leaving behind a cacoephalic deposite, which weakens the functions and impairs the structure of the renal organs. Dr. W. also believes that there are cases of albuminaria, connected with some amount of structural disease, which are far from proving fatal, and which are not inconsistent with a considerable amount of health and duration of life. — (Loc. cit.) It has also been proved, by the observations of M. Solon, that the urine in one eleventh of patients affected with acute diseases may be expected to become albuminous at some period or other before their recovery, owing, probably, to a modification of secretion, occasioned by nervous influence. It remains, perhaps, to be proved whether these cases are to be regarded as instances of a tendency to granular deposit, arrested along with the local and general reaction which it accompanies, or the result of an accidental functional disturbance in the renal apparatus.

It is unnecessary, however, to enlarge on this point. In the present state of our knowledge, we are hardly authorized, we think, in inferring the existence of a special lesion of the kidneys from the mere presence of albumen in the urine. All the circumstances are to be taken into account, which are known to give rise to the presence of this proximate principle in the renal secretion.] 92. b. Dropsical effusion into the cellular tissue, or into shut cavities, or into both, generally takes place in the course of chronic as well as of acute cachetic nephritis; but the alterations of the urine described above may continue for many months before it appears, and without being attended by any disturbance besides debility, impaired appetite, and an unhealthy appearance of the countenance. However, if the patient be not carried off by some casual disease, or by some of the attendant or contingent maladies which so frequently complicate cachetic nephritis, he will certainly become dropsical, sooner or later. Anasarca is the most common form of dropsy, the eyelids and face becoming puffy in the morning, and the ankles and feet oedematous in the evening. When edema of the lower extremities is caused by this malady, it does not so readily or so entirely subside in the morning as when it is produced by disease of the heart. M. Rayer justly remarks, that nephritic anasarca is more sensibly and rapidly aggravated by exposure to cold air than any other form of anasarca; and I have observed the chronic form of the nephritis disease suddenly changed into the acute by this cause, with a rapid increase of the anasarca, and with effusion into the serous cavities. Ascites not infrequently supervenes, especially when disease of the heart or liver is associated with disorganization of the kidneys. Effusion into the pleuritic and pericardial cavities sometimes also occurs in the advanced stage of this malady. Urea is generally detected in the effused serum, besides albumen and the usual saline substances.

93. e. The blood undergoes remarkable changes in this malady, especially in the advanced stage, as Dr. Christison has very ably shown. I believe that this fluid is affected at an earlier period than is usually considered, and generally before any dropsical effusion takes place, if not before the urine itself, or even the kidneys, betray disease. This, however, cannot be readily determined; for the state of symptoms does not always indicate the propriety of blood-letting, and the patient rarely has recourse to medical aid at so early a period. The questions are, whether or no the changes in the blood are consequent upon, and caused by those of the kidneys, or whether the latter depend upon the former, or whether both proceed either cotemporaneously or successively from some other state of disorder. These must be adverted to hereafter; at present I must note only the alterations which take place in the blood in connexion with this malady. The serum of the blood is reduced in density, has more or less of a milky appearance, and it contains less solid matters. The amount varies in different cases — from 1060 or 1081, the density of health, to 1022, 1029, or even 1019; and the solid contents being reduced from 100 or 105 in one thousand, to 68, 64, or even 61. The reduction is considered by Dr. Christison to affect the albuminous equally with the saline ingredients. It occurs only where there is an abundant discharge of albumen with the urine; but then invariably, owing to the loss of albumen, the serum conglutates loosely when heated. This physiologist, established, as early as 1829, an important fact, which has since been confirmed by several writers, namely, the presence of a large quantity of urea in the blood. He states that urea is invariably found in the serum at all stages of the disease where the daily discharge of it by the urine is materially diminished, that is, to about one third of the natural amount. Hence it may be discovered in the early stage, if the quantity of urine have not been much increased by incidental causes beyond the being abnormal at this period; but if the urine be thus increased, it may not be detected, or traces of it merely. 94. The proportion of fibrin in the blood is commonly increased in the early stage of the chronic malady, although not so greatly as in the acute form. Dr. Christison considers the quantity of dry fibrin to vary in healthy blood from 25 to 52 parts in ten thousand; but in the acute state, or stage of the disease, he has seen it as high as 82, and as low as 30 parts, the variation being entirely depending upon the degree of general vascularity of the local inflammation which is present. The proportion of haematoxine or of colouring matter he believes not to be materially affected at an early stage, when the patient has enjoyed good health previous to the attack; but such a state of health I consider rarely to exist just before cachetic nephritis is produced — rarely before even the acute form of the disease; many of the supposed cases of this form, occurring in healthy persons, being actually cases of simple nephritis, which also is often attended by a slightly albuminous state of the urine. I have never seen a case of this malady in a person who was quite healthy just before its commencement. All that is known of the state of the blood in the early stage is, that the serum is deficient in albumen, and that it generally contains more or less urea; and that the proportion of fibrin is often increased.

95. d. As the disease advances, the blood presents much greater changes than the above: 1st. It separates into a less bulky clot rel-
nately to the quantity of serum, which is generally not so lactescent as in the early stage. The coagulum is also not so frequently buffed or cupped as in this stage or in the acute state; but it often assumes these appearances when general reaction or local inflammation supervenes. In many cases the clot is remarkably small and contracted, forming scarcely a fourth part of the whole weight of the blood. 2d. The density and solid contents of the serum, which were much reduced in the early stage, gradually return to the healthy standard, or even exceed it at a more advanced period, unless when reaction occurs, and when the urine becomes highly coagulable. In the most advanced stage, where there is very little coagulability of the urine, the density of the serum may amount to 1030, and the proportion of the salts and albumen to the entire blood may be as high as 970 in ten thousand, the healthy standard being 280 to 800 according to Laceart, and 816 to 853 according to Christison. Where, however, reaction or inflammation has occurred in this stage, both the density of the serum and the proportion of the solids are greatly reduced. 3d. The area often disappears from the serum in the middle stage; but it commonly reappears in the most advanced stage, and is sometimes present towards the close in larger proportion than ever; this is owing chiefly to the quantity of urea and its combinations passed in the urine during the twenty-four hours at these different periods of the disease. 4th. The fibrin is usually in natural proportion after the early stage is passed, and becomes abundant only when reaction is produced and when the blood is decidedly buffy. Dr. Christison states it to vary from 27 to 43 parts in 10,000 as the malady proceeds, and from 55 to 85 parts where reaction or inflammation occurs, the clot being thickly buffed. 5th. During the progress of the disease, the colouring matter remains gradually but rapidly reduced; and ultimately, if the patient be not carried off by some severe complication, it forms less than a third of the healthy average. In some cases the reduction is partly owing to blood-letting, but it is quite as great where no vascular depletion has been practised. On examining the blood with the microscope, the red globules are observed to be less numerous than in health, and mixed with them are seen other globules of a whiter colour and of a larger size than they. Doctor Christison observes at this stage there is no preternatural disease which so closely approaches haemorrhage as this in impoverishing the blood. It thus appears that, in the advanced stage of chronic cachetic nephritis, the proportion of haematosine in the blood is invariably and greatly reduced; the other morbid changes are variable; the solids of the serum are most frequently defective, but sometimes in excess; and often, especially if the disease be very far advanced, the serum also contains uric acid. 82. In the four cases of Bright's disease which the author has described, the blood in four cases of Bright's disease with the following results. (See table.)

Christison, found as the result in 13 cases of analyses of blood in Bright's disease, that the water varied from 808 to 837 parts in 1000, the average composition of healthy blood being 775; the solid constituents, from 113 to 191 (average in healthy blood, 224.3); fibrin, from 2.7 to 85 (average in health, 3.8); of blood corpuscles, from 56 to 133 (average of healthy blood, 137.1); of residue of serum, from 52 to 97 (average in health, 83.4). Andrews and Gayarre have arrived at very similar results.

96. The leucophaeotic, or sallow and bloodless state of the countenance, characterizing the progress of the malady, is owing to the changes in the blood. A pale, transparent, waxy hue is gradually induced; or a peculiar dingy or brownish tint, which is most frequently observed in persons of a dark complexion, although sometimes also in those who are fair, and readily suggests the probable existence of this malady when seen by the observing physician.

97. Besides the above changes and symptoms, there are generally a marked diminution of the perspiration, and more or less dyspnoe: there are sometimes also vomiting and diarrhoea. However profuse the latter may be, it rarely causes any sensible diminution of the dropssial effusion when this has taken place. The dyspnoe is generally owing either to bronchitis, to pulmonary edema, or to hydrothorax, or to some other affection of the lungs or heart, which may have been antecedent to, contemporaneous with, or consequent upon the renal disease. 98. c. The duration of chronic cachetic nephritis varies from a few months to several years. The time of its commencement is always ascertained with great difficulty, as patients frequently do not apply for advice until dropsy appears. [When once the characteristic changes take place in the urine, some form or other of dropsy, generally anaesarea, may be expected to occur, with much confidence, unless some intercurrent disease carry off the patient. When effusion does take place, it is impossible to say truly how long he may survive. In most instances, the dropsy continues until death, presenting, like the disease of the kidneys, remissions and exacerbations at longer or shorter intervals, or, perhaps, occasional amendments so considerable and so durable that the patient is enabled to attend to his affairs without interruption for months, or even years; and until the disease, assuming a more active form, confines him to bed, and then terminates fatally, more or less rapidly, in consequence of some secondary malady, as some cerebral affection, or pleurisy, pneumonia, pericarditis, gangrenous cysterns, or obstructive diarrhoea, with or without vomiting and fever. 99. C. Appearances of the Kidneys after Death. —These appearances have been very fully described by the authors already mentioned, and especially by Dr. Bright, Dr. Christison, and
M. Rayer. The last-named writer describes six forms of organic lesion—two, more especially, belonging to the acute, and four to the chronic disease—presenting features more or less distinct or peculiar. But these forms of lesion may be found united in the same case when the disease has attacked, successively and at longer or shorter intervals, different portions of the two kidneys. In almost every instance both kidneys are affected, although very often unequally. In one case only have I seen in the one organ a very slight alteration when the other was very remarkably diseased.

100. First Form.—The size and weight of the kidneys are very much increased—from 4 ounces, their ordinary weight, to 8, or even to 12 ounces. Their consistence is greater, but they are not indurated; and their surface is morbidly red, and spotted over with a number of red points of a deeper colour than the rest of the organ. On dividing the kidney, the increase of bulk is found to be owing to an increase in the solid substance, which exhibits numerous red spots similar to those visible on the surface, and which, according to M. Rayer, correspond to the glands of Malphigii, highly injected with blood. I have found these glands not only injected, but their central cavities either obliterated or filled with a whitish or yellowish granular matter, which I have considered to be albuminous in its nature. The tubular structure, compressed between the muscular prolongations of the cortical and vascular substance and the enlarged or tumid Malphigian bodies, is of a duller red, and its striae are less apparent than in the healthy state. The mucous membrane of the calices and pelvis is sometimes injected, and exhibits vascular arborizations on its surface. This first stage of the disease is rarely observed, as it seldom proves fatal until ulcerative changes have occurred. It should not be confounded with congestion consequent upon disease of the heart or upon other maladies, more or less simple nephritis, in which latter the kidney is harder and redder, and almost always presents purulent points disseminated through its substance (§ 36).

101. Second Form.—The volume and weight of the kidneys are still increased; but their consistence is not quite so great as in the first form. The lobules are more distinct than in health. The special character of this form is the very remarkable commixture of anemia and hyperemia, which gives a marked appearance to the surface of the organ. On incision, the cortical structure is found still swollen, but it is now of a pale yellowish hue, spotted with red; and there is a marked line of demarcation between it and the tubular structure, the colour of which is reddish-brown.

102. Third Form.—The kidneys are still larger and heavier than in health; but they do not present any red patches or marked appearances. The cortical substance, both on the surface and when divided, exhibits a tolerably uniform pale or whitish-red colour, passing into yellow. In some cases it is still paler, and closely resembles the hue of the flesh of the ccl. Minute vessels, injected with blood, appear here and there, and more rarely small brownish patches or large whitish granulations, produced by an old deposition of lymph. The papillae of the tubular structure often present red indentations; and the mucous membrane of the pelvis and calices is sometimes thickened, and here and there injected; but these latter changes are also found in simple nephritis.

103. Fourth Form.—This form is what has been designated by Dr. Basseur the granulated texture of the kidneys. The size and weight of these organs are still increased. Their external surfaces, usually of a yellowish colour, are dotted, and sometimes covered with minute red or whitish or brownish spots, which are often elongated, appearing as if small portions of milk curd had been irregularly spread over them. These granulations are generally most numerous and distinct at the two ends of the organ; they are not prominent, the surfaces of the kidneys being quite smooth, but are imbedded in the cortical substance. On dividing the kidney from its convex to its concave side, its cortical structure exhibits, as in the second form, a yellowish colour, which contrasts strongly with the red line of the tubular substance. The cortical structure is swollen, and occupies a considerably larger space than in health, particularly in its prolongation between the cones. The milk-white spots, or granulations of Dr. Basseur, instead of being rounded and distinct from each other, as they usually are on the outer surface of the organ, now appear like irregular flocculent lines, which seem to be continuous with the divergent striae of the tubular cones. When the incision has been well made in the direction of these striae, this arrangement is very distinctly seen, especially at the periphery of the kidney and the base of the cones, where the granular degeneration is generally most conspicuous. In some cases the granulations, although very distinct on the surface of the organ, can hardly be observed in the substance of the cortical structure; while in other cases they are scattered through every portion of it, even to the small prolongations which penetrate into the bases of the tubular cones. The granulations become more distinct if the kidney has been macerated for some time in water; their dull white colour then stands out more obviously from the surrounding cortical structure.

104. Fifth Form.—The kidneys are larger, heavier, and have their lobules more distinctly marked than in the healthy state. They appear as if a great number of minute granis of the semolina were sprinkled on their surfaces under their soft, indistinct, yellowish cortical substance. These minute granules are Malphigian glands enlarged by albuminous infiltration, and are distinct from the yellowish particles sometimes observed in the cortical substance, which are also small granulations of lymph, accidentally met with in this and in other varieties of nephritis. This form of lesion is much more rare than the preceding; but, like them, are generally attended, during life, by dropsy.

105. Sixth Form.—This corresponds with the third variety described by Dr. Basseur. The kidneys are sometimes larger, but often smaller than in the healthy state. They are hard, and more or less irregular and tuberculated. Few, or perhaps none at all, of the milky spots or granulations are observed on their surfaces; but a certain number is always found when an incision is made into the cortical structure.
The surfaces of the organs are indurated, corrugated, and mammulated; but, although studied over with minute asperities, they do not exhibit the genuine granulations of Bright. In some cases, however, the anatomical characters of this form of the disease are so closely alike to those observed after simple chronic nephritis (§ 22), that it would be scarcely possible to point out the distinction between them if the phenomena presented during the life of the patient were not taken into the account.

In this advanced stage of the disease the investing membranes are almost always thickened, at least in several points, and strongly adherent.

106. The other changes of structure sometimes observed in connexion with the above forms of lesion are neither very remarkable nor necessarily connected with them. They may occur in any of the varieties of nephritis. Alterations of the urters, urinary bladder, prostate, and urethra, are merely evidences, and are sometimes observed. But extensive changes of the lungs, heart, stomach, intestines, liver, serous membranes, &c., are very often found in addition to those existing in the kidneys, and are either primary, or consecutive upon the renal malady, and in either case more or less intimately connected with it. To this subject, however, more particular attention will be directed hereafter.

Droplastic effusion most commonly exists either in the cellular tissue or in the split cavities, and much more rarely in the vessels of the brain or the subarachnoid canal. The quantity of fluid effused is generally large. Sometimes the cellular tissue contains a gelatinous fluid instead of serum.

107. The above lesions, with the exception of those found in the first and fifth stages of forms of the disease, are nearly such as are described by M. Raver. Besides these, however, there are various other alterations of the kidneys and urinary passages, which are occasionally seen in connexion with them. Of these, the commonest are the granular deposits, and those with the disease seem to be congestion or fibrous concretions in the emunctory veins, and signs of inflammation or of its consequences in these veins; but these have not been observed either frequently or with requisite precision.

The granular deposits and other changes described in the second and other forms of lesions above enumerated, are chiefly consequences of those described in the first form of the changes in the Malpighian bodies, and in the cellular structure generally, which, owing to the deposits of albuminous-like matter in them, present different appearances, according to the amount of such deposits, and of the alterations of surrounding tissues occasioned by them. These alterations have frequently reached their farthest limits before death occurs, and before they come under observation.

108. I have already stated (§ 100) that the granular deposits first noticed by Dr. Bright in connexion with dropsy, and described by him by the name of "granular degeneration of the kidneys," appear to originate in the albuminous bodies of Malpighi. Since the time of this anatomist, and more particularly by Ferrein, Bertin, Schumanski, Eysenhardt, and Marpes, the Malpighian glands or bodies have been viewed as the structure more immediately concerned in the secretion of urine. As such they have been described by Meeckel, Cloquet, and others, who observe that these bodies, glan-

109. From what has been stated above (§ 100), I infer that inflammation of the Malpighian corpuscles takes place in echecistic nephritis; that an albuminous deposit forms in them, giving rise to a granular appearance; and that, as the changes of these bodies and of the cortical structure advance, the other tissues are thereby altered more or less, until at last the tissues compressed by them become condensed or atrophied, and the substance of the organ farther altered in consequence. These changes in the kidneys, which are nearly the same in both, especially the earliest changes, as the inflammatory state of the Malpighian corpuscles, and the commencement of granular deposits in them, are excited by previous changes in the blood, as contended for hereafter (§ 114, et seq.); and the associated maladies arise chiefly from the same cause, and from farther alterations in it, owing to the morbid state of this very important emunctory.

[Dr. George Johnson recently read a paper before the Royal Medical and Chirurgical Society of London (Nov. 11, 1815; Lond. Lancet, Jan., 1816, p. 81), in which he maintained that "Bright's disease" consisted in a diseased state of the secretory or epithelium cells which line the urinary tubes; that these cells naturally contain a minute quantity of oil, in the shape of globules, which, in this disease, is much increased; in short, that there is a fatty degeneration of the kidney, analogous to the fatty degeneration of the liver, described in recent pathological works. Dr. J. supposes that this accumulation of fat in the secretory cells is the result of constitutional causes, that it necessarily leads to the engorgement and dilatation of the tubules which they line, and that one or more consequences follow, that these cells naturally contain a minute quantity of oil, in the shape of globules, which, in this disease, is much increased; in short, that there is a fatty degeneration of the kidney, analogous to the fatty degeneration of the liver, described in recent pathological works. Dr. J. supposes that this accumulation of fat in the secretory cells is the result of constitutional causes, that it necessarily leads to the engorgement and dilatation of the tubules which they line, and that one or more consequences follow, that these cells naturally contain a minute quantity of oil, in the shape of globules, which, in this disease, is much increased; in short, that there is a fatty degeneration of the kidney, analogous to the fatty degeneration of the liver, described in recent pathological works. Dr. J. supposes that this accumulation of fat in the secretory cells is the result of constitutional causes, that it necessarily leads to the engorgement and dilatation of the tubules which they line, and that one or more consequen-]
neys in this disease, the fatty condition was in only one case sufficient to attract attention; that there are other deposits besides that of oil, as that called cacoplastic (badly organized) by Dr. Williams, such as we find in other organs and tissues which have been the seat of unhealthy inflammation or degraded nutrition. This matter, Dr. Q. states, has been generally observed to assume 1. The form of nucleated cells, varying in size and shape, and also in the number and character of the nuclei; 2. As simple granular matter, nucleated cells being fewer in number; 3. A distinct filamentous or fibrous character. The deposits in the kidney, according to Drs. Quain and Williams, assume the following characters: 1. The simple enlarged mottled kidney, the surface of which, on removing the capsule, is generally smooth. In this the deposit consists of simple nucleated cells, more or less mixed with granular matter. This form is analogous to the hypertrophied mottled liver. 2. The truly granular or atrophied kidney, the surface of which is rough, irregular, and generally of a pale-red colour. In this form, the filamentous tissue, contractile in its nature, as such formations always are, exceeds the quantity of the cellular or granular matter. This latter sometimes extends to the convoluted extremities of the tubes. The contractile tissue surrounding the tubes and bodies can be readily supposed to give a rough or granular formation. This form resembles the hob-nailed or gin-liver. 3. The large, flabby, fatty-looking kidney. In this the quantity of fat exceeds the amount of the other matters present. The fat is present in the substance, and probably in the tubes themselves. This resembles the fatty degeneration of the liver. Minor modifications of these forms are produced by the relative proportions present. There is no reason to suppose that one condition is the necessary antecedent of another, but that the character assumed in the first instance may be permanent. (See Williaim’s Lect., in Lond. Medical Gazette, 1845; et Prime. of Medicine. Quain, in Lond. Lancet, Feb., 1846. Johnson, in Ibid., Jan., 1846.)

110. ii. Diagnosis.—A. The acute form of cachetic or albuminous nephritis is readily recognised by the coexistence of an albuminous, and often a sanguinolent state of the urine, with the rapid development of anasarca, and occasionally of serous effusion into some internal cavity. In a few cases, no dropsy takes place; but then the state of the urine, in connection with febrile irritation and derangement of the general health, will sufficiently indicate the nature of the disease. It may, however, be mistaken for simple hematuria; but, in this latter, pure blood passes, mixed with the urine, and fibrinous concretions or filaments, or even small clots of blood are voided; while these circumstances do not occur in cachetic nephritis. In hematuria, moreover, one or both regions of the kidneys are more palpitating, and more tender than in this disease. The urine also is rarely passed without pain, or having the same appearance at different hours of the day—circumstances rarely existing in this form of nephritis. In simple nephritis, and in some cases of the eruptive fevers, the urine contains albumen in a slight degree and for a brief period, but there is generally also a due proportion of urea, and the urates, and other saline matters, and hence the urine is not specifically lighter.

111. B. The Diagnosis of chronic cachetic nephritis is more uncertain than that of the acute. When in a patient who experiences only trifling, if, indeed, any pain in the loins, the urine is found of a low specific gravity, and contains albumen with only a small proportion of urea and the urates, the existence of chronic cachetic or albuminous nephritis is almost certain, especially if he be free from disease of the heart. And, even when there is disease of the heart, the mistake is rare, for, if the congestion of the kidneys is due upon disease of the heart give rise to the presence of albumen or of blood globules in the urine, the quantity is small, and only occasionally observed; and the specific gravity of the urine, and the proportion of urea and urates, are not materially affected. The dropscial effusion, also, caused by disease of the heart usually commences in the lower extremities and extends upward, whereas that arising from disease of the kidneys is often first perceived in the face.

112. M. Rayer remarks, that when, after a few days’ indisposition, a patient is affected with serious cerebral symptoms, or with repeated attacks of vomiting, without dropsy, and when, at the same time, the urine is strongly charged with albumen, and is of a low specific gravity, and if we cannot detect any disease of the heart, or of the bladder or urethra, the existence of chronic albuminous nephritis may be regarded as more probable than that of a primary cerebral affection. And if it be ascertained that the patient has been exposed to wet and cold, or addicted to the abuse of spirituous liquors, or affected with dropsy some months before, the presence of renal disease may be asserted with still greater confidence. The milky or whey-like appearance of the serum of the blood is no proof of the existence of the disease under consideration, for it has been very frequently by Hewson, Trail, Birmingham, myself, and others, in various other diseases besides this; and urea has been found in the blood after simple nephritis, and in atrophy of the kidneys, when the urine was not albuminous.

113. iii. Complications and Relations of Cachetic Nephritis to Other States of Disease.—I have already stated that cachetic nephritis rarely occurs without some previous disorder, or even actual disease, and that such
disorder is generally characterized by impaired organic nervous energy, by imperfect assimilation, and by the consequently morbid state of the blood. I have, moreover, contended (§ 114, et seq.) that the inflammatory condition of the kidneys in the acute form, and the lesions of these organs in the chronic, are consequences of these antecedent morbid conditions; and that several of the affections, which I now proceed to notice, in relation to cachectic nephritis, often exist in a slight degree, either occasionally in, or concomitantly with, the development of this malady; while others, or even the same affections in different cases, do not appear, or at least are not manifested, until consequentially upon the renal disease. From this it will be evident that I view cachectic nephritis as a consecutive or secondary malady, and that the various affections with which it is more or less intimately connected are either pre-existent to it, or coexistent with it, or consequent upon it; that it should be recollected that the associated affections or complications are rarely single; that disease of several viscera, besides the dyspeptic effusion, generally appears in connexion with the renal malady even in the same case; but this will be seen more fully in the sequel.

114. A. Relations of Cachectic Nephritis to Disorders of the Digestive Organs.—a. The mouth and pharynx are rarely affected in connexion with this disease unless consequentially upon it, when aphthous, and even ulceration of the pharynx, may occur at an advanced stage. It has been observed that mercureatums more readily affect the mouth and salivary apparatus in the course of chronic cachectic nephritis than in most diseases. —b. The stomach is more or less disordered either previously to or at an early stage of this malady. At this early period the disorder of the stomach consists chiefly of the more severe symptoms of dyspepsia; but nausea and vomiting are frequently complained of, and generally occur early in the morning, or when fasting, even if they are all, in many instances, progressive manifestations of successive changes in the economy, affecting more especially the circulating, or the assimilating, or the excreting organs, according to their several predispositions to disorder, or to inflammatory action, or to structural change, or to the influence of incidental causes and extraneous agents; while in other cases, certain of them may occur as coincident effects of pathological causes—of pre-existing disorder, especially of that already specified. It should be recollected that the associated affections or complications are rarely single; that disease of several viscera, besides the dyspeptic effusion, generally appears in connexion with the renal malady even in the same case; but this will be seen more fully in the sequel.

115. c. The intestines are more or less affected in many cases of this malady, and most frequently in the form of diarrhoea. Both Dr. Christie and M. Raver have noticed the frequency of this complication, it having occurred in more than half of their cases, but Dr. Broun and Dr. Proctor have observed it less frequently. It is observed chiefly in the chronic disease, and is sometimes preceded or attended by colicky pains in the abdomen, and occasionally by vomiting; but, in this latter case, there is often also pericarditis complicating the malady. The diarrhoea is generally consequent upon the renal disease, and it sometimes assumes a dysenterical character; the stools containing blood, and more rarely a bloody or watery discharge; but, in some cases, they have no influence in diminishing the attendant dropsy, which may even increase during the diarrhoea. After death, the intestines do not always present lesions co-ordinate with the amount of disorder during life. In many cases, little or no redness of the mucous surface is observed. In others, redness of this surface, with enlargement of the follicles, with or without ulcerations, and often with anaemia of other parts, is remarked. Frequently, although the diarrhoea has been great and obstinate during life, the mucous membrane, and, indeed, the intestinal canal, have been anaemic throughout. Ulcerations are most common near the termination of the ileum, and in the large intestines. In the former situation they are generally confluent; in the latter, disseminated and small.

116. d. Peritonitis in rare instances occurs consequentially upon cachectic nephritis. Cases of this complication are recorded by Dr. Broun, Dr. Gregory, Dr. Christie and others. In some instances the peritonitis is granular or tubercular; in others it is attended by considerable effusion of a sero-puriform fluid. The peritonitis may be consequent upon enteritis, with or without ulceration (see article Intestines); or it may arise without the intestinal disease having been manifest. It is generally caused by the influence of cold and humidity during the existence of the renal dropsy, and is often not the only affection complicating this latter; both pleuris and pericarditis, either singly or conjointly, being also present. In these cases, the symptoms of peritonitis are more or less manifest, generally with vomiting, diarrhoea, etc.; but as frequently they are by no means decisive.

117. e. Lesions of the liver are often found in connexion with cachectic nephritis; but, in many cases, the leison is slight. Dr. Broun found the liver quite sound in 40 cases out of 100; the change was slight in 35, and serious in 18 cases. M. Raver states that this organ was more or less altered in about a third of the cases which he examined after death, in some throughout its whole extent, in others only in parts. It was enlarged in a small proportion of instances (one sixth), and chiefly in those cases where the heart was also diseased. Occasionally some portion of its peritoneal sur-
face was adherent to adjoining parts. It was softer than natural in a few instances, but it was much oftener harder, or even indurated, and diminished in bulk. In this latter case its surface was irregular, of a deeper colour than usual. When divided, its substance was found tuberculated, presenting the lesion which has been denominated *cicatrix*, or the tubercular liver of drunkards. This particular lesion seems to be more frequently associated with granular kidney than any other alteration of the liver. In some cases the liver is enlarged, pale, and fat; a portion of its structure leaving an oval shape in paper. In a few instances, it contains large whitish tubercular masses. The bile is generally more or less changed from the healthy state. It is probable that the advanced stages of these lesions are consequences of the renal malady; but it is at least equally probable that their early stages, or the functional disorders preceding them, exist antecedently to the development of this malady. The nephritic disease and the attendant dropsy are not in-frequently further associated with affections of the spleen, or of the alimentary canal, or with chronic peritonitis. The complication with hepatic disease is often rendered manifest by the usual symptoms of chronic affections of the liver, and attended by vomiting, diarrhoea, and ascites.

118. The Spleen and Pancreas are sometimes diseased in cachectic nephritis. In all the cases in which the liver is affected, the spleen is also more or less altered, most frequently enlarged, and occasionally its substance is loaded with yellowish accumulations analogous to those found in the liver (Raver). The structure of this organ is sometimes softened, occasionally firm or indurated. The pancreas has been found diseased only in a few instances, and in a slight degree. The disease has in a few instances appeared in the course of pregnancy, and M. Raver states some cases thus associated.

119. As far as I have been able to observe the phenomena of the early stage of cachectic nephritis, and to learn the history of the patient's previous ailments, there has been more or less manifest disorder of the digestive organs, generally of a functional kind, but probably advancing to structural change in some cases, as the disease made progress. The influence of such disorder upon the state of the blood, and upon the processes of secretion and excretion, is sufficiently evident. In all these cases, and before dropsical effusion or vascular reaction had taken place, depression of the organs of assimilation, each and everyone, consequent upon the functional disorder of the alimentary tract, and of assimilation, were more or less remarkable. The vascular excitement, which sometimes appears at an early period of the disease, is the consequence, as I have already shown, of the morbid state of the blood, and of its influence upon the ganglial and vascular systems.

120. B. Relations of Cachectic Nephritis to Diseases of the Respiratory Organs.—a. Inflammation of the Throat, extending to the pharynx and larynx, occurring in the course of scarlata, sometimes is continued, with more or less severity, during the progress of the renal dropsy following this fever; and when the larynx becomes affected, the disease of this part may be so remarkably severe as to be speedily fatal; this form of complication, however, is not so frequent as inflammation and ulceration of the larynx, trachea, and even of the larger bronchi, which so frequently occur in the course of phthisis, the pulmonary malady giving rise not only to the affection of the respiratory passages, but also to renal disease and its consequent anasarca. In two cases, in which there existed a terebral taint, the progress of which I closely watched, and where it was difficult to decide whether the laryngeal or the pulmonary disease occurred first, the dropsy appeared at early periods of their progress, advanced remarkably far, and accelerated the fatal issue.

121. b. Bronchitis is one of the most frequent affections consequent upon renal disease. M. Raver states, that he has observed it in seven eighths of the chronic form of this malady. The bronchitis that occurs is rarely acute; it is almost always chronic; and while the respiration is very slightly affected in some cases, it is much accelerated, and very difficult in others, particularly at an advanced period of this malady. The matter expectorated is chiefly muco, occasionally thick and yellowish, in some instances glairy, and in others very abundant. The bronchitis generally aggravates the disease, and is sometimes the more immediate cause of death. It frequently occurs without any manifest cause; is rapidly propagated throughout the bronchi; is little influenced by treatment or ameliorated by depletions; is accompanied by slight expectoration, minute ramifications and air cells, and extensive edema of the lungs. Its more acute form is sometimes followed by lobular pneumonia. On dissection, the mucous membrane of the bronchi is found red throughout.

122. c. Pneumonia sometimes occurs as a secondary complication in the advanced stage of cachectic nephritis, and is more or less extensive and severe. The inflammation attacks sometimes several lobes, sometimes only the whole or part of a lobe, occasionally it affects many lobules of the lungs. In this latter case, the inflamed points are disseminated and isolated in the substance of the organ, some of them being in the state of red hepatization, others of gray hepatization, and closely resembling the lobular form of pneumonia, which occurs after morbid poisons, and sometimes after surgical operations. One or both lungs may be affected, more frequently both. The symptoms and signs of this pneumonia are usually masked by the general cachexia of the cachectic nephritis, and by the complications of the heart, and by other pulmonary lesions. Even the stethoscopic signs are ascertained with great difficulty, or are altogether absent. The expectation also is seldom characteristic of the disease, being more frequently catarrhal or bronchitic, than of the kind distinctive of pneumonia. Hence the inflammation is either latent, or not detected during life. In some cases, however, the spita and the stethoscopic signs evince the existence of the disease. This complication is most dangerous, owing to the state of the constitution, and to the inefficiency or even injurious effects of blood-letting, and of many other means of treatment. It is often associated with pleuritis, or with bronchi-
tis, or even with both, when it occurs consecutively upon renal disease.

123. d. Pleuritis is rare as a secondary disease, in its simple form, in connexion with cachectic pleuritis; but associated with pneumonia, or with pulmonary tubercles, and with serious effusion in the pleuritic cavities, or with pericarditis, it is by no means infrequent. It is generally latent or overlooked, or masked by dyspnea or by bronchitis. It is sometimes chronic, and occasionally acute and manifest. In some of the more chronic, in a few of the latent, and in cases, the disease assumes much of the character of hydrothorax, owing to the amount of fluid effused, and the slight grade of inflammatory action.

124. e. Edema of the lungs, with or without bronchitis or bronchohormea, is the next frequent secondary affection to bronchitis which occurs in the course of albuminous nephritis. Dr. Bright and M. Raven found this lesion in about one third of the fatal cases. Empysema of the lungs occasionally occurs, and pulmonary suppuration more rarely, in the progress of the renal malady.

125. f. Tubercular consumption is very frequently connected with cachectic nephritis, but the connexion is most commonly of a different kind from that usually observed in the other pulmonary affections with which this malady often becomes complicated in its course; the renal disease is almost always consequent upon the tubercular malady. M. Raven believes that, in rare instances, the latter may be secondary of the former. But, although I have seen very many cases, since 1828, of renal dropy supervening in the course of phthisis, I have never met with one in which this order was reversed. The renal malady may appear during any period of the tubercular disease, and in every form of it; in the most acute and febrile, and in the most chronic and apyretic. Generally the urine becomes more or less albuminous before any signs of anasarca appear. In a few cases the urine has been albuminous, and less dense than natural, in the advanced state of the disease; and the kidneys have been found granular after death, and yet anasarca had not occurred. This may have arisen from the continuance of the cumulative perspirations, as these often cease upon the occurrence of the anasarca. Diarrhoea frequently continues during the renal disease, without diminishing the dropsical effusion. Bronchitis, pneumonia, pleuritis, laryngitis, pneu-mothorax, pleuritic effusion, or edema of the lungs, or even two or more of these, may further complicate the tubercular malady and its consequent renal disease.

126. c. Relations of Cachectic Nephritis to Diseases of the Vascular System — a. Diseases of the heart are often associated with cachectic nephritis, but the connexion between them is not altogether evident. In some cases the cardiac, in others the renal disease seems to be primary. The frequency of this complication, also, is not fully ascertained. M. Raven states, that it occurred in one fifth only of his cases, while Dr. Braügg found it in sixty-four cases out of the hundred. The affection may appear, in some instances, as the primary, in others as the consecutive, and in others as an accidental malady; and yet both it and the renal disease may only be the more or less remote effects of previous changes in the states of organic nervous power, and of the circulating fluids, either of which may precede the other in the order of succession or sensible manifestation, in different cases, or in different circumstances. This view of the subject, which is equally applicable to some other complications of this malady, has been unaccountably overlooked by those who, in most respects, have written well on the disease, and contributed greatly to its history and elucidation. The occurrence of this complication has great influence upon the production and increase of the dropsy generally consequent upon the renal malady, and usually causes the anasarca to commence in the lower extremities. Dr. Braügg and Dr. Christie both think that the cardiac disease is most frequently secondary, while M. River believes that the kidneys are oftenest consequent upon it; and I consider that interrupted circulation through the heart and lungs favours remarkably the occurrence of the chronic malady of the malady. That the urine is often albuminous in persons affected with disease of the heart, when there is no serious affection of the kidneys, cannot be denied; but if, along with this character, it is of a pale citrine colour, strongly coagulable, and of a low specific gravity, these are strong proofs of the presence of structural disease of the kidneys.

127. b. The pericardium often contains a small quantity of the blood serum, from four to five ounces, in fatal cases of cachectic nephritis; but rarely so much as to constitute true pericarditis. Lesions of the pericardium may be either antecedent to, or consequent upon those of the kidneys. The relative dates of these lesions may be often inferred from the history of the case, in connexion with their appearances upon dissection. There can be no doubt that, when the heart or its valves are diseased, the pericardium becomes more liable to inflammation, or to the seat of effusion; and that this liability is increased by the morbid affection of the blood and the morbid state of the blood. Hence old lesions of the pericardium, or recent changes in it, or even both, will occasionally be found after renal dropy, although they may be detected with difficulty during life, whether they be associated with other cardiac lesions or not. The remarks I offered above (§ 126), respecting the complication with cardiac disease, apply here; the pericardiac lesion may be either primary or secondary in accordance with both it and the renal malady may be only the consequent effects of anterior disorder, some exciting or concurring cause, as cold and humidity, developing these two diseases as effects of this disorder, which may not have been manifested, especially in these organs, if such exciting or determining cause had not been in operation.

128. c. Endocarditis is also sometimes associated with cachectic nephritis, and is most probably consequent upon the morbid state of the blood in the advanced stage of the latter malady. It may be present either simply or complicated with pericarditis or other lesions of the heart. M. Raven thinks it not always possible to say which of the two affections is primary or secondary. He believes them, in a
very few cases, to be almost coetaneous; but, in a much greater number, he considers the endocarditis to have preceded the renal malady. I think that the order of morbid procession is different from this in most instances.

129. d. Various lesions of the heart, of its valves, and of its orifices are found in connexion with albuminous nephritis; and these morbid states may be farther associated with alterations of the serous surfaces of the organ, or with disease in some other important viscera, as the lungs, the bronchi, &c. Among these, lesions, hypertrophy, dilatation, &c., of some one of the chambers, dilatation of the orifices, insufficiency of the valves of the heart, &c., are not uncommon; but it is unnecessary to specify the various combinations of disease which present themselves in this class of cases, as they vary much in different instances. These lesions favour the supervision of the renal malady by causing congestion of the kidneys.

130. e. The blood-vessels sometimes present alterations of structure in cachectic nephritis, consisting chiefly of atheromatous and ossific deposits, with or without dilatations, and various states of the veins; more rarely of aneurismal dilatations, and of the consequences of inflammation. Dr. Bright and M. Raver have found evidence of pre-existing inflammation of the renal veins; and have remarked that the arterial dilatations through the granular kidney were not so easily penetrated by an injection as those of a sound kidney.

131. iv. Relations of Cachectic Nephritis to Cerebral Affections. — Cerebral affections sometimes occur in the course of the renal malady, and chiefly in its far advanced stage, and in its more acute form. These affections consist of comatose, apoplectic, or convulsive seizures, and of more or less sudden death, with insensibility. In many of these cases there is little or no appreciable lesion of the brain; but more frequently there is a diminution or absence of the veins found within the venous sinus under the arachnoid. All these affections are consequences of the renal malady, or, rather, of that change of the blood which is connected with and augmented by the renal disease. In a few instances, lethargy or coma precedes death for a considerable period, from which the patient may be partially roused, but in which he immediately afterward falls, the comatose state becoming gradually more profound, and passing into apoplexy, with sertorius breathing, or into convulsions, or into a related state of apoplexy and convulsions. The serum within the ventricles or under the arachnoid, in these cases, has been found by Dr. Barlow to contain urea. Extravasation of blood in various situations within the cranium, as in the substance of the brain, in the ventricles, or between the membranes, or true apoplexy, in the course of cachectic nephritis, has been observed by Dr. Bright, Dr. Christian, and M. Raver, but this, probably, was only an accidental complication: it is of rare occurrence.

132. D. Relations of Cachectic Nephritis to Diseases of the Skin and Cellular Tissue. — Chronic eruptions on the skin, indolent and gangrenous sores and ulcers of the extremities, erythema, and erysipelas, are sometimes associated with the renal malady. When they appear during the distension occasioned by the dyspnceal effusion, both their occurrence and the unfavourable form they are apt to assume chiefly arise from this circumstance. But in earlier periods of the disease they proceed, in a great measure, from the existing cachectic state of the constitution and the change in the blood, disposing any injury or irritation of the skin to pass into inflammation, which, owing to these states, often assumes an ashenie or spreading character. This form of complication is not infrequent or complicated with disease of one or more of the abdominal and thoracic visera.

133. E. Relations of Cachectic Nephritis to Eruption and other Fevers. — The appearance of this disease, in connexion with these fevers, has been almost confined to scarlatina. A case, however, has been published by Dr. Gregory, in which it was consequence upon measles in a serofulous girl. The occurrence of dropy, with scanty, bloody, or coagulable urine, subsequently to scarlatina, especially to the less severe forms of that disease, and in some epidemics more frequently than in others, has long engaged the attention of medical writers. Calvo, Borsieri, Storck, Plocziz, Rosensteil, Wells, Blackall, and Reil, have noticed the state of the urine, and the peculiar character of the dropy, after scarlet fever, but have not connected the disease with inflammation or other lesion of the kidneys; and, until very recently, the dependance of this form of dropy chiefly upon an inflammatory state of the kidneys was not ascertained or even suspected. Dr. Fischer, in a Memoir on the Treatment of Scarlatina, published in Hufeland's and Oznann's Journal (Feb., 1821, st. 53), remarks that the kidneys are often severely affected in the latter stages of scarlatina; that they are in a state of congestion, which is readily converted into inflammation by diuretics, and especially by those which are stimulating and acid. He adds, that he long considered the vomiting, and ventricle of the brain, which proceeds expeditiously consecutively upon scarlet fever, to be caused by disease of the brain; but further observation and careful dissections proved to him that it was symptomatic of disease of the kidneys. He subsequently endeavoured to ascertain the symptoms which marked this affection of the kidneys at its commencement, and he found them in the urine, which became more scanty, of a deeper colour, sometimes tinged with blood, or even containing pure blood, when the vomiting appeared. Mr. Hamilton details a case in his account of an epidemic scarlatina, &c. (Ed. Med. and Surg. Journ., vol. xxxix., p. 145), in which the same appearances as are described under the first form of lesion (§ 100) of the kidneys were found in a patient who died from this consecutive disease. Respecting this connexion of renal dropy with scarlatina, M. Raver remarks:

134. 1st. That in certain cases of scarlet fever, particularly during the period of desquamation, the kidneys become more or less albuminous dropy, without dropy occurring; at the same time, the kidneys are congested with blood, or present lesions corresponding with those belonging to the first form, which is commonly produced by cold and humidity, or by the abuse of spirituous liquors. 2d. That the dropy sometimes observed after scarlatina, in its course, and as respects its exciting or de-
terming cause (cold and humidity); in its general characters, and the alteration of the urine attending it; in its abdominal, thoracic, and cerebral complications; in the structural lesions observed after it; and as to its nature and treatment, differs in no respect from the acute and chronic albuminous nephritis produced by other causes, and appearing under other circumstances. In some instances are fully supported by my own experience, and by the evidence recorded by Bright, Wood, Stark, Alison, Graves, Seymour, Guerwent, Raver, and others.

135. When cachetic nephritis takes place after scarlatina, it commences about the close of the third or beginning of the fourth week from the appearance of the eruption. The patient, although he may have previously recovered, becomes uneasy and somewhat feverish. His sleep is disturbed, his appetite is impaired, and sometimes nausea and vomiting are present. A few days afterward, a puffiness is noticed about the eyelids, gradually extending to the face and neck, and thence to the extremities and trunk. The constipation, at the same time, becomes pale and cachetic. Sometimes the edema appears suddenly, and almost simultaneously, over the whole surface of the body. The urine is commonly much diminished in quantity, and voided frequently and with difficulty. It is of a deep reddish brown, and often contains a portion of blood mixed with it. Generally, a flocculent whitish matter may be seen suspended in it, resembling unclarihed whey, or, when there is any admixture of blood in the urine, like the water in which raw meat has been washed. Its specific gravity is more or less below the healthy standard. The action of the heart is frequently strong or tumultuous; the skin is hot, and the breathing is quick, and oppressive. Pain in the head, in others the chest, and in others the abdomen, is the chief seat of suffering. Such usually is the acute form of the disease as occurring consecutively upon scarlatina; but it has occasionally appeared more suddenly, particularly when the patient has been exposed, at or soon after the period of desquamation, to cold and humidity, and it has then, in a few cases, terminated fatally in forty-eight hours after its appearance, from the superintendence of coma, or convulsions, or asphyxia. In the chronic state consequent upon scarlatina, there is commonly little or no fever, and the action of the heart is much less excited. The symptoms are less severe, and more gradual in their appearance and progress. The urine is deeply coloured, but always albuminous, and of lower density than natural.

136. In the acute form of the disease consequent upon scarlatina, vomiting, dilatation of the pupils, slowness and irregularity of the pulse, stupor, dropy, cramps, convulsion, &c., sometimes appear, and indicate a most dangerous affection of the brain, often with serious effusion within the ventricles or under the arachnoid. Pulmonary complications are very common in the acute cachetic nephritis following scarlatina. These are either inflammation of the bronchi, or of the lungs, or of the pleura; or serious effusion in the cavities of the pleura or in the pericardium, or edema of the lungs, these effusions being consequent upon an inflammatory or congested state of these parts, the vessels, owing to the cachetic condition of the constitution, and to the states of vital power and of the blood, being incapable of throwing out coagulable lymph, but allowing a liberal discharge of serum. These inflammatory complications were frequently observed in the epidemic scarlatina which occurred in Florence in 1784, and which was described by the Florentine physicians "mortuorum cadavera sequens, inveneruntque pulmones, pleuram, intercostales musculos, diaphragma, renes, et intestina plus minusque inflammatione corrupta." Cachetic inflammation of the kidneys may occur after scarlatina, the urine being albuminous, and yet no anasarca may take place. Generally, in these cases, there is either a very scanty secretion or an entire suppression of urine, and the patient is more or less suddenly carried off by internal congestion or inflammation, or serous effusion, stupor, coma, paralysis, convulsions, or asphyxia ushering in dissolution. The occurrence of this form of nephritis after other fevers, as typhoid, remittent, and intermittent fevers, has not hitherto been observed.

137. F. Relations of Cachetic Nephritis to Scrofula.—Most of the instances of this disease that I have observed have been in children and adults of the scrofulous diathesis, and the experience of Bright, Gregory, Christison, Hamilton, and Raver is to the same effect. Strumous children who are insufficiently clothed and fed, and exposed to cold and humidity, are liable to be affected with this malady; and some of them possessed of this constitution become the subjects of this form of nephritis without being exposed to these exciting causes; and, indeed, all the patients who are attacked with it, independently of these causes or of intemperance, more especially those who are young, present more or less decided evidence of a scrofulous taint, which acts, as shown hereafter (§ 148, 152), both as a predisposing and as an exciting cause. In many of these cases, evidence of anterior scrofulous disease is manifest, while in others scrofulous abscesses or diseases of the bones coexist with chronic cachetic nephritis.

138. G. The connexion of this malady with the syphilitic taint has been pointed out by M. Raver; and it may be doubted whether or no this connexion is owing to a syphilitic cachexia or to the means which had been employed to cure it, as a liberal or excessive use of mercury. Wells and Blackall ascribed the appearance of dropsy with coagulable urine, in such cases, to this particular cause. In two cases, both professional, but not medical men, this form of nephritis occurred during an advanced stage of their maladies. They both had had severe secondary syphilitic symptoms, for which mercury had been employed, and soon afterward tubercular consumption manifested itself. During the treatment of this latter, the usual signs of cachectic nephritis appeared, and hastened death much sooner that it probably might otherwise have taken place. A similar instance is recorded by M. Raver.

139. H. The connexion of cachetic nephritis with rheumatism has been insisted upon by Dr. Christison, who remarks that, in every instance of obstinate chronic rheumatism that
comes under his care, he examines the state of the urine as to its coagulability and density. The rheumatic affection which is sometimes thus connected is commonly of the neuralgic kind, and precedes, rather than attends, the dropscial affection. This complication occurs chiefly in those who have been habitually exposed to cold and humidity. The connexion of this form of nephritis with gout is comparatively rare.

[Dr. Williams, of London, has recently treated of this affection (The Med. Times, Jan., Feb., 1815, p. 375, &c.) in so able a manner that we think some of his views well worth presenting to the reader. Dr. W. does not regard albuminuria as purely inflammatory, but places it under the head of congestive diseases of the kidney, affecting the cortical structure. It occurs in two forms, acute and chronic; and that it is the result of congestion simply, Dr. W. thinks is evidenced by the fact that, in cases of obstructive diseases of the kidney, attend- ed with great congestion in the venous circulation, the urine becomes albuminous for a time, and the same occurs whenever any febrile affection supervenes on this congestive state of the vessels, the albumen disappearing from the urine as this affection is removed or diminished. Hence we often find albuminous urine in congestive fevers, and in the paroxysms of fever, and especially in scarlatina, in which there would seem to be a tendency to disease in the kidney itself. Hence it is that Babour's disease is so often caused by exposure to wet and cold, in persons whose kidneys have been previously excited by intoxicating liquors, &c. Here there is a predisposition to congestion of these organs, and the influence of cold, acting on the whole surface, drives the blood inward, and the congestion that ensues interferes with the secreting powers of the kidney, and the secretion of albumen is a natural consequence of the disease of the organ.

After noticing the symptoms usually characterizing the acute stage of the disease, as pain and tenderness in the loins, feverishness, and dry state of the skin, thirst, accelerated pulse, nausea, vomiting, and various nervous symptoms, as delirium or stupor, anasarca, rheumatic pains about the joints, with effusions under the capsules containing some of the constituents of the urine, he proceeds to state that fluxes also occur from the mucous membranes: human bronchitis is frequently present, with diarrhea, and a variety of symptoms which arise from the retention of urica in the blood, thus poisoning the system, and producing a noxious effect on all the functions. These secondary effects, caused by the retention of urica and the other constituents in the blood, differ according to the predisposition of the individual; in some we observe nervous depression, in some vomiting, diarrhea, and flux from the mucous surfaces; in others, affections of the serous membranes, dropsy, and low inflammations, &c. Owing to a deterioration of the red globules, and diminution of the albumen and fibrin, the blood becomes preternaturally thin, hence causing a disposition to effusion into the several tissues. The prevention of the proper excretory function of the kidney thus impairs the healthy condition of the blood, and all the other sequele and complications are owing to this cause. Hence nutrition is impaired—that function by which the growth of the textures is supplied; but if it goes on, the nutritive material, from the loss of colouring matter in the blood, is of a low or degraded character, and hence any new deposit that takes place presents a less organized property than in the natural condition, constituting what Dr. Williams calls the cachectic exudation as it arises out of the granular degeneration of the kidneys, the deposition of tubercle in the lung; functional and organic derangements of the liver; atheromatous deposits in the coats of the blood-vessels, rendering them brittle, and liable to rupture, and often leading to apoplexy; hypertrophy and dilatation of the heart are also occasioned by the same imperfect constitution of the blood, besides a multitude of other changes, as chronic diarrhoea, terminating in ulceration of the intestines, and liable to deposit of the cellular substance of the stomach; and, in short, all the chronic diseases of the system. All these are referred by Dr. W. to a primary diseased state of the kidney, leading to a retention of excrementitious matters in the system, which, from their poisonous effects, sometimes occasion coma, stupor, and sudden death. Serofula, or the tuberulous diathesis, Dr. W. thinks, is one of the causes of granular degeneration, inflammation as it causes to a degree disorganization of the textures of the whole system. Intemperance, bad diet, and low living are also frequent causes of this affection. Its connexion with gout and rheumatism, and chronic diseases of the heart, is too obvious to dwell upon. Congestion of the heart from functional disease of the organ will, sooner or later, terminate in structural disease. Owing to the impaired secretion of the kidneys consequent on such congestion, superfluos or morbid matters are retained in the system and are liable to deposit in the different organs. In chronic albuminuria, as remarked by our author, the kidneys become contracted and atrophied, owing to a wasting of the texture, as in cirrhosis of the liver. This is occasioned probably by the deposition of the granular matter around the vessels, thus compressing their structure; and as the vessels are pressed upon, the blood is unable to pass through them; the nutritive supply is thus cut off, and there is a wasting away of the tissue, causing a reduction in the bulk of the organ in proportion as the disease advances. Owing to the same cause, the quantity of albumen and urica in the urine is diminished, and the watery portion increased; there is no room for the solid parts of the urine to pass through, and the watery portion alone is excreted.]

140. iv. Nature of CACHETIC or ALBUMINOUS Nephritis.—From what I have already stated with reference to the causes and the complications of this malady, views as to its nature, and more especially the one entertained by the author, may be readily understood. Hitherto it has not been sufficiently considered as a merely secondary disease, all the phenomena in any way connected with it being considered rather as signs and symptoms of its pre-existence, in some one or other of the forms of lesion described above (§ 100, et seq.), than as concomitant changes, many of which depend more upon antecedent...
disorder than upon the associated or otherwise related affection of the kidneys. The questions, therefore, are: 1st. In what does this primary disorder consist? 2d. In what manner does the renal malady arise consequentially upon it! and, 3d. Wherefore is this consequent disease so very generally associated with others, in some degree or other, and in what manner, if already advanced, will render it unnecessary to enter upon lengthened details in answering these questions.

141. 1st. The several connections connected with the origin of the malady—the predisposing and the concurring and exciting causes; the existence and the character of antecedent disorder affecting either the general constitution or the functions of some vital organ—all combine in evincing that the earlier morbid states are impaired organic nervous power, and, consequently, insufficient sanguification and assimilation, with disordered secreting and excreting functions. It will necessarily follow, even from an early stage, or from a slight grade of these morbid conditions, that the blood will be more or less affected, and that a change in the blood will, according to the nature of such change, affect also other organs.

142. 2d. It is difficult to state with any degree of precision what are those changes which have already impaired organic nervous power, and consequently weak digestive and assimilative functions, will produce in the blood at early stages of their existence; but, in more prolonged periods of their influence, the results are frequently remarkable to the senses, although not so precisely determined by chemical or physical analysis. It is probable, from the results of observation and of analysis as partially employed, and from analogy, that the chyle is not only changed in the general substances and subsequently changed into healthy blood; that the serum contains more oily or fatty matter than natural, the result of insufficient assimilation; and that the several constituents of the blood, in relation to each other and to the system in which they circulate, are held together by a weaker vital affinity. During this state of the organic nervous power and of the circulating fluids, the excretory functions necessarily become impaired; and, although those substances which are the ultimate results of assimilation may not be abundantly produced, certain of them, as urea, may be present in excess in the blood, owing to insufficient excretion, especially by the skin and kidneys. The resulting morbid condition of the blood will thus become an exciting cause of vascular disease of the kidneys progressively advancing to organic change; and, once these important eliminating organs are diseased, the blood will become more and more altered, and sanguification the more impeded or altogether arrested. In all cases, also, both kidneys will be affected; for as in other diseases, where the causes are constitutional, consisting of cachectic states, or of changes in the blood, double organs, or similarly constituted tissues, will experience similar, or even identical changes.

143. 3d. The chief reasons for the appearance of cachectic nephritis in connexion with other maladies are apparent in the very condition or circumstances of the constitution, and of the health of persons in which it occurs. There is not only the pre-existing impairment of the digestive and assimilating powers just insisted upon, but there are also, in many cases, other antecedent maladies, which are always attended by weakness of these functions, as phthisis, scrofula, scarlet fever, &c., and which readily give rise, especially in certain states of predisposition, to the renal malady as a secondary or more remote effect. In these cases, the associated or related disease is primary, and favours the production of that state of the blood which affects the circulation, and ultimately the structure of the kidneys. Other complications are either associated results of the previous disorder—are equally with the renal malady effects of the previous changes in the states of organic nervous energy, and of the blood—or they are consequences of the disease of the kidneys, through the medium of the blood, a morbid state of this fluid being much increased by the affection of these organs; and being such as readily influences or irritates parts which, from predisposition, former disease, or the influence of concurring causes, or prevailing influences, become more liable to those consequent affections.

144. The dropsy so generally attending this malady arises from more than one of the pathological changes above detailed, or the morbid or early state of the disease, and especially when it is consequent upon scrofula, the anaemia is chiefly owing to the weakened vital affinity subsisting between the constituents of the blood, and to the weakened tone of the extreme capillaries. Probably something is also owing to the suppressed functions of the skin: exhalation from the external surface of the integuments being interrupted, it becomes increased into the articular tissue. The action of the kidneys is also impaired in most of the acute states of the disease; the watery parts of the blood become excessive; excrential plethora is thus produced, and effusion takes place from the overloaded vessels. In the chronic and far advanced states of the disease, the dropsy is owing chiefly to the change in the blood itself; to its thin and impoverished condition, and to impairment of the vital affinity between its several constituents, and between it and the blood-vessels. That the dropsy is not owing to excess of serum, is shown by its coexistence with a free discharge of urine, and with diarrhoea, and with an anemic state of the vascular system, in many instances. It may, however, be increased by the suppressed perspiratory functions of the skin.*

145. v. Prognosis.—The very serious and dangerous nature of this disease may be inferred from what has already been stated respecting it.—I. In the acute state, death some

---

* (N. C. Corliss) makes two distinct varieties of this disease (Land. Med. Times, April 5, 1843), corresponding to the acute and chronic states of Copland and Williams. In the first, he says that "the kidney becomes larger than natural, of a mottled yellow colour, which gradually spreads over the whole organ, and the tubuli uriniferi open towards the cortical part of the kidney. In the other variety, the kidney becomes smaller than in health, the tubuli uriniferi traverse a much greater space through the kidney than in the former, running, in this variety, almost to the capsular covering; its surface becomes studded with minute tubercules, which project above the capsule, as if numerous granulations had been cast up through, and sunk into, the cortical portion of the kidney; the two varieties corresponding, in fact, to hyper trophy and cachexia of the liver.)
times takes place suddenly, owing to the rapid development of disease in the brain, lungs, or pericardium. Hence the propriety of attending to the states of these organs as long as the urine continues to be albuminous or sanguinolent. This form of the disease is less dangerous when it occurs after scarlatina, or during the early stage of pregnancy, than in other circumstances. The nature of the chief causes should always be considered before a prognosis be given in any case; for when the malady proceeds chiefly from intemperance, the chance of associated visceral disease, although it may not be very manifest, and the danger, are always increased. The prolonged influence of cold, humidity, and of low or damp residences, generally occasions a more dangerous malady than the temporary operations of these causes.

146. B. In the chronic form, the prognosis is still more unfavourable than in the acute: a fatal issue may be more remote, but it is more certain ultimately. As long as the urine is coagulable, and of diminished density, the patient is in a most precarious state, from the tendency in these circumstances to dropy, pleuritis, pericarditis, cerebral affections, and to various other maladies, which assume the most dangerous forms when associated with renal disease. Any marked diminution of the quantity of urine, when it is of morbid composition, should always be viewed with great suspicion, as often preceding the maladies now mentioned. A still more remarkable diminution of the quantity of urine, or its entire suppression, is generally a precursor of a cerebral attack, and of a fatal issue. The more manifest, also, the cachectic state of the constitution, and the more important the affection complicating the renal malady, the more unfavourable does the prognosis necessarily become, and still more so when these two circumstances are conjoined in the same case.

147. An increase of the quantity of urine, relatively to the amount of fluid taken, coincidently with a diminution of the dropy and of the albumen in the urine, is generally a favourable omen; but, unfortunately, it is not rare to see this change arrested suddenly in the course of a few days, and followed by an increase of all the symptoms. A return of the specific gravity of the urine to the natural state, owing to an increase of the urea and salts naturally existing in it, coincidently with a marked diminution of the albumen, is a very favourable circumstance; but it is very rarely observed in the chronic form of the disease. The diminished density, on the other hand, of the urine, is an unfavourable circumstance, more particularly if the quantity voided be not augmented. Upon the whole, the prognosis in this form of the disease should depend upon the number and nature of the primary concomitant or consecutive affections complicating it, rather than upon its duration and history. Of these affections, some are acute, as cerebral attacks, pneumonia, pericarditis, &c., and speedily fatal; others are chronic, as scarola, tubercular consumption, organic lesions of the stomach, or of the liver, or of the heart, the syphilitic cachexia, &c., and place the patient in equal, although not so immediate danger.

148. VI. REMOTE CAUSES. - A. THE PREDISPO-

sing causes of cachectic nephritis are whatever depresses vital power, and tends to render the system cachetic. The serofulous diathesis and a syphilitic taint, the former especially, favour the operation of the more direct or exciting causes. This disease rarely attacks infants, or very aged persons; but it is frequent in children, in the acute form, chiefly as a sequela of scarlatina, and occasionally in the chronic form in children of the severely depraved state, both primarily and consecutively upon scarlatina, and upon febrile or other disorders. It is most prevalent in cold and humid countries, and in places where spirituous liquors are most indulged in. It occurs more frequently in males than in females, probably in consequence of the former being more exposed to its exciting causes; and it is most prevalent between the ages of twenty and fifty. My own observation fully confirms the following statement of Dr. Christison. In several cases, he observes, in almost all those of a chronic nature, as well as in a few of the acute, the disease appears to be formed gradually, without any obvious exciting cause, under the influence of some depraved state of the constitution. And even in many of the acute cases, arising apparently in decided exposure to cold, the malady has silently originated in some constitutional cause at an earlier period, recent exposure having merely indulged and stimulated a pre-existing affection, or given an acute character to pre-existing essential symptoms. It is clear, too, from the character of the disease in the generality of instances, as well as from the very peculiar nature of the morbid deposition in all, that there must always coexist some constitutional infirmity, or otherwise some essential predisposing cause. This circumstance, however, does not exclude from the disease the constitutions of the robust and active frame; for we have witnessed it in persons of robust habit and powerful frame; and M. Sołtov makes the same remark as to his experience. But a robust frame is not incompatible with infirmity of constitution in respect of morbid disposition, as is familiarly exemplified by phthisis.

149. In this country, that state of constitution which results from habits of intemperance is the most influential in predisposing to the disease. Dr. Christison remarks, that from three to four fifths of the cases he has met with in Edinburgh have been in persons who were habitual drunkards; or who, without deserving this appellation, are in the constant practice of using ardent spirits several times in the course of the day, and of occasionally indulging to intoxication. In these persons, this habit is both a predisposing and an exciting cause, no other remote cause concurring to develop the morbid conditions constituting the disease. In the cases of the latter description among which we find both tubercular liver and granulated kidneys, and the resemblance between both kinds of lesion is very close. In many, however, of the cases which appear thus to originate, it will be found upon a strict examination—upon inquiring into their previous states of health, their hereditary predispositions, their apparent diathesis, and the evidences of either external or internal pre-existing affections—that they present more or less conclusive
proofs of the scrofulous constitution; habits of intemperance, and various other concurring or exciting causes, chiefly aiding this condition in originating the disease. The frequency of its occurrence in persons who have had enlarged or inflamed glands, or have presented other evidence of scrofulous or tuberculous affections in early life, and in persons labouring under tubercular consumption, is an additional proof of the truth of this inference. Among this class of causes, intemperance in sexual indulgence and manustipation may be added.*

150. Previous disease of the digestive, assimilating, and circulating organs of the stomach, liver, lungs, and heart—tubercular formations, and continued and eruptive fevers, more especially scarlatina—favour more or less the occurrence of the malady. In many instances, scarlet fever both predisposes to and more directly occasions it; no other causes but this being apparently concerned in producing it.

151. b. Exciting Causes.—a. Exposure to cold and humidity, or to either singly, and whatever has the effect of suddenly checking perspiration, as drinking cold fluids when the skin is perspiring, are the most frequent causes of the acute state of the disease; which most frequently occurs in persons who are most exposed, by occupation, to change of air or the inclement weather, or who live in cold and damp cellars or localities. These causes also often co-operate with others, not only in originating the malady, but also in producing relapses or exacerbations. They frequently, even in their slighter grades, are more or less influential in developing the disease after scarlatina, especially during or soon after the period of desquamation.

152. b. The chronic form of the disease is generally occasioned either by intemperance or by the prolonged influence of cold, humidity, and low, damp residences, or by both classes of causes. M. Rayer considers cold and damp the most frequent cause of the disease in France. Poor, inanitious, or unwholesome food, physical misery and destitution, are also influential in producing it. The inordinate or liberal use of mercury was considered by Dr. Wells and Dr. Blackall to be occasionally productive of albuminous urine; but Dr. Rayer has met with no proof of this effect of mercury. He states that there is no stage of syphilis or of scarlatina of feverish or even of a sub-acute state of the urine. I have seen two instances of this change in the urine in pregnant females, but had no opportunity of ascertaining the results in these cases. The preceding diseases which seem to be most influential in exciting, as well as in predisposing to cachetic nephritis, are scrofula, scarlatina, disorder of the functions of digestion and assimilation, diseases of the lungs, of the heart, and of the liver, and the syphilitic taint. It appears in the advanced course of tubercular consumption in a very large proportion of cases, and is always the consecutive affection, as remarked by M. Solan and Dr. Christison; but this connexion of the disease is more fully insisted upon above (§ 125).

153. vii. Treatment.—The treatment of this disease should depend much upon the form it assumes, upon its stage or duration, upon the causes which have induced it, and upon the complications it presents.—A. In the acute form and early stage of the disease, the treatment should be decidedly antiphlogisitic, but yet with strict reference to the predisposing and especially causes. — a. Blood-letting, general or local, is always necessary, especially at the commence- ment of the disease; and it should be carried to an amount which the circumstances of the patient and the degree of febrile action will sug- gest. In the majority of cases, cupping on the loins is the most appropriate method of vascular depleation; but, in the most acute states, and in more robust persons, a general blood-letting should be employed; and, in those, cup- ping on the loins may be even repeated in some instances. In children, after scarlatina, cupping should be the chief or only mode of depletion.

154. When the anasarca is great, resection should be practised with caution, as respects this operation itself; for, although there is a necessity for blood-letting, there is a great tendency to inflammation of the vein, if the incision be imperfectly closed, or exposed to the air. It is chiefly in the febrile, acute, and early stages of the disease, that vascular depleation can be employed with advantage, and especially when the disease is caused by exposure to cold and humidity. When acute or sub-acute symptoms appear in the course of the chronic form of the malady, even local depletions should be practised with caution; the previous and present states of the disease, the complications, and the constitutional and vascular conditions being the only guides by which the practice ought to be directed. In most cases, cupping is a preferable mode of depletion to the application of leeches, inasmuch as the quantity and state of the blood drawn are more accurately ascertained by the former, and crypsipelas is less likely to follow it than the latter.

155. b. In the acute and early stage of the malady, the warm or vapour bath may be employed, and be aided by warm bed-clothes, so as to promote the cutaneous transpiration. Diaphoretics may also be prescribed; and their operation may be assisted by warm dilluents, demulcicnts, &c., containing small quantities of nitre, or the species of nitric ether. If the patient leave his bed, especially if the season be cold, the clothing should be warm, and he ought to wear flannel from head to foot, and avoid currents of cold air and stimulant bever- ages.

156. c. Purgatives are always requisite, and the more so when the dropsalial effusion is great. They ought to be exhibited at the commencement of the treatment, and instantly after the first blood-letting. The selection of purga- tives should be guided by the complications, by the form and amount of the dropsy, and by the state of the urine. The compound jalap powder, elaterium, gamboge, the more common purgative pills (see Appendix), the salina aperic- ents, &c., may be prescribed according to cir- cumstances, and to the states of the stomach and bowels. When vomiting, or much irrita- bility of stomach is present, blood-letting, as just advised, will often allay this symptom, and prepare for the exhibition of purgatives, which
KIDNEYS—CACHETIC INFLAMMATION OF THE.

may be conjoined with coliculism; but if this symptom continue, carisate or the hydrocyanic acid will generally allay it. Dr. Pott remarks that, when the more active symptoms have subsided, the purgatives may be associated with diuretics; or the diuretics may be given alone, as the case may indicate. Of diuretics, the nitrate, tartrate, or super-tartrate of potash, Cunninghame's leeches, and the substillic acid nitrici, are among the best, and may constitute a part, at least, of the prescription. Blisters are doubtful remedies; though, if not kept applied too long, they may be sometimes useful. But strong mustard poultices, or other irritants producing speedy and decided effects, are preferable. When diarrhea accompanies this state or stage of the disease, warm baths, small doses of opium, or of Dover's powder, and leeches applied to the stomach or anus, are the most beneficial remedies.

157. When the urine has assumed its usual quantity and properties, we may conclude that the acute state has subsided; though the urine will be found to contain more or less serum for a considerable time subsequent to the attack, particularly after meals. In the latter stages, purgatives must be given with caution; but diuretics are occasionally required to the last; and warm baths are often of service, particularly when the skin of the patient, and shortly before the hour of repose. If, after a week or two, the quantity of albumen in the urine again become increased, and if other signs of a recurvature of the renal disease be present, cupping on the loins should be repeated, and this may be followed by the application of external irritants, and these by emollient cataplasm in the same situation. During the acute stage of the disease, the diet and treatment should be antiphlogistic. M. Ray er states that he has found a milk diet, continued for some days after the subsidence of the acute symptoms, of great service.

158. Treatment of the Chronic Form.—While the treatment of the acute disease is simple, that of the chronic is difficult and complex; and while it is often efficacious in the former, it is generally ineffectual in the latter. In the majority of cases, all that we can hope to effect is, to arrest or suspend the morbid action; a complete cure is hardly within our reach. The treatment, nevertheless, should embrace the various considerations suggested by the states of the urine and kidneys, by the attendant dropy, by the constitution of the patient, and by the antecedent disorder and present complications.

159. a. Whenever there is reason to suspect the existence of active congestion of the kidneys, either from a feverish state of the system or from local ulcerations, cupping on the loins may be resorted to; but we should be careful not to employ too large depletions, more especially when the renal malady has been prolonged and is far advanced, or structural lesion very serious. Great mischief will be done by lowering the powers of life in these circumstances, and the local change will be increased rather than diminished by the deploration. Unless at a very early stage of the chronic malady, the medicinal state of the blood, and even its deficiency, forbid the abstraction of it unless in small or moderate quantity, when the supervision of acute or sub-acute symptoms, or of inflammatory attacks of other organs, as of the pleura or lungs, demands a recourse to this measure; for the occurrence of these attacks during the course of the renal disease is the consequence of the attendant state of the blood chiefly, and not of the lesion of the kidneys per se—a state of the blood which generally contributes to the removal of bloodless or albuminous fluid. When the nature of the complication may seem to require it. The circumstances which more especially should suggest great caution in prescribing even local deploration are, debility and a manifest cachetic appearance consequent upon previous ill health, or a chronic continuance of the renal disease. The coexistence of chronic incurable maladies, as tubercular phthisis, lesions of the heart and valves, particularly insufficiency of the valves, disease, the growths in the stomach, the latter contra-indicating a recourse to general or local blood-letting.

160. b. In the chronic as well as in the acute form of the malady, warm or vapour baths, flannel clothing next the skin, and the avoidance of cold, humidity, spirituous liquors, and other exciting causes, are requisite. M. Ray er states that he has found selions, issues, and other exotories in the loins very advantageous; and that the friction or slow dripping of the tiincture of causticaries, given for a long time in emulsion, have also been of service. I have given equal quantities of this tiincture with the tincture of the sesqui-chloride of iron, with marked benefit, in a few instances. Iodurried and mercurial ointments have been prescribed to the loins without any service; and the balms have been taken internally with little or no advantage.

161. c. In the more advanced states of the disease, preparations of iron, judiciously chosen, and combined with other medicines, are often more or less beneficial. I have seen more advantage derived from them than from any other class of medicines. The circumstances of particular cases can alone suggest these preparations which should be selected. When the dropsical effusion indicates a recourse to hydrogogue cathartics or to diuretics, some preparation of iron should be added, particularly when the facility or cachetic dropsy is very manifest.

162. d. Of all diuretics, M. Ray er prefers a deoration of the wild horsetail. It may be made a vehicle for other medicines. He agrees, however, with Dr. Brown in having little confidence in the most of diuretic remedies, and thinks that Dr. Christison has overrated their value. In this disease, many substances disordor the stomach, thereby farther impair digestion and assimilation, and accelerate its unfaororable progress. Many diaphoretics, particularly when given in full doses, have this effect, as Dover's and James' powders. The deoration or tincture of guaiacum is the best of this class of medicines, especially when the skin is cool as well as dry. Diaphoretics, diuretics, and purgatives or aperients, when clearly indicated, should be selected and joined with strict reference to the states of the digestive organs, of the vital powers, and of the circulating fluids, as shown in preceding sections. It is clearly necessary to a neglect of such observance that an injudicious recourse to punctures of the skin has been had in this disease, in or-
to allow the escape of the effused fluid. The states of the system just alluded to favour the occurrence of inflammation and consequent gangrene of the punctured parts. Dr. Proud advises a recourse to a seton or issue in the region of the kidneys, and to the infusion of Diosma with sarsaparilla. As a diaphoretic he prefers the extract of ammonia, and, as the disease proceeds, the persea branis, or the na na, combined with other medicines, according to the circumstances of the case.

163. C. The treatment of the complications of cachectic nephritis is always difficult and often hopeless. When they assume an acute form, they must be promptly met, and subdued or arrested within twenty-four hours from their appearance. If they are of a chronic kind, we can expect only to palliate the more urgent symptoms. Of the diseases which are associated with the renal malady, it will be necessary to notice the treatment only of a few; for the means which are appropriate to the rest are either so manifest, or depend so entirely upon the circumstances of individual cases, that the physician will readily perceive them, and apply them accordingly.

164. a. In relation to diseases of the digestive organs (§ 114), the treatment of cachectic nephritis requires the utmost attention to diet and regimen. The food should consist of articles which are the most readily assimilated, especially of the lighter kinds of animal food, and of milk boiled with farinaceous substances. The bitter tonics, sarsaparilla with liquor potassae, or lime-water, or with Braxton's alkaline solution, and other restoratives, are especially necessary when the dyspeptic affection is attended by acidity and flatulence. In these as well as in other circumstances, the preparations of iron, but especially the Mist. Ferri Composita, are also beneficial, and should be taken for a considerable time. When irritability of stomach or vomiting is present, cressote, with or without opium, is a valuable medicine. When the bowels are also irritable, opium or morphia may be combined with cressote with advantage; but, in other cases, the latter may be given with biters and aromatics. Hydrogenbic acid may also be prescribed in similar combinations. If diarrhoea be present, opium, cetraceous mixtures or powders, linum, and aromatics, are requisite. In either of these affections, also, embrocations or fomentations may be applied over the epigastrium and abdomen, consisting chiefly of rubefacient and diarrhetic substances, sarsaparilla with liquor potassae, or cream of tartar, or with morphia, which are usually to be employed internally, or the nitrate of silver, or the acetate of lead, may be given with opium, &c. If peritonitis supervene, vascular dejection ought to be promptly prescribed; but with the knowledge that in most states of the disease, and in the more advanced stages especially, the loss of blood is not attended by much advantage. This is particularly the case if the dropsical effusion is considerable, and leucophlegma or cachexia manifest. The peritonitis in these circumstances is most successfully combated by fomentations with warm turpentine applied over the abdomen, and by opium with camphor taken internally. Lesions of the liver or spleen, even when recognised, are hardly influenced by medicine, when associated with this malady. The exact nature of the hepatic lesion frequently cannot be ascertained during life; and, if correctly inferred, the most appropriate treatment is neither manifest nor generally beneficial. In these, as well as in other unfavourable complications, the chief indication is to support the powers of life by attention to diet, by residing in a dry and warm air, by taking gentle restoratives with alteratives, and by attending to the alvine excitations.

165. b. The associations of this disease with affections of the respiratory passages and lungs require the most cautious use of the remedies usually prescribed for either the former or the latter; and those which are most serviceable for the one are most injurious for the other.

—A. Bronchitis is generally extended to both lungs; and, although it may be slight for a time, it may be suddenly aggravated so as speedily to terminate life. In most cases, the treatment advised for the more asthenic states of Bronchitis (§ 81, et seq.) should be adopted. The former is the more difficult to treat. When it appears in the course of this malady, the disposition to effusion requires the prompt use of suitable means; but these means are not the same as are generally found serviceable in the early stages of common pleurisy. Blood-letting and mercury must be sparingly, cautiously, or not at all prescribed; while the repeated application of blister, of the turpentine fomentation, &c., and a recourse to the hydrodate of potash internally, with other remedies suggested by circumstances, are most to be depended upon.—3. Pneumonia, also, when it occurs, generally affects both lungs, and is often of the kind usually denominated asthenic or nervous. Unless in the earlier stages of the nephritic disease, and in the more robust subjects, vascular dejections are seldom beneficial in these complications. A free use of tartar emetic, aided by external derivation, is much more deserving of confidence, especially in pneumonia, than depletions; but all means often fail in these cases. The same remarks are applicable to pleuro as well as to bronchitis. When it appears in the course of this malady, the disposition to effusion requires the prompt use of suitable means; but these means are not the same as are generally found serviceable in the early stages of common pleurisy. Blood-letting and mercury must be sparingly, cautiously, or not at all prescribed; while the repeated application of blister, of the turpentine fomentation, &c., and a recourse to the hydrodate of potash internally, with other remedies suggested by circumstances, are most to be depended upon. When the nephritic malady arises in the course of phthisis (§ 125), the latter is generally accelerated in its progress, whatever treatment may be adopted. As diarrhoea still continues to be more or less distressing, astringents, absorbents, and opiates are requisite, especially the sulphate of iron or of copper, with opium and cressote. The consecutive anasarca is commonly attended by a subsidence of the colliquative perturbations, and is said to absorb itself. The fragment is removed to the vapour bath; but the hectic is never permanent. Indeed, no plan of treatment is found of lasting service in this complication. I have employed the Mistura Ferri Composita, or other preparations of iron, conjoined with other medicines suited to the circumstances of the case, in this complicated state of disease. And although, in some instances, benefit was manifestly derived from them for a time, an unfavourable issue ultimately occurred.

166. The associations of cachectic nephritis with diseases of the heart and vascular system (§ 126) are no less hopeless than those with maladies of the lungs. The lesions of both the kidneys and the heart are reciprocally aggravat-
KIDNEYS—Cachectic Inflammation of the.

cation, treatment has little influence in arresting or in impeding the progress of either. The means most influential in producing the latter effect are those which promote digestion, assimilation, and free excretion. To support the powers of life, and at the same time to procure the discharge, by the several emunctories, of assimilated, effete, and injurious matters, are the objects of treatment by which internal excreta may be directed. These being recognised and guiding our practice, the choice of means should altogether depend upon the features of individual cases.

167. d. The association of this disease with cerebral affections (§ 131) is chiefly contingent upon the acute state of the former, and are then owing to imperfect assimilation and excretion, and to consequent excrementitious plethora; congestion or scroo effusion being thereby much more frequently produced than organic lesion of the brain itself. In those more acute states of this complication, cupping over the mastoid processes, or on the nape of the neck, blisters in these situations, active purging, stimulating embrocations on the loins, and the other means advised for the acute form of this malady, (§ 153) are to be chiefly resorted to. When cerebral affections occur in the advanced course of the chronic state of cachectic nephritis, the dependence which is placed on exhausted vital power, in connexion with vascular anitation; coma or lethargy being the most frequent forerunners of dissolution.

168. e. Cachectic nephritis consequent upon scarlet fever (§ 133) is the most favourable form of this malady; and when it assumes the acute state, the treatment should not materially differ from that advised above (§ 167). General or local blood-letting, purgatives, vapour or warm baths, diaphoretics, diuretics, and warm demulcents, the warmth of bed, warm flannel clothing, and removal to a warm, dry air, are the chief means of cure. If the disease be unattended by fever, if it become chronie, and the powers of life sink, stimulants and restoratives, particularly the tincture of the sesqui-chloride of iron, with the tincture of cantharides, warm, medicated baths, embrocations, blisters, &c., over the loins, are then requisite. If complications appear in this state of the disease, they must be treated contemporarily with the principles already insisted upon; but this subject is more fully discussed in the article on SCARLET FEVER.

169. f. The treatment of the other associations of cachectic nephritis mentioned above hardly requires farther remark. When the disease is very obviously complicated with scrofula, and particularly with scrofulous abscesses or ulcerations, the Mistura Ferri Coposita, liquor pectoris, with small doses of the iodide of potassium, sarsaparilla, the iodide of iron, &c., and other restorative remedies, with change of air, or change to a dry and warm atmosphere, and attention to the digestive, assimilating, and excretory functions, are most deserving of attention. The frequent occurrence of the disease in the scrofulous diathesis indicates the propriety of having recourse to the same means as have been found most beneficial in scrofulous affections. The appearance of cachectic nephritis during secondary syphilis (§ 138), or consequent upon it, although occasionally ob-
ate, as yet, but little acquainted with the best means of counteracting the effects of diseased blood, though there can be but little doubt that hydrogogue cathartics do this by expelling area. It has been ingeniously suggested whether matters containing oxygen in excess will have any influence in this respect. The _Indian hemp_ (Apocynum cannabinum), which is a powerful hydrogogue cathartic and diuretic, has been tried, with considerable advantage, in the New-York hospital, in these cases, in the form of decoction and extract. We have known such positive benefits result from its use in the treatment of this disease, that we think it well worthy of recommendation. The disadvantage attending it is the extreme uncertainty of its effects; these, we think, may be partially obviated by greater care in gathering and preserving it. A portion of its activity depends on a volatile oil, which escapes by drying and long exposure to the air. The troublesome symptoms attending the acute form of this affection are to be combated in the usual manner—vomiting by effervescing potions, or mustard, with the epigastic; diarrhoea, by the ammoniac, as the sublimate of zinc and copper or acetate of lead; bronchitis by blisters, opium, &c.; dropisal accumulations by hydrogogue purgatives and diuretics. Perhaps, however, there is no class of remedies more decidedly useful in the treatment of this affection, and all its complications, than diaphoretics. The patient is to be kept warm in bed, and a gentle diaphoresis kept up for a considerable time by external warmth and mild diaphoretics, and, in the cases we often find a decided improvement both in the quality and quantity of the urine, independent of other means. Dr. Osborn even assures us that, in treating of this disease, he found that "when ever general perspiration came on, either spontaneously, or in consequence of medicine, the cases always terminated favourably." In addition to the diaphoretic remedies already mentioned, we may name the acetate of ammonia, carbonate of ammonia, with camphorated mixtures, and the ammoniacal metal of venisection. We are inclined to believe, with Corahen, that when the disease has arrived at that stage which this writer terms cirrhosis of the kidney, it is nearly, if not altogether, incurable. Dr. Williams recommends in this form cupping at the loins, and hydrogogue purgatives, repeated from time to time, according as the strength of the patient will bear, together with external counter-irritants, warm, vapour, and hot air baths, warm clothing, &c. Croton oil, or the _Emp. tarm. ant._, forms the best substitute when hydrogogue counter-irritation. In addition to the diaphoretic already mentioned, we think the _sulphure of potassium_ one of the best. Tonics we regard as indispensable, for, by improving the general health, we increase the tone of the relaxed vessels of the kidney. The best of this class of remedies are quinine, nitric acid, combined with casecarilla, pareira brava, disossa, or uva ursi, iodide of potassium, sarsaparilla, and especially the persesquinimate of iron. The bowels are to be kept free, and all aggravating causes avoided. In addition, as cold, consisting of exercise, irregularities of diet, use of stimulating drinks, mental depression, &c. Mercury is regarded by many as a hazardous remedy in every form of this disease. Dr. Bell, however, of Philadelphia (Bell and Stokes’ Pract., vol. i, p. 539), states that, "as a purgative either alone, and followed by castor oil, or rhubarb and magnesia, or combined with jalap or rhubarb, it is entitled to a preference over most of the class. In the first mode, it is particularly useful where diarrhoea is present, a complication contra-indicating resins or irritating purgatives. In smaller doses, as of one or two grains, or an equivalent proportion of blue mass, I know of no medicine, next to antimony, which acts generally so well on the skin, by rendering it soft and moist, certainly none which acts so well on the mouth and teeth. Indeed, one of the peculiar advantages of these mercenial preparations is their ready and tranquillizing operation on inflamed secretory glands and surfaces. My own experience makes me as confident of the propriety of administering calomel or blue mass after venesection, for an excited kidney, whose secretory function is impeded, as I would be of its use in a similar condition of the liver. Where bronchitis is associated with a peculiar disorder of the kidney, Dr. Bell also states, that he knows no adequate substitute for the calomel. So far as we have observed, our experience in the use of this article coincides with that of Dr. Bell. It should, however, be recollected that salivation is easily induced in this disease, and, when brought on, produces highly injurious effects."

170. III. _Inflammation of the Pelvis and Calices of the Kidney._—Synonym. _Pyelitis_ (Bell, Stakes’; &c.)—_Pyelitis, Rayer._—_Pyelitis, Payza._

171. Inflammation of the mucus membrane lining the pelvis and calices of the kidneys is distinct from the species of nephritis already described, not only in its seat, but also in its symptoms and consequences. It sometimes assumes an acute form, but more frequently a _sub-acute or chronic_ state. It may affect the pelvis and calices of only one kidney or of both; and it may be limited to a portion only of their surface, or extended to several calices.

172. i. Symptoms.—Pyelitis assumes varied states, according to its grade of activity, its causes, and other circumstances. It sometimes attends or supervenes upon _catarrhus vesicae_, or inflammation of the mucous surface of the bladder; and it sometimes even follows _gonorrhoea_, especially when suddenly checked by astringent injections, and _retentions of urin_ from strictures or other causes. But it occurs in its most definite and best marked form when it proceeds from the irritation of sabulous or calculous matters in the excretory portion of the kidneys, or is connected with the termination of a calculus. It is occasionally also, connected with certain cutaneous affections remotely allied to syphilis.

173. a. When pyelitis supervenes upon _catarrhus vesicae_, or upon _gonorrhoea_, the symptoms are usually uncerainness, or more or less pain and sense of heat in the loins, attended by low febrile action, sympathetic irritation of the testicles, and sometimes by nausea, particularly when the secretion of mucus or macro-puri form matter is unusually large. If the inflammation of the mucous surface of the bladder still continue, the symptoms referable to this viscus predominate, and often mask those more immediately connected with the kidneys. In
all cases the symptoms should be examined in
connexion with the states of the urine.

174. B. When pyelitis arises from the irrita-
tion of calculi of sabulous substances in the
excretory portion of the kidneys, the symptoms
vary with the constitution and age of the pa-
tient, and with the nature, and form, and situa-
tion of those substances. When a calculus or
calci are situated so as not to obstruct the
passage of urine from the organ, the inflamma-
tion is frequently slight and limited in extent.
But when it is large, and is situated at the out-
let of the pelvis, or at or in the commencement
of the ureter, so as to obstruct more or less, or
entirely to close this opening, the parts above
the obstruction are generally become inflamed
throughout and less readied by urine, mixed with
mucus, and often with puriform matter and blood.
In these cases, the kidney is greatly increased in bulk, and the local and general
symptoms aggravated.

175. Pyelitis from calculi may be slight, and
not exceed a state of irritation not amounting
to that grade of inflammation developing gen-
eral febrile reaction. In such cases, the grat-
ually matters pass from the calculi into the pel-
vis, and thence, by the ureter, into the bladder,
occasioning only more or less pain in their
transit.
But when the calculi, from their size,
sharpness, or roughness, irritate greatly these
parts, or cannot readily pass along them, in-
flamatory action, with more or less severe
symptoms, is produced.

176. a. In the more acute cases, a sharp, severe,
or lancinating pain is felt in the region of ei-
ther kidney, descending thence, in the course of
the ureter, to the bladder, and if only one
kidney is thus affected, the urine always
contains some mucus and blood. On cooling,
the mucus appears in the urine in the form of
flocculi, which afterward fall to the bottom
of the vessel, and the blood globules, when pres-
ent, form a slight layer on the surface of the
sediment. All these symptoms may quickly
cease when the calculus has passed into the
bladder, and the urine becomes natural.

176. b. When calculus remain in the calices or
pelvis for a considerable time the inflamma-
tion becomes chronic, and the pain ceases to be
acute. The patient complains chiefly of union-
siness or of weight in the region of either kid-
ney; but pain, sometimes obtuse, at other
times sharp, occurs upon a sudden effort, or
unusual movement of the trunk, or when riding
either in a carriage or on horseback, and the
pain generally extends to the bladder and the
course of the ureters, and to the testes and
lumb corresponding with the affected organ.
Numbness as well as pain of the lumb is often
also felt. Decubitis on the abdomen, or on the
side opposite the affected organ, where one
only is affected, straining at stool, coughing,
neezing, a deep inspiration, the warmth of bed,
&c., generally augment the pain; which, how-
ever, may be slight, although several calculi
are contained in the pelvis and calices. These
pains, thus varying in severity and character—
being occasionally slight, sometimes colicky
and severe—frequently are independent of any
febrile action; but they are usually attended by
retraction of the testes, and by a reddish,
scanty, and mucous state of the urine, which
is slightly coagulable by heat. Sometimes the
urine is sanguinolent; at other times it is per-
fectly transparent, particularly after diuretics
and demulcents have been freely used. These
different states of the urine may be observed
in the same person in the course of twenty-
four hours. Upon cooling, uric acid, or the,
salts, are deposited with the blood and mucus,
these latter forming the surface of the sedi-
ment.

178. When the gravel consists of uric acid, as
is as most frequently the case, the urine is acid,
and the sediment contains rhomboidal crystals
of a yellowish-red colour. When it consists of
the phosphates, the urine is alkaline and tur-
bid at first, and various cloudy sensations,
frequently observed, that when the concretion is lithic acid,
the quantity of mucus in the urine, though con-
siderable, is not so striking and characteristic
as it sometimes is when it consists of the oxal-
ate of lime. This arises partly, perhaps, from
the diminished quantity of mucous secreted, and
partly from the quantity of lithate of ammonia
and other matters usually present, which in-
volve and conceal it. Where the calculus is
oxalate of lime, the mucus is sometimes void-
ed in great transparent, greenish gelatinous
masses of considerable tenacity, which occa-
sionally, in passing down the ureter, excite all
the acute symptoms. When the renal concre-
tion consists of phosphate of lime, the sym-
ptoms are much the same, and the mucus often
contains the earthly matter intermixed with it
in considerable quantity.

179. c. At a more advanced stage of chronic
pyelitis from calculi concretions, irregular
chills or rigours occur, especially towards night,
or after a meal, and various unusual sensations
are felt in the loins—as of pulsation, of tension,
of numbness, and even of cold—which often
extend down the corresponding thigh. The
urine is sometimes sanguinolent, but oftener
turbid and whitish, allowing a puriform and
white, or slightly greenish-white, sediment to
fall, consisting chiefly of pus and urinal salts.
The discharge of blood in the urine is occa-
sionally the first remarkable symptom, espe-
cially when the pellets of both calculi have
passed, and frequently the urine becomes tur-
bid and puriform, and passes frequently and in
small quantity, with or without sabulous mat-
ter in it. In the course of the disease, the pa-
ton experiences exacerbations, characterized by
more acute symptoms, by vomiting, and fever.

180. The urine is usually bloody or purulent
every time that it is voided, unless one kidney
only is affected, and the secretion from the
diseased one is partially or entirely interrupted.
Great variations, however, both in the frequen-
cy of the calls to pass the urine, and in the
physical and chemical characters of it, are ob-
servable. When purulent urine coming from
the inflamed pelvis of a kidney is retained only
759

KIDNEYS.—Pyelitis.—Diagnosis.

partially in its cavity, it is mixed in variable proportions with the urine from the other kidney, which may be then perfectly healthy. Hence the urine may, in the course of the same day, be different in appearance at different times—it may be charged with pus or blood, or with both, at one hour, and be clear and healthy at another hour. The urine, therefore, should be frequently inspected. In some cases, M. Ray-
er states, the suspension for a time of the un-
healthy urine is accompanied with an aggravation of the renal distress, and with a febrile state of the system, probably in consequence of the ureter of the affected organ becoming obstructed, and the urine therefore accumulating in its pelvis. The symptoms usually sub-
side when the urine exhibits a purulent admix-
ture. When this fluid is at all purulent, it is
found also albuminous; the amount, however, of the coagulum produced by heat or mori- nce acid is by no means proportionate to the quantity of urine contained.

181. d. When chronic pyelitis has existed for a long time, and the excretion of urine along the ureter is much obstructed either by the presence of a calculus in it or in the pelvis, or by any other cause, a swelling may sometimes be distinctly felt in the lumbar region, the swelling occasionally evincing an obscure fluctuation, and appearing irregular or lobular on examination. This tumour is formed by the accumulation of puriform matter in the cavity of the pelvis and calices of the kidney; and, when very large, is felt in the corresponding flank, where it may extend from the margin of the ribs to the iliac fossa. M. Rayer has seen tumours formed by purulent matter dis-
tending the pelvis and calices of the kidneys weighing as much as from ten to fifty pounds. Owing to the development of such tumours, the lumbar region is more or less swollen, enlarged, and deformed on the affected side. On percus-
sion, the swelling emits a dull sound behind, and generally also anteriorly, unless the colon, distended by air, prevents it. When, how-
ever, the tumour is large, the colon is general-
dly pushed aside by it. The right kidney, when thus distended, sometimes adheres to the mar-
gin of the liver, and thus seems, on percussion and palpation, to form one structure with this organ, and is often mistaken for a tumour, or for enlargement of it. Tumour thus formed of the left kidney is not so readily mistaken for enlargement of the spleen, unless the examina-
tion is very superficial. When the tumour is very large, it generally seems knotted or lobu-
late, and fluctuation may be perceived in it. Pain is rarely acute in this state, although it may be produced by pressure or succession of the trunk.

182. e. In a few instances, the mucous mem-
brane of the pelvis and calices of the kidney surrounding the calculus becomes thickened, indurated, so as to secrete little or no purulent matter, and these parts form, with the atro-
phied substance of the kidney, a sac, or shell, more or less closely surrounding the calculus. If the opposite kidney is healthy, this change, made manifest by the tense superior pole of the sac, may be perceived by the pa-
ient experiencing no pain, and the urine contain-
ing no pus: but if disease, calculus, or ob-
struction affect the sound organ, suppression of urine and death soon take place. In the

less severe and chronic cases of the disease, suppression of urine and death may also occur, especially when both organs are seriously af-
fected, or when calculus obstruct both the pelvic outlets or ureters.

183. These several states of pyelitis may be
denominated nearly as M. Rayer has named them: 1st. Pyelitis, characterized by sharp pain, or
nephritic colic, and suppressed or scanty urine ($\S$ 176, a); 2d. Pyelitis with mucous
urine and occasional pain ($\S$ 177, b); 3d. Pye-
ritis with purulent urine, and without renal tu-
mours ($\S$ 179, c); 4th. Pyelitis with purulent urine and with renal tumour ($\S$ 181, d); and, 5th. Atrophy of the kidney, the urine being generally clear (182, e).

184. ii. Diagnosis.—Pyelitis may be mista-
ken for several other diseases; for a mucous or purulent state of the urine attends inflamm-
ation of the bladder or urethra; and lumbar pain exists in rheumatism, nephralgia, &c. Tumour of the lumbar region also proceeds from dis-
cases connected with the kidneys. Nephritis in acute simple nephritis is sometimes as severe as in pyelitis, but seldom as severe or as sharp as in pyelitis caused by calculi. In this latter, the pain occurs in paroxysms, or presents ex-
acerbations, and is more disposed to shoot in the direction of the ureter, and to be attended by retraction of the testes of the correspond-
ing side. The existence of mucous or purulent matter in the urine will also assist the diagnos-
tis.—b. True nephralgia may be confounded
with calculous pyelitis; but generally the pain of the latter is more acute and cutting, or lacer-
ating than in the former, and is obviously connected with gravel, calculi, and other chan-
ges of the urine, above described; while the former very rarely occurs, unless in connexion
with hysteria or with irritation of the uterus.

—e. In lumbago the pain commonly affects both sides alike and at the same time, instead of being felt chiefly or altogether in one side, as
in pyelitis; is more continued, and does not extend, in the course of the ureter, to the blad-
ner; and is not accompanied by the movements of the trunk. Lumbago is generally without
fever, and often preceded by rheumatic pains in other parts.—d. Hydatids in the kidneys are
seldom attended by much pain, unless they pass into the pelvis of the organ, and occasion inflam-
mmation there or in the calices, where the pains, although less acute, and the other symp-
toms are nearly the same as in calculous pye-
ritis. The passage of hydatids with purulent
urine will generally indicate their source in the
kidneys when pain is referred to the renal re-

gion, but not with certainty, for they may come
from cysts connected with the bladder, but
this is a very rare occurrence.—e. In some
rare cases of suppression of urine the pain in the
region of the kidneys has been severe, and the
patient has been carried off by cerebral affec-
tion; and yet all the structures of the kidneys
have been found free from marks of inflamma-
tion. In some cases, very large calculi may
lodge in the pelvis without causing either much
inflammation or much pain. Occasionally, also,
the pain has been felt in the situation of the
opposite kidney to that which contained the
calculus, or in some part still more remote
from the irritated organ. Instances where very
large calculi were formed in the kidneys with-
out having produced any marked symptoms, or even much disorganization, are recorded by Baglivi, Hoelle, Hennig, Boralli, Pozzi, Morgagni, De Haen, Van Swieten, Howship, and others.

185. f. Caries of the vertebrae is generally attended by a dull pain, but it cannot be mistaken for pyritis, unless paraplegia, with retention of urine, and changes in this fluid, take place, and then pyritis may actually supervene. The state of the vertebral column, and abscess appearing in some one of its usual situations, will generally show the nature of the disease. The abscess is accompanied with pain, which is continued and often severe, extending from the lumbar region to the pubis and top of the thigh, the trunk being bent forward, and to the affected side. Motion of the thigh is extremely painful, and edema of the limb often occurs. If suppuration take place, the abscess increases the edema, but its situation is lower, and more anteriorly than that of the puriform collection in the pelvis of the kidney consequent upon pyritis. If the abscess open into the bladder, the pus is accompanied with pain, which is more difficult, as in a case recorded by Mr. Howson. —h. Ancymia of the abdominal aorta gives rise to pain, very much resembling nephritic colic, or the renal pain attending calculus in the kidney. The pulsation of the tumour, the evidence furnished by auscultation, and the state of the urine, will, however, indicate the disease. When tumour is inconsiderable or absent, the nature of the lesion is obscure, particularly in its early stages. —i. Induration of a portion of the colon in the vicinity of the kidney can hardly be mistaken for pyritis, for the state of the bowels, and the appearance of the urine, will prevent them from being confounded with one another. —k. Hysterical pains in the region of the kidneys are characterized by abundant, pale, and transparent urine, and by other indications of hysteria (see the article). Hysterical patients are, however, liable to disorder of the excretion of urine, but not to those characteristics of this fluid attending inflammations of the kidneys; and they are prone to attribute various deceptions connected with the performance of this function.

186. B. The excretion of mucus and neopuriform or purulent matter in the urine may take place in other diseases besides pyritis, and especially from acute or chronic inflammation of the bladder, which may simulate disease of the kidneys; this latter also, in its turn, often simulating disease of the bladder. In all cases, it is most difficult to determine, by the appearance of the urine, whether the kidney or the bladder is inflamed; in some cases both are affected, although not equally. In most instances, the urine is cloudy and viscid in cystitis, and there is pain and uneasiness in the bladder, but there is no pain or swelling in the loin, nor any of the sympathetic feelings depending upon pyritis. The urine is generally less puriform and opaque than in this latter disease; the dysuria attending which is usually connected with the presence of pus. However, if the puriform urine of pyritis be alkaline, it will become both cloudy and viscid; and the secretion from the inflamed surface of the bladder is not always cloudy. The absence of pain in the region of the bladder, while severe or sharp pain is felt in either lumbar region, will also assist the diagnosis.

187. C. The tumours consequent upon chronic pyritis, with occlusion of the outlet of the pelvis or ureter, may be confounded with others, and it is sometimes of importance to form a correct diagnosis between them. —a. M. Ray remarks, that a collection of urine in the pelvis of the kidney, owing to obstruction of the ureter (hydro-nephrosis), causes a tumour or enlargement of the lumbar region, very closely resembling that produced by an accumulation of pus in the same situation; that both are lobulated, dull on percussion, and evince fluctuation; but in the latter the sense of abdominal pain, or becomes painful on pressure, and is attended by fever—phenomena which seldom accompany the collection of urine merely. Besides, when the passage from the kidney is not entirely obstructed in pyritis, the urine is somewhat puriform and opaque. —b. An abcess seated in the cellular tissue in the vicinity of the kidney may be mistaken for purulent collection in the pelvis of this organ; but in the former, the pus is superficial and manifest than in the latter, and there is generally a discharge of the sub-cutaneous cellular tissue in the lumbar region, an edema never met with in the latter. Cases, however, may occur of an abscess forming externally to the kidney in connexion with an accumulation of purulent urine in the pelvis and calculus; these are rare, and occur chiefly when a fistulous opening is formed between the pelvis and the adjoining cellular tissue. Ulceration, caused by calculi penetrating the pelvis, may give rise to a collection of pus which may open either externally or into the colon, or even into some other viscus; and one or more renal calculi may be voided in these situations, either subsequently to or along with the discharge of pus. The origin of these fistula is shown by the urinous odour of the discharge and by the presence of uric acid, or of the urinous salts, or of calculi; still, these signs may be wanting for a time, although one or other of them may recur from time to time.

189. d. Tumours, or swellings in the region of the kidney, may proceed from other diseases than the above, and render the diagnosis of distention of the pelvis and calculus of this organ by puriform matter more or less difficult. These diseases are cysts in or near the kidney, containing hydatides; simple, or sessile, or urinous cysts of large size; tumours developed in the supra-renal capsules; aneurysm of the abdominal aorta; enlargements of the spleen; tumours or cysts connected with the right lobe of the liver; enlargement of an oeisy; accumulations of fecal matters in the cecum or colon; and
extra-uterine pregnancy. Of all these it is unnecessary to take particular notice. The recollection that these may severally closely resemble; in their situation and local signs, the consequences of chronic pyelitis now under consideration, and the attention to the existing phenomena which the recollection will excite, cannot fail of guiding the practitioner to a right conclusion. The history of the case, the sympathetic pains, the states of the stomach and bowels, and, above all, the appearance of the urine and the circumstances attending the excitation of it, will receive from him the fullest consideration, and serve to point out the seat of the affection.

190. iii. Prognosis.—Pyelitis in its first or acute form (§ 176), arising from urinary concretions, is generally not attended by danger when one kidney only is affected; but the second, and more especially the third and fourth states of the chronic disease, are always of more or less serious moment, even when one kidney is implicated: if both organs are diseased, the prognosis is still more unfavourable; for the contingencies of ulceration of the pelvis of the kidneys, of atrophy of their structure, of suppression of urine and its consequences, and various other results of less frequent occurrence, are to be expected in a large proportion of such cases. Anticipations should be still more unfavourable if a puriform collection in the pelvis of the organ arise from obstruction at its outlet, and thus form a tumour in the loins, unless it opens externally: in this latter case, it often terminates favourably. The complications of chronic pyelitis with other lesions of the kidney or of the urinary organs, or with other affections of the body, render the prognosis extremely unfavourable.

191. In cases of tumour or abscess of the kidney consequent upon the obstruction of a calculus, as described above (§ 187), suppuration and ulceration may proceed, as already mentioned; and if the swelling point in the loins, the calculus or calculus may escape in this situation, by the spontaneous or artificial opening of the abscess, and the patient recover. Proceeding upon the results of such cases, some physicians have recommended, in some instances, an incision should be made into this tumour at a proper period of its progress, or that caustic should be used in opening it. Each of these modes of procedure may be resorted to, and be successful in cases to which they are severally appropriate. It is most probable that, in the successful cases of these operations on record, the calculus had passed by ulceration from the pelvis of the kidney into the cellular tissue exterior to it, and that they had been extracted from an extra-renal abscess formed by it.

192. iv. Complications. — A. Inflammation of the pelvis and calices of the kidney occurs more frequently in connexion with inflammation of the vascular and tubular structures than in a simple or uncomplicated state; or, in other words, pyelo-nephritis is more common than either simple nephritis or simple pyelitis. — a. When pyelitis is the primary affection, nephritis often supervenes; and, as a consequence of the former, or of pyelo-nephritis, atrophy of the cortical and tubular structure is the most frequent. Ulercation and perforation of the pelvis of the kidney is less common than atrophy of the organ; but when it takes place, abscess external to the kidney generally forms, with or without the escape of the calculus that caused it. Although one kidney is affected, still functional disorder may, at the same time, be extended by sympathy to the other. Calculous pyelitis of both kidneys is not rare. M. Rayer refers to several instances of the double malady. In the more prolonged cases of chronic pyelitis of one organ, the other either remains healthy or is hypertrophied consequent upon increased function.

193. b. Pyelitis is often attended by hemorrhage from the kidney, particularly when caused by calculi along the lumbar vein. An acute critical of pre-existing pyelo-nephritis, the inflammation of the substance of the organ being abated or altogether removed by the discharge. This association has been aptly named, by M. Rayer, hemorrhagic pyelitis and hemorrhagic pyelo-nephritis, and is certainly not of unfrequent occurrence in connexion, especially, with calculus in the kidney, although the sanguineous state of the urine constitutes apparently the chief, but actually the least important part of the malady.

194. c. Pyelitis, in any of its states, may be associated with disease of the prostate gland, or of the bladder, or of the urethra, or of all of them, and these affections may be further complicated with stone in the bladder. In the majority of such cases, the ureter or ureters are also affected, being either dilated or constricted, or both dilated and constricted, in different or alternate parts. Sometimes the coats of the ureters are thickened; and occasionally a complete obliteration of the canal, in one of them, is found in some points, which are either excluded by a whitish, firm, albuminous deposit, or are reduced to a fibrous chord. Mr. Coulson very ably remarks, that when a urinary vesical calculus has been formed for years, and has brought on severe symptoms, and especially when attended by stricture of the urethra or enlarged prostate gland, the kidneys, though before healthy, become involved; the severe dysuria causes enlargement of the ureters from distention of the retained urine, and inflammation extends along them, even to the kidneys themselves. The pelvic cavities become altered in shape and enlarged, the infundibulum extended or unfolded, and the internal membrane of all the cavities thus acted upon, from repeated attacks of inflammation, is thickened, and furnishes a catarrhal secretion. The parenchymatous substance of the kidney is more or less absorbed, the mammmary projections are obliterated, spurious hydatids occupy the cortical part, and all the serious evils, ulceration, contigous abscess, or gangrene, are met with as sequelae of vesical calculus.

195. When pyelitis is associated with inflammation or other diseases of the bladder or prostate gland, the severity of the symptoms in these organs may render obscure or altogether mask the affection of the kidneys; and this is the more likely to be the case, inasmuch as pyelitis is commonly the consecutive or superinduced malady: and it may even continue after the disease of the bladder has been removed. It is a more rare occurrence for pyelitis to propagate itself along the ureter, so as to occasion true cystitis, and it is met with chiefly when sab-
ulous or gravelly matters, occasioning pyelitis, pass into the bladder, and inflame it or the urethra, or when purulent matter from the pelvis of the kidney produces the same effect, which, however, seldom arises unless this matter is retained for some time in the bladder, or undergoes some degree of decomposition, or occasions an ammouniacal state of the urine, or unless the urine is more or less alkaline when it passes into this viscus. It should be recollected that, when great irritation is produced by calculi in the kidneys, severe symptomatic pains are sometimes felt in the bladder, without any actual disease existing in it; but it is much more common to find very serious lesions in the kidneys, although no pains in the bladder. Hence it is to the substances of the organ or bladder, or calculus there, being the only apparent malady. Thus it has happened that able surgeons, before undertaking the operation of lithotomy or of lithotripsy, have examined attentively the regions of the kidneys, without detecting any signs of disease of these organs; and yet, after the operation has been performed, a violent rigour or shiver has taken place, followed by fever and death; and, upon dissection, not only have calculi and pus been found in the pelvis of the kidney, but the substance of the organ has been more or less inflamed or otherwise altered. These latent states of pyelitis occur not only in connexion with vesical calculi, but also with other maladies of the bladder and prostate gland; and they are latent merely from want of due attention to, or due knowledge of, the states of the urine attending the renal disease, this fluid generally containing purulent matter, or pus globules, readily miscible with it, and very distinct from the glairy mucous sediment accompanying chronic cystitis—the urine in pyelitis being puriform, that of cystitis being mucous and glairy: when, therefore, the one disease is complicated with the other, there is commonly a mixture of puriform matter with a mucous or a glairy substance; and the one predominates over the other, according as the one disease is more severe than the other. Some modifications, however, of the urine in these diseases and in their complications, arise from the saline constituents or deposits, which often change the appearances of those morbid alterations, in an alkaline state rendering purulent urine more glairy than its acid or neutral conditions. Moreover, it should be recollected that, in very chronic and prolonged cases of cystitis, the urine is often more or less purulent, or contains pus globules mixed with mucus.

196. Whenever disease of the bladder or of the excretory urinary canals is attended by retention of urine, there is a great risk of the superinfection, not only of pyelitis, but also of nephritis, as a consequence of and in connexion with pyelitis—either this latter simply, or pyelo-nephritis, occurring as a result of the disease of the excretory urinary apparatus; and the malady, thus superinduced in the kidneys, may be acute or sub-acute in the one organ, and chronic in the other.

197. d. Calculous pyelitis, in any of its forms, may be associated with pregnancy; for, when there are calculi in the kidneys, they are more likely to give rise to inflammatory irritation at this period than at any other; unless, indeed, soon after delivery, when calculous pyelitis occasionally takes place.

198. c. Pyelitis is sometimes complicated with other diseases; but it is unnecessary to describe fully the phenomena attending it when thus associated. A large number of the maladies with which it is most frequently connected will serve to direct attention to the subject, and will suggest to the physician when such complications may exist or supervise. Pyelitis may occur after injuries or diseases of the spine; and may be farther associated with lesions of the bladder and prostate gland. In all such cases, especially when interruption of the excretion of urine takes place, cerebral affections of a most dangerous kind are apt to appear. Moreover, cases of urethral gout, diseases of the vascular system, and fevers, are not uncommonly accompanied by pyelitis; indeed, there is scarcely a malady which may not be complicated with it, particularly in persons far advanced in life.

199. B. Pyelo-nephritis, or inflammation of the pelvis, calices, and substance of the kidneys, is the most important of the above complications, and occurs oftener than either nephritis or pyelitis simply.—a. In pyelo-nephritis, the inflammation takes place in the pelvis and calices, and rarely in the substance of the organ. Hence it generally proceeds from the same causes as are productive of pyelitis, as the irritation of calculi, interruptions to the excretion of urine, and inflammation propagated from the urethra, bladder, or ureters, &c. It is more prevalent in males than in females, and in persons advanced in age than in the young. In these respects, however, it agrees with the other forms and complications of nephritis, deaths from this disease, according to Mr. Farr's letter to the registrar-general (Third Annual Report of Births, Deaths, &c.), being in the proportion of 21:20 males to 7:60 females, or nearly 3 to 1, in the years 1838 and 1839; and from diseases of the urinary organs generally being 1:275 in the former to 2:259 in the latter, or 12:750 to 2:590, or about 6 to 1, in the same years.

200. b. Pyelo-nephritis may be either acute or chronic; it may be limited to one kidney, or extended to both; and it may be more or less acute and chronic, or both, according to the organ than in the other: it may, moreover, present the following states, according to its causes and prominent characters: it may be, 1st. Simple inflammation of the pelvis, calices, and proper structures of the organ; 2d. Inflammation of these parts in connexion with gravelly or calculous substances; 3d. Inflammation accompanied with hemorrhage, or hematuria; and, 4th. Inflammation with a disposition either to albuminous exudations or to gravelly affections in the state of constitution of the individual and intensity of the disease. Of these, the last is the most uncommon.

201. c. In these forms of pyelo-nephritis, mucus and pus globules may be detected in the urine; but they will not be observed in simple nephritis, or when the inflammation does not extend to the calices and pelvis of the kidney. When pyelo-nephritis follows lesions of the urethra, prostate, or bladder, it commonly extends to both organs, but do not present the same extent and grade of inflammation.
When it proceeds from injury, or when the disease commences in the cortical and tubular structure (a comparatively rare circumstance), and extends to the calices and pelvis, or when it is caused by calculi, then only one kidney is generally affected.

202. C. Peri-nephritis, or inflammation extending to the fibrous, cellular, and adipose tissues surrounding the kidney, rarely occurs, unless after injuries or wounds implicating this organ and those tissues, and when calculous pyelitis is followed by ulceration and perforation of the pelvis of the kidney, and by renal fistula. It is chiefly in these circumstances that peri-nephritis is usually met with, and it is then associated either with nephritis, or with pyelitis, or pyelo-nephritis.

203. a. It rarely appears in a primary and simple form, and as rarely can be detected as such during life, or until it passes into abscess, when it assumes nearly the form of abscess consequent on pyelitis with perforation of the pelvis of the kidney (§ 187). Instances, however, have been recorded of primary inflammation of the cellular-adipose substance surrounding the kidney after injuries, and the impression of cold; but it is more common as a consequence of the passage of purulent matter into the circulation, of severe fever or erysipelas, of ulcerative perforation of the colon; and in these circumstances it has been found chiefly upon examination after death. Peri-nephritis more frequently follows ears or fracture of the vertebrae, and in these, as well as in other circumstances of its occurrence, generally gives rise to abscess of greater or less extent. When this takes place, fulness or swelling of the loin of the affected side, with obscure fluctuation and edema of the sub-cutaneous cellular tissue over the part, is usually present. When abscesses form in this situation, they may involve the kidneys, pelvis, and ureters, more or less, and they may extend to and open in immediately adjoining viscera, or parts considerably remote.

204. b. When peri-nephritis is simple, or has not involved the kidney, pelvis, or ureter, and is independent of disease of these parts, it is generally obscure. The urine does not present the characters marking the presence of nephritis or pyelo-nephritis; but there is much tenderness of the loin and symptomatic fever, soon followed by edema and swelling. As soon as purulent matter forms, it increases, and accumulates between the peritoneum and lumbar membranes in the loin, as well as in other parts of the body; or it may open into the peritoneal cavity, or into the colon or rectum; or it may make its way in other directions, as in the lumbar region, or at or near the angle formed by the spine and posterior part of the crest of the ilium, on either side of the lumbo-sacral or lumbo-iliac ligaments. When the abscess is opened early in these situations, particularly the latter, recovery may take place; but this result will depend chiefly on the nature of the original disease, or of its causes and associations. These abscesses have usually been denominated lumbo or paraspine abscesses, and are more fully noticed in the article Abscess.

205. c. Gangrene is a much rarer termination of peri-nephritis than suppuration. In a remarkable ease of the primary and simple form of this malady—the inflammation apparently commencing in the cellular-adipose tissue surrounding both kidneys—recorded by Dr. Turner (Med. Trans. of Coll. Phys., vol. iv, p. 226), the disease followed exposure to a current of cold air after being overheated by prolonged exercise on horseback. Severe pains were felt in the loins, and the symptoms were altogether violent and obscure. The urine was natural in quantity, and there were no unusual calls to pass it. Death speedily ensued. On examination, the cellular-adipose tissue surrounding both kidneys was enveninous; the capsules of both organs were inflamed; but the substance of the kidneys was only slightly inflamed.

206. d. Peri-nephritis may, therefore, arise from inflammation extending from the kidney to the surrounding cellular-adipose tissue; but this rarely occurs, unless the pelvis of the kidney is perforated by ulceration, especially in calculous pyelitis, as shown above (§ 187); and when such perforation occurs, a renal fistula is often formed. It is consequent on the pus or bacteria of peri-nephritis arise independently of disease of the kidney, it may be either primary and simple, or it may be consecutive of other maladies, especially of lesions of the parts in the vicinity, and of constitutional disease, as alluded to above, and more fully in the article Abscess.

207. d. Renal Fistula.—Renal fistula may follow wounds implicating the kidneys, or their pelvis or ureters; but they are more frequently the consequence of inflammation of the pelvis and calices, which become distended and fistulous matter, owing to obstructions to its passage to the bladder; and these obstructions are commonly caused by the impaction of one or more calculi in the pelvis or ureters. The accumulated matter may find its way, by ulceration and distention, into the surrounding cellular tissue, and thence open either in the lumbar region, or near the crural arch, or in the colon or duodenum, or in the peritoneal cavity, or in the corresponding pleural cavity or lung. These fistulous communications extend from the pelvis and calices into the cellular tissue upon which the posterior aspect of the kidney rests. In these cases, an extra-renal abscess, more or less extensive, forms, and proceeds in one or other of the directions just named. The most frequent and most favourable situations in which it points are the lumbar region and near the crural arch. In the other situations where a fistulous communication has been formed, or in the examination of a patient who has died, the fistula disclose the nature of the lesion, and, in some cases, prove the accuracy of the diagnosis which had been formed from the swelling in the region of the kidneys, and from the nature of the matters voided during the life of the patient.

208. v. Treatment of Pyelitis.—A. In the early and acute state of pyelitis, the chief intention should be to diminish local vascular action, and to alleviate the more urgent symptoms. Local blood-letting, by cupping over the loins, or the application of leeches to the perineum and around the anus; the warm bath, or the semicuprum; muellinious and emollient beverages; opium, or other anodynes, with demulcents, &c, are the chief means by which this indication may be fulfilled. When pain is very acute, and is attended by suppression of urine, frequent
vomiting, or spasmodic attacks, cupping on the loins should be decidedly employed and repeated, and be followed by the warm bath: pills, containing camphor, opium, or belladonna, may be taken: friction or embrocations with any of the liniments prescribed in the Appendix, to which opium or the extract of belladonna has been added, may be applied to the loins or abdomen, and emollient and laxative enemata with henbane may be administered. The preparations of ether, or the spirits of nitric ether, with the compound tincture of camphor, the alkaline carbonates, and anodynes, may likewise be prescribed in metallic pessaries, mixtures, and in some cases with opium or other of the preparations of calcicum. The more violent symptoms generally subside in a few hours, owing either to the change in the position of the calculus, to which they are generally owing, or to its passage into the bladder. In some cases, the calculus or calculi, or gravelly matter, is passed with the urine, and relief is obtained. In these more severe attacks or paroxysms, and where the above means have been employed without relief, dry enemata or poultice, or over the course of the ureter, may be tried. When a calculus is obstructing, and irritating, one of the ureters, as indicated by the seat of pain, and by the sympathetic phenomena, I have found this means sometimes successful. Purgatives, especially calomel, or calomel with opium, followed in a few hours by castor oil, or any suitable purgative draught, or by emollient and laxative enemata, are generally of service. Excretory and standing with the feet on cold stones, sometimes advised in these circumstances, have appeared more injurious than beneficial; but ipecacuanha or emetic tartar, conjoined with opium, and given so as to occasion more or less nausea for some considerable time, has occasionally been of service. When the acute symptoms indicating the presence of a calculus in the pelvis of the kidney, or in the ureter, have subsided, and the patient has not voided it, the urine still continuing to be charged with mucus, a catheter or sound should be passed into the bladder, in order to ascertain whether it is in this viscus or not, so that it may be removed by such medical or surgical means as may be deemed most appropriate.

209. B. The second indication is to remove chonic inflammatory action in the kidney, and to counteract the disposition to form calculi, or gradually to dissolve them by physical means suited to the morbid condition, and to the presence and state of the urinary deposits—A. This indication is more especially appropriate to the chronic, or second and third stages of the disease (§ 177–9). The morbid condition of the urine, in most of these cases, is owing to the states of digestion and assimilation, in connexion with excess in the quantity, and with inattention to the quality and congruity of the food. The chronic inflammatory action existing in the kidneys is also thereby perpetuated, and in its turn assists in determining the seat and form of the urinary deposits. In these states of disorder, a restricted diet, or a diet suited to the states of constitutional power, and to the amount of exercise habitually taken; attention to the digestive, assimilative, and excreting functions; regulated exercise in the open air; occasionally small cuppings on the loins, or a seton or issue in this situation, or a recourse to terebinthinate embrocations applied on the lumbar region, and various remedies taken internally, may be prescribed.

210. In this state of disease alkalies and the alkaline carbonates, in various forms of combination, have been employed. But they are not suited to all cases, nor is a persistence in the use of them without inconvenience, or even devoid of risk. Even in those cases for which they are most appropriate—where uric acid deposits are observed—they may so impair the digestive functions as to increase the evil they are employed to remedy. In every case, the selection of internal remedies should be directed by the chemical state of the urine, and particularly by its acidity and alkalescence.

211. b. When the urinary deposit indicates the presence of the lithic acid, calculi in the kidney—the most frequent form of concretion, especially in gouty and phlegoric persons—cupping freely on the loins, calomel with calcicum or henbane, and brisk purgatives; alkaline and gently diuretic substances in mucilaginous and mastic mixtures; a farinaceous or milk diet, simple diuretics, and regular exercise in the open air, are the most beneficial means.

212. c. When we infer, from the nervous and the hypochondriacal state of the patient, and from characters of the urine, that the affection of the kidneys is connected with the oxalate of lime concretion, depletions and evacuations are not so requisite as in the foregoing circumstances. The means which are most serviceable for removing this form of concretion are diuretic purgatives, or drench, and especially the dilute nitro-muriatic acid, with either the nitrous ether, or the hydrochloric ether. In addition to these, sedatives, as henbane, the compound tincture of camphor, the warm bath, regulated diet, consisting of animal food and the purest farmaceous articles, attention to the digestive and excreting functions, and exercise in the open air, are generally beneficial.

213. d. When the affection of the kidneys is connected with the cystic oxide or phosphatic concretions, as caused by the caeclectic, debilitated, or exhausted state of the constitution, and by the alkalescent condition of the urine and the composition of its deposits, a course of sarsaparilla; warm rubefacient or terebinthinate embrocations and fomentations on the loins, or setons or issues in this situation; demulcents and sedatives, and the remedies just mentioned (§ 212), may then be employed.

214. e. During the chronic state of another calculus, the means already advised (§ 208, et seq.), warm fomentations, warm diuretics, and sedatives; emollient enemata; nauseating doses of ipecacuanha, or of antimony; the various kinds of soap, with opium, belladonna, or henbane; the infusion of Diosma, with medicines appropriate to the nature of the urinary concretion; and citrate of ammonia or nitre in demulcents, may be prescribed according to circumstances.

215. f. When the chronic states of pyelitis are characterized by a puriform state of the urine, the infusion of Diosma, or the infusion, decoction, or extract of urerum, of paracira, [or of pyro anumbellata], may be prescribed, and be conjoined with anodynes when pain is complained
of. If, in connexion with this state, the uric acid gravel be formed, or if the urine be acid, and if the patient manifest a gouty diathesis, the alkalies or alkaline earths may be also given, or ammonium and cantharides may be combined with these, and with narcotics: or, still more advantageously, with colchicum. The balsam and terebinthinate remedies have been recommended in cases of chronic pyelitis with puriform urine, and are often very serviceable; and they may be exhibited in the combinations just mentioned, or consolidated to a pulilis consistency by means of magnesia, when the urine is acid; but their effects should be carefully watched, for as the acidity of the urine lessens, or alkalizes, or even neutral, the nitric or hydrochloric acid, or the nitro-hydrochloric acid, combined with the others above mentioned (§ 212), and with tonic restorative or alterative remedies, should be employed. Dr. Proust justly remarks, that when the affection of the kidney seems to be of a scrofulous character, the same general principles of treatment as have been developed with respect to the nature of the renal concretion should be kept in view; but that when it is in its opening in the pelvis, it is probably more fibrous, and when left long to itself, are arguments in favour of an early recourse to the operation. It should also be recollected that those collections, particularly when they involve, by perforation of the pelvis of the kidney, or otherwise, the cellular tissue on which the organ rests, are generally fatal if they open internally, or otherwise than in the more favourable external situations, or when not aided by art. The circumstances of the case, and the progress of the tumour, will determine the surgeon whether or not the operation should be performed by incision only, or by incision and puncture, or by catherization and incision. M. Rayet, who is favourable to the performance of the operation under the circumstances now alluded to, assigns the following states as not admitting of having recourse to it, and surely no one could contemplate it in such cases: 1st. When it is supposed, from the symptoms and history of the case, that both kidneys are affected, and probably contain calculi, and while extra-renal abscess is not yet formed—an abscess the opening of which should not be deferred; 2d. While the puriform matter continues to pass off with the urine; while the renal swelling is but slight, and there appears to be no risk of the immediate perforation of the pelvis of the kidney; while the kidney of the opposite side continues to discharge its duties, or performs an increased function; 3d. While serious or dangerous lesion exists in the bladder or prostate gland, or in one or more of the other viscera.

218. When, however, the renal tumour forms in a person of previously good constitution, and is painful, notwithstanding vascular depletion, mucilaginous drinks, and warm baths; if there be much symptomatic fever, with nocturnal exacerbations; if the stomach and bowels are irritable; if the tumour becomes more painful on exercise; and if suppuration of urine takes place, or if inflammation extend to adjoining viscera, the propriety of having recourse to the operation of nephrectomy becomes more manifest; and still more so if fluctuation in the tumour is more superficial and extended, showing a large accumulation of pus to have formed in the cellular tissue between the kidney and lumbar muscles. The great depth of the abscess, and the slowness with which it makes its way to the external surface, as well as the risk of suppuration, or changes of position that may take place, will lead the surgeon to think of an early operation. The great depth of the abscess, and the slowness with which it makes its way to the external surface, as well as the risk of suppuration, or changes of position that may take place, will lead the surgeon to think of an early operation.

219. IV. Of various organic lesions of the kidneys.—I. Of Haemorrhage in or from the Kidneys.—Haemorrhage, generally to a small amount, often accompanies inflammations and active congestions of the kidney, especially the acute form of cachetic nephritis, and pyelitis when caused by renal concretions. In these cases, the blood is mixed with the urine, in the form of blood globules, sometimes with mucus, and occasionally with both mucus and pus globules. Renal haemorrhage may take place: 1st, from the external surface of the kidney; 2d, into some part of its substance; and, 3d, from the interior of the calices and pelvis.

220. A. Haemorrhage very rarely takes place from the external surface of the renal capsules, unless after wounds and other injuries. Blood sometimes is effused between the surface of the organ and its fibrous capsule, most frequently owing to injury, and, in rarer instances, to great congestion of the organ, either consequent upon inflammation of the emunctory veins, or upon interrupted circulation through the right side of the heart.
221. B. Hemorrhage into the substance of the kidney occurs in the form of petechiae or ecchymoses, as in malignant and adynamic fevers, seury, and purpurea hemorrhagica; or of larger deposits or collections, as in cerebral apoplexy—the renal apoplexy—of French pathologists—so as to form considerable clots. These latter are rare, and when the patient lives for some time after their occurrence, the coagula are found to have undergone similar changes to those manifested by them in other viscera.

222. C. When blood exudes from the surface of the calicis and pelvis, it may either accumulate there and in the urerter, or it may pass off more or less intimately mixed with the urine. The latter necessarily proceeds from injury, contusion, succussions of the pelvis, or in a carriage, or on descending stairs; or from inflammation, congestion, or other diseases attended by obstructed return of blood by the renal veins; or from calculous pyelitis. When the hemorrhage in this situation occurs suddenly, and in considerable quantity, the blood may coagulate either in the pelvis or in the urerter, and thus occasion more or less obstruction to the passage of urine from the kidney to the bladder; such is not frequently the case, for the blood commonly passes along with the urine, presenting appearances varying with its quantity, with the state of constitution and of disease, with the nature of the secretions accompanying it, and with the duration of its retention in the bladder.

223. Hemorrhage from the calicis and pelvis of the kidneys may be: 1st. Symptomatic of diseases of these organs; especially of renal calculi, or cancer and fungous hematomas, and of those just enumerated (§ 220–222); 2d. Constitutional or essential, or dependant upon diseases characterized by depression of vital power, by weakened vital cohesion of the soft solids, and by a morbid state of the blood, as in malignant or adynamic continued and eruptive fevers, in purpura hemorrhagica, seury, &c.; 3d. Supplemental, or caused by suppression of accustomed or of periodic discharges, and become recurrent or periodic, as when it follows suppression of the hemorrhoidal discharge, of the catarrh, of epistaxis, &c. and, 4th. Endemic, which is also observed; but M. Rayet mentions it among the endemics of the Isle de France. In the second of these varieties of hemorrhage from the kidneys, the blood is always very intimately mixed in the urine, is never coagulated, and generally imparts a dark colour to the fluid. In the others, it may be connected with fibrinous shreds in the urine, or with coagula, generally very small. The quantity of blood varies from the slightest tinge to a very copious admixture, or large proportion of it, in the fluid voided. The blood may flow from only one, or from both kidneys: it generally is exuded from both in the 2d, or the constitutional form of the above varieties.

224. Persons subject to, or suffering renal hemorrhage, generally complain of pain, or of a sense of weight in one or both loins, generally increased upon firm pressure; but these feelings may be wanting in the essential or constitutional form of the disease. Occasionally the pain is acute, or is colicky, particularly when it proceeds from calculi in the kidney, or from fibrinous clots obstructing the pelvis or urerter. When it arises from vital depression and the state of the blood, the hemorrhage may be so great as to occasion general anemia, a result rarely occurring in other circumstances.

225. ii. Congestion, or hyperemia of the kidney, is sometimes found after death from diseases, when this state was scarcely expected to be seen. It is most frequently found in connection with diseases of the heart, particularly those attended by interrupted circulation through the right side of this organ; and when the return of blood by the renal veins is impeded by any lesion, either of them or of related parts. Sometimes the engorgement is so great, that the blood rushes out when an incision is made in the kidneys. It may affect one or both kidneys, always both when the cause is constitutional, or when it depends on disease of the heart, and in diabetes. When the congestion is considerable, the kidneys present a chocolate colour, and are large or swollen.

225. iii. Anemia of the kidneys, also, is occasionally observed after death from diseases in which this state of these organs could hardly be anticipated. It is observed chiefly in persons who have died of chronic maladies, as phthisis, cancer, chlorosis, uterine hemorrhages, and the advanced stages of granular degeneration of the kidney due to the disease, nephritis, in connexion with dropsy and scanty urine. In some cases, the kidney is so pale as to contain scarcely a drop of blood; and this state may extend to all the organ, or may affect only, or chiefly, the cortical or the tubular structure. In other instances, the kidney is pale in patches, or natural or red in others, generally in the cortical substance. Occasionally it presents a yellow colour, which is either uniform or partial; and in some cases the whole structure of the organ being remarkably diminished in vascularity. When they are thus bloodless, they are sometimes, also, soft and flaccid, but they are occasionally, also, firm, and even varnished, and, moreover, atrophied. They are, however, more commonly granulated, as about to be noticed, and as described above (§ 103). The functional derangements consequent upon this state are chiefly a serous, morbid, or defective state of the urine; dropsical effusion; &c. And a diseased or poor condition of the blood, or deficiency of its red globules.

227. iv. The Nutrition of the Kidneys is sometimes much altered—a. Occasionally they are much larger than natural, without any lesion of structure. This simple hypertrophy is often limited to one organ, particularly when the other is wanting, or is much smaller, or when it is destroyed by disease. Hypertrophy of one kidney has been observed where two renal arteries have been transmitted to it; and also where it received, besides its ordinary supply of nerves from the semilunar ganglion and lesser splanchnic, several branches from the second lumbar ganglion (Lumbar). Hypertrophy of both kidneys is often observed in cases of diabetes. They are enlarged, or rather distended, by the augmented vascularity or congestion, and the granular deposits of the early stages of cachectic nephritis, than, distinctly speaking, hypertrophied.

229. iii. Hypertrophy of the kidneys may be consequence upon anemia or granular deposits, or both, or it may be independent of both. It has
been observed in connexion with smallness of the renal artery, with compression of the organ by large tumours in the vicinity or attached to the uterus, with calculi stopping up the pelvis or ureter, and with cancerous disease of remote parts. In rare instances, no cause by which it could be explained has been detected. Atrophy may be either general or partial, in respect of the anatomical constituents of the organ. General atrophy may affect one or both kidneys; it is characterized merely by the diminution of volume, without change of structure. It is sometimes found on dissection of cases in which no marked disturbance of the urinary functions was observed during life. Partial atrophy of the structure of the kidneys is found chiefly in the advanced stages of chronic cachectic nephritis (§ 87), when the enlarged Malpighian bodies, and the granular deposits in them, have pressed upon and atrophied the vascular and tubular structures, especially the former. Partial atrophy occurs more rarely without granular deposit, and, in this case, the cortical or vascular tissue is chiefly altered, the bases of the tubular cones almost resting on the fibrous coat of the kidneys, or being separated from it only by a delicate layer of the vascular substance. In some instances, there are evident depressions between the cones, arising from the loss of the vascular structure.

229. c. Softening and induration of the kidneys sometimes occur. The former is often accompanied with increased vascularity or congestion. This association may be considered as conclusive evidence of inflammation, particularly when any of the consequent changes described above (§ 38, et seq.), as being met with in proper nephritis, are also observed; and is occasionally seen attending calculi in the kidneys, and various chronic alterations of the structure of the bladder, as thickening of its coats, and brownish coloration of its mucous membrane, enlargement of and purulent secretion from its follicles, &c. But softening of the kidneys may exist, also, independently of increased vascularity, the substance of the organ being remarkably pale, or of a peculiar gray tint. M. Andral has observed this change where there had not been any sign of disease of the urinary passages.

230. d. Induration, like softening of the kidney, is attended either by increased vascularity or by diminished vascularity and blanching of its structure. The former state is generally accompanied with some degree of hypertrophy of the organs, whereas the induration is of the pale kind, is rarely attended by enlargement, but commonly by general or partial atrophy. M. Andral remarks, that the pale induration presents two grades: in the first, the kidney is firmer than usual, but it retains its natural structure; in the second, a more advanced stage of the first, its tissue is so condensed, hard, and white, as nearly to resemble cartilage. This second grade of induration is sometimes partial, or confined to two or three of the tubular cones.

231. v. Acute secessions and formations in the substance of the kidney arc, 1st. Strum, contained in small simple cysts, with serous parietes, which adhere but slightly to the surrounding tissue, is frequently met with in the cortical structure, and less frequently in the tubular. The serum is generally limpid and colourless, occasionally slightly yellowish or gelatinous. These cysts are frequently numerous, generally small, particularly in the tubular structure, but they are sometimes large in the cortical substance. They are more rarely met with in the cellular tissue surrounding the renal vessels; but they occasionally acquire a very large size in this situation, and cause proportionate wasting of the parenchyma of the organ. When the cysts are thus developed, their cavities are sometimes divided into several compartments by transverse septa. Serous cysts are found in the kidneys after death from various diseases. They are observed after the several forms of nephritis. I have seen them frequently in cases where death was caused by the more chronic diseases of the heart.

232. 2d. Fatty matter is sometimes found in the cortical substance of the kidney. M. Andral has observed it, particularly when this substance was pale or yellow, sub-serving the theory. It is connected, he thinks, with a special predisposition in the individual to the secretion of fatty matter. The existence of oil in the blood in considerable quantity, in some cases, particularly when digestion and assimilation are impaired, renders it by no means singular that the secreting structure of organs circulating so much blood through them as the kidneys should become imbued with this substance.

233. 3d. Purulent matter is often found in the kidneys. Abscesses sometimes form; occasionally they are very small, and the surrounding structure is scarcely altered; more rarely they are extremely large, the whole organ being converted into a purulent sac, which is generally divided into compartments. This sac may even surpass the size of the kidney so much as to produce a tumour distinguishable through the abdominal parietes. The bulk of this purulent sac is seldom less than that of the kidney, unless it be bound down by adhesions produced by inflammation of the adjoining portions of the peritoneum, or be surrounded by a collection of pus in the cellular structure. The septa dividing the compartments of the sac often consist of a hard, lardaceous substance. The matter thus formed in the kidney may pass off by the ureter, or it may find its way in various directions, as explained above (§ 207).

234. In some instances the purulent matter, instead of existing in the form of a distinct abscess, is infiltrated through the substance of the kidney, giving rise to a number of whitish specks, from which it may be squeezed. M. Andral thinks these whitish specks have been mistaken for and described as tubercles. This infiltration generally co-exists with purulent formations in other organs, particularly in the veins: I have met with this purulent infiltration of the kidney in a fatal case of puerperal metritis, in which pus had formed in the sinuses of the uterus. M. Andral has observed it after abscess in the right iliac fossa, and a similar case is recorded by M. Gillette (Journ. Hebdom., t. xi., p. 75.)

235. 4th. Granular deposits, and their origin, have been described above. They exist in the vascular or cortical structure, and sometimes are found, also, in this structure, where it extends between the tubular cones. They are
KIDNEYS—Organic Lesions of the.

Small, whitish bodies of various sizes, somewhat firm, and of a rounded form. In some cases they are few, in others they are very numerous and crowded together, filling and distending the cortical structure, and even occupying the intervals between the cones of the tubular structure. In some instances they project beyond the surface of the organ, and are distinguishable through its fibrous coat. In others they occupy chiefly the more deep-seated parts of the cortical structure.

The deposition of ossific matter has been very rarely observed in the kidneys, and then chiefly or only in the fibrous capsules of the organs, and in the arteries of aged persons. Cases are recorded by the older writers in which portions of the substance of the kidney are said to have been ossified; but they are not detailed with any degree of precision, and cannot be relied on. The external cysts of hydatids are sometimes partially ossified.

237. 6th. Gelatinous matter has also been observed in the kidneys, recorded by MM. Andral and Raykr. This substance resembled a strong jelly of a pale colour, or a solution of starch, into which the whole cortical structure of the organ was transformed. A case occurred to me some years since in a mulatto boy, where this substance existed in one of the kidneys.

238. 7th. Melanos of the kidneys is very rarely met with, and never affecting this organ alone. In the cases where the kidneys were affected by this taint, recorded by MacSwell, Fawdington, Petit, Raykr and Cu-mel, several other viscera were similarly diseased. (See Art. Melanosis.)

239. 8th. Encephaloid matter has been found in the kidney, either in small masses, occasioning no alteration of the size or form of the organ, or in considerable tumours, or in the form of fungus hematothcs, and greatly increasing its bulk. Sometimes the kidney is wholly transformed into this substance, and forms a very large tumour, which may eventually fill the pelvis entirely. It has been met with more frequently in young persons than in adults and those advanced in life. This matter may either form in the kidney, without appearing in any other organ, or it may coexist with similar productions in other parts. M. Andral states, that it sometimes seems deposited in the substance of the organ, and at other times lodged in its small vessels. It seldom is indicated during life, unless when, in connexion with this disease in other parts, a tumour is detected in the region of the kidney, and a considerable quantity of blood is passed in the urine: its existence may be then suspected. Other forms of cancerous or malignant disease are very rarely found in the kidney, and then chiefly consecutively of its existence in some other part.

240. 9th. Tubercles are not often found in the kidneys, and when they are met with in these organs they always exist, also, in some other viscera, and do not differ from those of the brain.

They may be recognised by their dull, white aspect, commonly with a slight grayish yellow tint, by their friability, and by their amorphous appearance under the microscope. They are either distinct or confluent. They sometimes soften, and the softened matter finds its way into the pelvis of the organ, leaving renal caverns or fistula. In some cases only a few tubercular germs are observed; in others, and when the degeneration is far advanced, it extends to both the cortical and tubular structures, to the calcees and pelvis, and even to the external membranes and ureters. They are often disseminated through the organ in the form of small grains the size of millet seeds. When confluent or grouped, they appear as masses of considerable size, but when the mass is divided it is sure to be composed of a number of smaller tubercles. In some cases, they consist of small connective tissue masses; being separated from the tubercles, which are most disposed to soften, and to occasion farther disorganization. The tissue surrounding them may be either sound, or paler than usual, or more vascular. When they soften, the tissue around them is generally injected. In most cases, the organ is not materially increased in bulk by them; in a few it is very considerably augmented. When they form in or beneath the mucous membrane of the calcees and pelvis, they are either distinct, rounded, or confluent, often of the size of the head of a pin, or they are grouped. In the former case, they render the surface rugous; in the latter, they produce elevated patches, of variable form and extent.

241. In sixteen cases of tubercles of the kidneys, M. Raykr found them 16 times in the cortical structure, 15 times in the tubular, 13 times in the mucous membrane of the calcees, pelvis, and ureters, and twice in the capsules of the organ. He has seen this lesion twice in new-born infants, and considers it rare in aged persons.

Of 16 cases, both kidneys were affected in 6; and of the 10 cases of affection of a single organ, the left was 7 times the seat of the disease.

242. The symptoms of this change are seldom such as to indicate its existence. It is only when the tubercles soften and open into the pelvis of the organ that the existence of the disease may be suspected, and then chiefly from the appearance of the matters contained in the various cavities. The tubercles seen in the urine into the bladder generally excite inflammatory action in the mucous surface of this viscous, and the patient's sufferings are usually referred to it, and the original seat of disease thereby masked.

243. 10th. Hydatid, or accephalocytes (the Accephalocycys sociales vel prolifera), are rarely found in the kidneys of men. They are generally numerous or multiplied, and contained in a mother cyst, which frequently occupies a large size, forming a tumour which may often be felt externally. They present the same appearance in this organ as described in the article Hydatids. The hydatid cist is developed in the substance of the organ, and, as it acquires a large size, it generally forms adhesions to the parietes of the calcees or pelvis, and opens into the renal cavity by one or more openings, through which the smaller of the hydatids, and the delicis of the larger, with the serum which accompanies them. The expulsion of the hydatids commonly occasions pain in the region of the kidney, and sometimes retention of urine or diminution of it, owing to obstruction of the pelvis or ureter by one or more of them. These retentions, occasional, or repeated, or more or less continued, may ultimately cause dilatation of the ureters and of the pelvis, and various changes in the struc-
KIDNEYS—Organic Lesions of the.

769

tures of the organ. The symptoms of hydatids in the kidneys are very equivocal. They frequently occasion but little disturbance until the mother cyst acquires a large size. It is chiefly by their presence, or by their deficits alone, that we can form a correct opinion as to their existence. In one case I thus recognised them; but the patient passed from my observation.

244. 11th. Worms are very rarely found in the kidneys. The Strongylus gigas, the Dicytus aculeatus, and the Spiroptera hominis, are the only worms found in this viscus. Their exact situation has not been fully determined. It is probable that they exist only in the pelvis of the organ, although they have been described in other parts of the body. Mr. Rawes has adduced many of the cases of this description on record, and, among others, those published by Messrs. Lawrence, Burnett, and Curling, and to which reference is made in the Bibliography to this article.

Dr. Gross describes a case of abscess of the kidney in a gentleman 40 years of age, who had long suffered under symptoms of chronic nephritis. On inspection, the left kidney was found reduced to a mere membranous shell, containing three pints of thin, chocolate-looking fluid. All the other viscera were healthy, excepting the stomach, which exhibited marks of former inflammation.—(Path. Anat., p. 697.) Dr. G. also describes a case of caverns of the kidney, occurring in a child 2½ years old. The body was excessively emaciated, the abdomen hard and distended, and the right lumbar region unusually prominent. All the intestines were firmly agglutinated together, and the mesenteric ganglions, of a white rose colour and very hard, presented one agglomerated mass of disease. Individually, they varied in size between a cherry and an orange. The entire mass nearly equalled a coconut, and embraced loops of intestine, the aorta, vena cava, and cholecystic duct. There were a few tumours on the anterior margin of the liver, similar to those of the kidney, and the mucous membrane of the colon exhibited patches of inflammation, with here and there a small ulcer.—(Ibid., p. 702.)

Case of the kidney has been observed by Dr. Weems, of Washington city (Am. Jour. Med. Sci., vol. xvi.), in a female 35 years of age, although there was no symptom present during life that could have caused a suspicion of the existence of renal disorder. The left kidney was found increased to the weight of 7 pounds, completely disorganized, and converted into a soft, bloody, cerebral mass, in which it was impossible to discern anything of the normal structure. The disease had existed for about four years, and been treated for an enlarged spleen.

Tubercles in the kidney have also been observed by Prof. Gross (Path. Anat., 2d edition, p. 702), in the right kidney of a young man 27 years of age, who died of psosas abscess. There were upward of 500 in the cortical substance, of all sizes between that of a mustard seed and a cherry stone. In some parts they were agglomerated, in others isolated. They were of a white, opaque appearance, semicartilaginous in their consistence, and evidently organized, since, in cutting through them, the existence of vessels could be distinctly traced, the blood standing upon the incised surface in minute dots. Externally the organ had a dark, mottled aspect, and in its interior were two tubercular excavations; one, situated in the superior extremity of the gland, was scarcely larger than a hazel nut; the other, which occupied the lower half of the viscus, was about the size of a turkey's egg, and filled with thin, ropy, whitish pus, destitute of smell. The abscess was lined throughout with a thick layer of lymph, and intersecting it in different directions were four rounded cords, the remains, probably, of the tubular texture, which resembled a good deal the fleshy columns of the heart, or the bands which we often see in tubercular excavations of the lung. The kidney was very little enlarged, and some tubercular matter was also found in the excretory passages, the cavity of the ureter having been nearly obliterated by it. In this case there were no tubercles in the lungs; the heart and brain were healthy; but strumous matter was abundantly contained in the lymphatic ganglions of the pelvis, and the seminal vessels were completely distended with it.—(Loc. cit.)

Serous cysts, though rare in the kidney of the human subject, are yet very common in the hog, and have often been noticed by Prof. Gross (Loc. cit.). Dr. G. also describes a cyst containing the right kidney, with two gallons of pure pus, in the body of a man 26 years of age. The sac was exceedingly vascular, and about the thickness of the human skin; it was formed mainly at the expense of the ureter, which was entirely closed, and was studded internally by a number of bony deposits, some of which were very firm and as large as a thumb-nail. The renal tissue was completely absorbed, and, in place of the papilles, were seven digital pouches, isolated, and large enough to admit a finger. "In a few instances," says Dr. G., "I have seen the kidney transformed into a substance resembling fibro-cartilage. In one of the cases to which I refer, the organ was less than one third of the natural volume, remarkably white, dense, fibrous, and creased sensibly under the scalpel on being cut. The fibrous capsule was inseparably adherent to the outer surface of the kidney, the ureter and funnel-shaped processes were obliterated, and seemed a trace remained of the tubular structure. The renal vessels, both artery and vein, were much diminished in size, and many of the larger branches, with nearly all the smaller ones, had disappeared.

This transformation sometimes recurs in small patches, which are generally of a light-bluish tint, and distinctly fibrous in their texture. The kidney has been found ossified in several instances in this country; in some, the earthly matter has been mostly confined to the uriniferous tubules; for an example of which, see Gross's Path. Anat., 2d ed., p. 706. See also, Ducklison's Practice of Medicine, 2d ed., vol. ii., for a very lucid account of renal and urinary affections. The reader, also, will do well to consult the "Clinical Lectures" of Dr. Graves, who denies that the albuminous state of the urine in dropsties, always, or even generally, depends on structural change in the kidneys, but who supposes that this condition often depends on mere functional derangement of the secreting organ.]
245. V. Morbid Changes in the Calices and Pelvis, and in the Ureters.—The mucous membrane, or, rather, the submucous tissue of these parts, is often simply congested without any other lesion; and this has sometimes been the only alteration discoverable when the patient has been passing bloody urine, with pain in the region of the kidneys and course of the ureters. In some cases, minute echymosis may be observed, in addition to congestion of these parts. This membrane sometimes appears thickened, either in parts or throughout its whole extent, producing temporary, or even permanent obliteration of the ureters. Vegetations from this membrane of a red, soft, fungous appearance, with a broad base, and varying from the size of a pea to that of a small walnut, have also been found in the pelvis of the kidney. M. Louis met with a case of great thickening of the walls of the calices, pelvis, and ureters, with increased capacity; the kidneys themselves being reduced to less than one-third of their ordinary dimensions. The mucous membrane in this situation, as in other parts, often secretes pus, and more frequently without being ulcerated than when this lesion has taken place. M. Andral has seen it covered by a false membrane resembling that of group. The submucous tissue of the pelvis and ureters has, as noticed above (§ 240), filled with a layer of tuberculous matter; but in such cases this matter has existed also in the substance of the kidneys as well as in the lungs.

246. Dilatation of the calices, pelvis, and ureters, sometimes to a remarkable extent, frequently takes place when any obstacle exists to the free passage of the urine into the bladder. The ureters are often greatly dilated in various chronic affections of the uterus, particularly when tumours form in the uterus and press upon the bladder, diminishing its cavity, or obstructing the outlets of the ureters. When the passage of urine along the ureter is situated near the kidney, the portion of this duct below it frequently contracts, and becomes even obliterated. Ulceration and perforation of the pelvis or ureter sometimes occur, occasioning extra-renal abscess and urinary fistula, as shown above (§ 187).

247. VI. Alterations of the Blood-vessels of the Kidneys.—A. The renal arteries have been found variously diseased, in rare cases only. Aneurism of the emulgent artery has been recorded in only two or three cases—by D. Nerielli (Ephém. Nat. Curieux, Cent. IX., p. 59, p. 142), L. Roupe (Nova Acta Phys. Med., t. IV., p. 67, 1770), and M. Dourlin (Journ. de Chirurg. et de Med., t. VII., ann. XII., p. 252). I saw a preparation at the Medical Society of London, many years ago, which appeared to indicate a small aneurism of the emulgent artery. Cartilaginous and ossific deposits have been found in the renal arteries of very old persons.

248. B. Inflammation of the emulgent veins sometimes occurs, generally in connexion with some form or other of nephritis. In most of these cases the canal of the vein has been nearly filled with fibrinous or albuminous concretions. M. Rayer observes that he has seen, in several cases of albuminous nephritis—the cachectic nephritis of the author—the renal veins filled with fibrinous concretions, and the coats of the vessel thickened. Not only may inflammation of the renal veins be connected with nephritis or structural lesions of the kidneys, but it may be connected, in other cases, with inflammation of the vena cava, or of the ovarian vein. I have seen several cases in which inflammation of the emulgent vein accompanied inflammation of the uterine and ovarian veins in the pericpental state. Similar instances have been observed by Dr. R. Lee, M. Ducrot, and others.

249. VII. Affections of the Nerves of the Kidneys have been noticed by writers, but lesions of the structure of these nerves have not been observed, nor, indeed, can such lesions, although existing to some extent, readily admit of detection. Painful affections, referred to the nerves of the kidney under the term of Nephralgia, are generally owing to the irritation of calculi, either in the kidneys or about to pass from the pelvis into the ureter; and is often a different name for what has been called nephritic colic, caused by renal calculi. Nephralgia may attend calculous pyelitis, as noticed above (§ 184), or may be merely that grade or state of irritation which occasions a manifestation of morbid sensation in the renal nerves, without inducing or being attended by inflammation—the sensible expression of irritation produced by a mechanical cause. Nephralgia is sometimes complained of in nervous or hysterical females, and is manifestly owing in them to irritation or excitement of the nerves of the uterus and ovaria, propagated thence to the nerves of the kidneys, in consequence of the intimate connexion of the sexual and renal nerves (see Art. Irritation). That the sensibility of the renal nerves should be morbidly excited in many cases of hystera is not surprising, when we consider the exaltation of function—the copious secretion of urine—which generally attends uterine excitement and hysteria.

250. The treatment of nephralgia will entirely depend upon its pathological relations. If it proceeds from calculous irritation, much of what has been advised for pyelitis depending upon this cause, and combining these with narcotic and external derivatives and rubefacients—with the diosma, camphor, hemban, opiate, alkanes, fomentations, warm baths, &c.—may be prescribed. If the nephralgia be hysterical, or be connected with uterine irritation, the treatment advised for the other affections of this nature (see Hysterial Affections, § 22) will generally remove it, and attention to the means there recommended, with the view of restoring nervous tone (§ 84), will prevent the recurrence of this affection.

251. VIII. Absence of the Kidneys has been noticed by several pathologists. The entire absence of both kidneys has been observed in the fetus by Oebelius, Buttnor, Everhard, Gilbert, Heckermann, Mayer, and others. Bilateral absence of the kidney is often wanting in aephalous fetuses, but that one or both exist when the whole or greater part of the spinal cord is present. Absence of one kidney has been met with on several occasions. Generally the existing kidney is much larger than usual, and sometimes double its ordinary weight; and it may be either placed naturally, or somewhat too high or too low. In two cases of this
description which occurred to M. Andral, one presented the supra-renal capsule of the side on which the kidney was altogether wanting fully developed, proving that the existence of the former does not depend upon that of the latter. The other case was important, inasmuch as the single kidney was in a state of disease, being studied with whitish granulations. The patient was a negro, apparently, on more examination, the kidney was only apparently single, being composed of the upper and lower combined together at the median line. There may, apparently, but one kidney, from the circumstance of the other being situated in the hypogastrum beside the bladder. Andral met with a case of this description.

252. IX. The situation of the kidneys may be unnatural, or uncommon. In a few instances they have been found united and placed, in the form of a horseshoe, across the spinal column. Numerous references to cases of this description have been added by Placet, and even in the direction, thus placed much lower than usual, and, in very rare instances, they may occupy the pelvis, or its brim; but only one of these organs has been found so low as to occupy the pelvis. Cases of this unnatural position of one kidney have been referred by the writers just named. Where this occurs in the female, the uterus is generally more or less displaced by the kidney; and, if the female thus circumstance becomes pregnant, serious consequences may accrue.

Instances of this kind have been recorded by M. Boinet (Arch. Gen. de Med., t. vii., 1835, p. 349), Dr. Holm (Bull. de M. Ferrussac, t. viii., p. 3), and Dr. Heusinger (Ibid., t. xvi., p. 131).

253. One or both kidneys—one especially—may be displaced by the pressure of an enlarged viscus, or by a tumour, abscess, or other cause. The displacement may be so great as to constitute a lienoma of the organ, as in the cases recorded by Haller, Mure, and others. One kidney may be less or more movable, owing to the state of the tissues surrounding and connecting with them, and to structural lesions of their substance, especially calculi and abscesses. Generally, however, lesions of the organ itself are but little concerned in giving rise to its mobility, either in a vertical or horizontal direction, although insisted upon by Riolan. Instances of this kind have been noticed by Velpeau, Gerdy, and Rayer, and several of them have been detailed by the latter writer.

254. The symptoms in these cases consisted chiefly of pains in the abdomen or loins and corresponding thigh; of hypochondriacal and colicky affections; of weakness or neuritic pains of the limb, and sometimes of edema of the thigh, or a moveable tumour detected in the abdomen. Most of the instances on record occurred in females, and the right kidney was almost exclusively thus affected. They appeared to arise from enlargement of the liver, distention of the eacium, frequent pregnancies, muscular efforts, &c., and, in some of them, peculiar dispositions of the peritoneum and of the blood-vessels of the organ were remarked. M. Rayer alludes to two physicians whose right kidneys were thus movable.

255. In cases of this description, the patient should wear a belt or support, as being the principal means of preventing as well as of removing the pains and other symptoms caused by this dropssion, the cold or tepid douche on the lous, and the horizontal position, may be advantageously recommended.
LACTATION—SLIGHTER DISORDERS OF

Knowledge, vol. ii., "Cow-dairy, or Amenon Magazine, b. i., p. 175—\[
\text{\textit{Pachyderm.}}\]

2. It is justly observed by Dr. Locock, that lactation in the human female, when naturally conducted, cannot be called a disease; but even under the most favourable aspect there are often circumstances which require attention and regulation, for the purposes both of alleviating pain and of preventing mischief. There are also frequent interruptions to this usually healthy process, and so many important questions connected with it, at various periods, arise as necessary to notice them, although briefly.

3. The intimate sympathy between the mamma and the uterus is evident even in the unimpregnated state. This is observed in connexion with menstruation, and in some diseases of the womb. In pregnancy the alteration in the breasts is well marked, and the quantity of milky serum secreted is sometimes very great, particularly towards the close of uterine gestation. Many women, however, have no appearance of milk before delivery, and yet have an abundance afterward.

4. I. SLIGHTER DISORDERS OF LACTATION—

a. After parturition, the infant is usually applied to the breast, as soon as the exhaustion more immediately consequent upon this process is partially removed, or generally within the first twenty-four hours; in order to draw out and form the nipple, before the breasts become hard or distended, and to encourage the flow of milk.

There is seldom any quantity of milk secreted, with first children, before the third day; but that day or one or two later, the breasts become swollen and hard, often hot and painful: the pulse is accelerated; and slight chills, febrile commotion, thirst, disturbed sleep, and occasionally slight disturbance of the sensorium, supervene. This constitutional excitement attending the establishment of the function of lactation continues until the milk is at its height, as it is termed: the breasts are then extremely hard, knotted, loaded, and tender. The swelling may extend to the clavicles and axilla, the glands in this latter situation being also enlarged; but a small quantity of milk will ooze out from the nipples, especially if the breasts be fomented or gently pressed. The act of sucking the infant is attended by great pain in the breast; but it is followed by relief, and as the milk flows, the hardness and swelling are diminished. After some hours, if the milk be freely drawn off, the sensations become more comfortable, and the process of lactation is duly established.

b. The above state of local and general disturbance ushering in this process may vary in grade from that described; but, when it is at all considerable, means should be used to alleviate the sensation: as soon as the febrile symptoms begin, a cooling saline purgative should be given, and repeated in twelve or twenty-four hours.
LACTATION—DISORDERS OF.

773

according to circumstances. In order to allay thirst, and to prevent the distention of the breasts, which copious draughts would occasion, cooling saline diaphoretics, or effervescent powders may be given, or a glass of cold water. When the infant cannot draw out the nipple of a hard or distended breast, or obtain the thick milk distending the ducts, an older child may be applied, or a grown person should do this, or have recourse to artificial means, such as the breast-pump, &c. Natural or artificial suction, fonduating the breasts with hot water, warm poultices, &c., generally relieve the local disorder, and promote a free discharge of milk.

So excessive a secretion of milk, or a considerable quantity of what has been called colossum, and has a purgative quality, thus serving to evacuate the meconium which loads the large intestines. When, therefore, the infant does not get the first draught of the breast, from being suckled by a wet nurse, or from being brought up by hand, a gentle purgative should be given to it; as diarrhoea or convulsions may arise from the retained meconium. In other circumstances, the exhibition of a purgative may be superfluous; for, as Dr. L. Lee has shown, a quantity of highly nutritious abumens is found in the small intestines above the situation of the excrementitious meconium, serving for the sustenance of the infant until lactation is fully established. A purgative, therefore, given before this process is fully commenced will carry off this substance.

7. d. The milk varies much in its properties, and even in its sensible qualities and appearance, during the usual period of lactation, according to the diet and circumstances. Indeed, in some cases, the milk is thick, yellowish, and abounds with cream; but, after a few days, it assumes the usual appearance, and becomes thin, bluish, and sweet. The taste and qualities of the milk are altered by several articles of diet, by repulsion, hot and close rooms, by medicines, and moral emotions, particularly those of a violent kind, and the infant is more or less affected by the quality of the milk. It is observed as to have a saline, a bitter, or an otherwise unpleasant taste, the infant relinquishing the breast instantly upon tasting it. So remarkable an influence may medicines have upon the milk, and through it upon the child, that a purgative taken by the nurse may affect the former without materially affecting the latter. Alkalies, mercury, various alteratives, and saline substances often act in a similar way. The colour of the milk may be changed somewhat, owing to an alteration of the colour of the milk, a little blue with it from the exterior or interior of the nipple. It is not infrequently altered by biliary disorders of the nurse. Dr. Lockock has seen four

instances where it was of a golden yellow hue, and where, upon standing, a thick layer of bitter cream, as yellow as pure bile, floated on its surface. In neither of these cases was the infant jaundiced; but, a very copious flow of bile being poured from the intestines by mercurial purges, the yellowness gradually disappeared; the child, till then, having been much griped and affected with diarrhoea. Yet in no cases where the wet nurses have been jaundiced has Dr. Lockock seen the milk yellow; and it is not uncommon for them to become thus disordered, owing to a sudden transition from a scantly diet to a full and luxurious mode of living. Milk may disorder the infant from merely being too rich. The remedy in this case is to purge the nurse, to cause her to take active exercise, and to abridge her diet.*

8. e. The properties of the milk are altered more or less by menstruation and pregnancy. Menstruation generally impairs both the quality and the duration of the milk. The infant often brings up the milk, becomes fretful and disordered in the bowels, the stools being watery, frequent, or of a spinach colour. When this is the case, the milk may be purged. The reason in the nurse should be suspected. The milk of the nurse may not only cause the milk to be scanty, watery, &c., but may also variably disorder the infant. It is supposed by many that suckling will prevent impregnation; and, owing to this notion, lactation is often continued for much too long a period, as respects the health both of the infant and of the nurse; but women very frequently do become pregnant even while suckling, while some do not. Dr. Rongrow found that there is no essential difference between the milk of pregnant ones or often during this process. Dr. Lockock is decidedly of opinion that those women who menstruate during lactation will more readily conceive than those who do not; and he has also remarked, as Dr. Hamilton has done, that both these occurrences are more common with first children; hence women under these circumstances are not, ceteris paribus, as eligible as others for wet-nurses.

9. H. This disordered is a morbidly aggraved form of the local and general excitement attending the commencement of lactation, and noticed above (§ 4). The febrile symptoms are much more severe than in it, and are ushered in by chills or a marked rigour. There are severe pains and throbbing in the head, flushed face, intraocular discharge of light and sound; excessive thirst, a hot and dry skin; a rapid, full, or hard pulse, hurried or loaded towards the heart; yellow or brownish urine, and sometimes a diminution of the lochia.

10. These attacks are commonly caused by a stimulating diet, a heated or close apartment; by over-exertion, disturbance, or mental agita-

* [In some cases, there is retention of the milk from visceral conformation of the nipple, such as its absence and its congenital or accidental imperforation. Sometimes the milk-ducts are obstructed from flattening or induration of the nipple, or from turbulence of the mammary; and in some cases the obstruction commences with depression of the nipples, which may often be remedied. Dr. Pratt, of this city, has invented a very ingenious artificial nipple, consisting of a small metallic sheath, with a valve or opening, and a more elastic cap of gum elastic, which is an excellent substitute for the natural organ. We have known it applied with instantaneous relief and success in cases of extravasated or retracted nipple, and hence we recommend it in all cases of this kind.]

* [Colombat gives the following test by which to judge of the qualities of human milk: "To discover whether the consistency of the milk is too thin or too thick, place a drop on one of the nails; if it adheres to it at first, and then detaches itself, it is in the natural condition; if the contrary case, it is not sufficiently consistent; while it is too thick if the drop adheres to the nail without spreading. In desity, fat women, the milk is generally thick; in nervous females it is thin, not very nutritious, and subject to slight alterations after the slightest vexation. Spirituous liquors, instead of milk, as many suppose, diminish the quantity of milk secreted." (Colombat de l'Exemp; transl. by Meigs. Phil., 1815)]
LACTATION—Disorders of.

11. b. The treatment of this disorder is very manifest: cooling saline purgatives, cooling diaphoretics, due ventilation, and a moderate temperature of the apartment; the encouraging of a copious flow of milk, and the avoiding of mental emotions and excitement of the senses, are the most influential means of cure; and generally provide a remission of the symptoms in the course of a few hours, and a copious perspiration. If, however, injudicious means be employed, and either the milk or the lochia, or both, be suppressed, very dangerous disease will supervene, and copious depletions will be requisite, with other remedies appropriate to the nature of the consequent mischief.

12. III. Excessive Secretion of Milk.—a. The secretion of milk may be excessive in reality, or only apparently. The former exists when the quantity secreted and excreted is inordinate, the breasts being distended with painful, and knotted, although the discharge from them is free, or even very copious; the latter obtains chiefly where there is deficient power of retaining the milk, a constant discharge taking place in the intervals between suckling. In most, however, of such cases, the quantity secreted is really augmented. In connexion with this excessive secretion, there is generally more or less constitutional disorder; for, as in the first instance, the breasts are distended with painful and knotted secretions, so they may be full of milk, the discharge from them is free, or even very copious; the latter obtains chiefly where there is deficient power of retaining the milk, a constant discharge taking place in the intervals between suckling. In such cases, as well as those characterized by deficient powers of retaining the milk, the frame of the nurse is exhausted by the inordinate discharge, and by the diversion of the nourishment from herself. In such circumstances, similar disorders to those observed in females who have suckled too long, or in those who are constitutionally, or from previous local morbid states, incapable of sucking at all, soon occur; they fast themselves, and the nurse sinks into a state of marasmus, or of hectic or of chronic debility, or becomes consumptive, or complains of dragging pains and weakness in the back or loins, &c., or presents the state occasioned by prolonged lactation about to be noticed.

13. b. The treatment in these states of disordered lactation should depend much upon the form which it assumes, and the effects it has produced on the general health. In the first form (§ 12), or when the secretion is very excessive, the breasts being swollen, hard, and tender, and the health not materially impaired, cooling diaphoretics, saline aperients, refrigerants, low or moderate diet, and avoiding sexual indulgence, are the most appropriate means. In the second form (§ 12), or when there is an insufficient power of retention, it has been proper to have recourse to topical astringents, as lotions of alum, zinc, &c.; but these are apt entirely to suppress the secretion of milk. Others, again, have advised the internal use of astringent tonics and the mineral acids; but these remedies frequently disorder the bowels of the infant. The preparations of steel, or of cinchona, or other vegetable tonics, the show-

er bath, or cold salt-water bathing, and a cool state of the breasts, are the most beneficial remedies.

14. IV. Under Lactation.—Lactation may be undue or improper as respects, 1st. The state of the nurse's constitution and existing state of health; and, 2d. The lengthened continuance of it. Females of a nervous, susceptible temperament, and weakened constitution; those who are predisposed to pulmonary consumption, to puerperal mania, or to insanity in any form; and those who have been chlorotic and very hysterical before marriage, frequently are incapable of suckling for any considerable time, without exhibiting indications of its injurious effects upon their constitutions, and even upon the infant also. These effects are usually the same as those which follow a too protracted period of lactation.

15. a. The duration of suckling should have strict reference to the health of the nurse and the state of the infant. Many begin, and continue to suckle for some time, with great success; but, owing to disturbed rest, insufficient food, and too frequent or too prolonged applications of the infant to the breast, the health of both nurse and infant ultimately suffers. Where lactation is judiciously regulated, and the health of the nurse is not impaired thereby, while strength and nourishment are preserved by a suitable quantity of food and drink, and the rest is not prevented by too frequent applications to the breast, the period may be protracted without injury to either the nurse or infant. But if the nurse menstruates, or becomes pregnant, the latter condition appears to be such a provision being made for the nourishment of the infant as its age, state of health, and its progress in the process of teething will warrant.

16. b. The symptoms of undue lactation are such as naturally result from a protracted discharge or drain, beyond the assimilating powers and strength of the nurse. When the infant is at the breast, or a short time after its application, she feels a sense of dragging in the back or loins, and of sinking in the region of the navel and pit of the stomach, with a feeling of emptiness, which continues for some time. After these have been felt for a time, the appetite fails gradually; general lassitude is complained of; the pulse becomes quick and feeble; alternate chills and flushes of heat come on, and the spirits sink, or are irritable or weak. Subsequently, emaciation, costiveness, headache, weakness of sight, loss of memory, thirst, dry tongue at night, and night perspirations supervene; and in some cases pulmonary consumption, in others symptoms closely simulating consumption, or a chlorotic or anemic appearance of the surface, leucorrhœa, neuralgic pains in various situations, or pleurodynia, and not infrequently that form of puerperal mania which I have described (see Insanity, § 534) as occasionally following undue lactation, are thus caused.

17. c. The treatment should consist of the immediate removal of the cause of the disorder. The infant should be weaned, and those disorders, if they have not made too great a progress, or gone on to organic lesion, will generally disappear before appropriate remedies. But unless lactation be terminated, such rem-
edies will often fail of being serviceable. This having been done, or being in progress, vegetable tonics, the compound steel mixture, or the acetate or other preparations of iron, cold or sea bathing, the shower bath, change of air, and light, nourishing food, in conjunction with such other means as the form of disorder thus caused will suggest, will generally restore the patient to health.

18. V. Suppression of the Milk.—The milk may be suppressed, or suddenly disappear from the breasts, at any period of lactation, but more readily very soon after delivery. The suppression may be total, or only partial; and it may be primary, or consecutive.—a. It may be considered as primary when milk does not appear at all in the breasts after delivery, and consecutive when a total or partial suppression follows the establishment of the process of lactation. The non-appearance of milk in the breasts is generally owing to some fault in the organization, or in the nervous energy of these glands; to want of constitutional power, or of necessary nourishment; to excessive discharges, whether haemorrhagic, lochial, or leucorrheal; to the occurrence of acute or inflammatory diseases; to the pre-existence of organic maladies; to mental distress and anxiety; to cold applications and astringents to the breast, and to various circumstances peculiar to individual cases. Frequently, instead of a total suppression, or non-appearance of milk in the breasts, there is merely an insufficient secretion, the quantity being much below that which is requisite to the health and growth of the infant.

19. b. The consecutive suppression of milk is generally owing to fear, sudden terror or fright, anxiety of mind, unpleasant news suddenly or unexpectedly communicated, grief, all the depressing passions and emotions, startling noises, disappointment, vexation, anger, &c. It may be occasioned also by severe attacks of disease, or by any of the causes enumerated above (§ 18). While the suppression of the lactal secretion may proceed from the development of inflammatory or other acute diseases, these latter may also arise from the suppression of milk caused by mental emotion, or by other occurrences. In the former case, it may be considered that the inflammation or sanguineous afflux, constituting these diseases, creates a diversion of the vital current from that quarter where it is necessary for the continuance of the lactal secretion: in the latter case, either the passage of the milk from the breast into the mass of blood, or the accumulation in it of the constituents requisite to the formation of this fluid, creates such a state of vascular plethora, or affects the blood in such a manner as readily to kindle inflammation, or cause congestion, effusion of serum, or other changes in organs disposed to such maladies either by original conformation or by an acquired predisposition. Dr. Looch states—and even more remarkable facts of a similar kind have been recorded by numerous writers of high character—that he has observed, when bleeding has been had recourse to in inflammatory diseases, with sudden suppression of milk, that the serum of the blood, when separated by rest, has been white, opaque, and bearing nearly all the characters of milk, excepting the formation of cream on its surface. It may also be observed, that when the milk has been driven back by active purgatives, a large quantity of milk-like fluid may be seen in the motions. However, a milky state of the serum of the blood, when it attends the purgatorial states, independently of any suppression of milk; and I have seen, in several cases, some years ago, in Queen Charlotte’s Lying-in Hospital, the serum effused in the peritoneal cavity, in fatal cases of complicated suppurative fevers, present a milk-like appearance, with clots like the curds of milk; and yet the secretion of milk was not suppressed during the disease. The same appearances have also been observed in cases where a suppression of the milk had occurred.

20. In rare instances, when the milk is suppressed, a vicarious discharge of it, or of a fluid very closely resembling it, takes place from various situations: this has been termed a translation of the milk, and in many of such instances the general health has not materially suffered. The situations where this vicarious discharge has occurred are, the mucous surface of the intestines; of the womb or vagina, in the form of leucorrhoea, the fauces and throat, the kidneys, &c.

21. c. The treatment, in cases of the non-appearance or of the suppression of the milk, must depend upon the causes producing it, the extent to which it has been carried, and upon the effects it has occasioned. When it is desirable to restore the secretion, the infant should be kept to the breast, or the breasts ought to be regularly drawn; and if the suppression be partial, or owing to insufficient nourishment, the removal of this cause will generally be sufficient to restore the secretion. Some females have an insufficient and watery or thin supply of milk, owing to the use of too much fluid, as weak tea, &c., and to a poor, vegetable, or watery diet, and living in low, damp situations and dwellings. A due supply of light animal food, of richer beverages, and living in a dry, pure air, will restore to these the healthy secretion of milk. If inflammatory or other diseases have resulted from the non-appearance or suppression of the milk, the treatment will necessarily depend upon the nature and character of such disease; keeping, however, in recollection this particular circumstance connected with their production.

22. There are two facts connected with the non-appearance or suppression of the milk which should not be overlooked. Some women dissemble, and wish to make it appear that they have no milk, or an insufficiency of milk, in order that they may avoid suckling. A few of these may have a fear of its effects upon their own health; but much more frequently, they dissemble, with a view of avoiding the trouble and confinement connected with suckling, and of preserving the form of their breasts. Hired nurses, on the other hand, often pretend that their milk is abundant and healthy when it is neither the one nor the other, or even when it is nearly gone. When the milk is gone, and when, in most instances, it cannot be restored, it will be found that the breasts do not swell nor become firm after a considerable time from the last period at which the infant was applied to them. The infant seems hungry, even upon
quitting the breast, and is constantly seeking to be applied, but quits the nipple, after having taken it for a very short time, with impatience and with distressing cries. It passes very little urine, it sleeps little, and is rapidly emaciated.

23. VI. The termination of the period of lactation becomes necessary when the infant is sufficiently old to be fed by many of the usual articles of diet, when it is from eight or nine to fifteen months old, and when it has four or six teeth, or more. But there are other circumstances which indicate the propriety of terminating the period of lactation, before it be prolonged to the term now named, and to which attention is more especially directed above (§ 16). When these exist, or when the child is dead, the secretion of milk should be gradually suppressed. A sudden suppression of this function might endanger the occurrence of phrenitis, of fever, or of internal inflammations. The safest means of accomplishing this end are, the exhibition of saline purgatives, and of refrigerants, a cold bathing diet, and a sparing use of fluids. If the breasts become hard and painful, a small quantity of milk may be drawn off and stimulating liniments may be applied to them. They should also be rubbed gently with warm oil. After a few days but little inconvenience will be felt, and in a few more the milk will have entirely disappeared.

24. In weaning an infant, however, the gradual withdrawal of it from the breast, and the partial feeding it, for some time previously to complete weaning, generally favour the dispersion or suppression of the milk, and prevent the occurrence of much disorder or inconvenience being felt from the cessation of this function. Still, the bowels ought to be kept very freely open, and purgatives should be given from time to time, or according to circumstances, otherwise loss of health, depression of spirits, disorder of the digestive organs, or some specific disease, to which a predisposition may exist, may supervene. (See, also, connected with this subject, the article Mamma.)

tergic suffocation, which arises from a variety of pathological states, which is entirely unconnected with any affection of the respiratory passages, and which is very distinct from true spasmatic cough, which is always attended by signs of inflammatory, bronchial, or catarrhal irritation, as shown in the article Croup (§ 14, et seq.). Again, to the affection which is characterized by stridulous respiration with laryngeal suffocation, and which is aptly enough termed "Laryngismus stridulus," Dr. Goon applies, with propriety. The presence of the disorder, the description truly belonging to the spasmatic cough of Wicmann, &c., or the acute asthma of infants of Millar; thinking that this affection is identical with that noticed by Clarke, Cheyne, Levy, Marsh, and others. These distinct disorders have been confounded together by other writers also, and more recently by Dr. Jov. I proceed to consider stridulous inspiration, or stridulous laryngeal suffocation of children. The affection most nearly resembling it, in this class of respiratory affections, is one which by itself is infrequent, and which I have described as a species of croup with predominance of spasmatic or nervous symptoms (see art. Croup, § 14, et seq.); both these distinct affections having come frequently under my care, especially during the fifteen years that I was physician to the Infirmary for Children, both in that institution and in private practice.

3. SYMPTOMS.—Crowing inspiration, with a sense of suffocation in the larynx, and a tumbled and purple countenance, commencing suddenly and after irregular intervals; the attacks being of very short duration, ceasing also suddenly, and not attended by cough, or other sign of irritation seated in the larynx itself.

4. A. Symptoms.—The earliest accounts of this disease, distinct from the affections with which it was and still is confounded, have been furnished by Drs. John Clarke, Monroe, Golis, and Cheyne, who have described it nearly in the following terms: The child is suddenly seized with a spasmatic inspiration, consisting of distinct spasms to fill the lungs, attended by a shrill noise; the eyes are staring, and the child is evidently in great distress, and seems threatened with suffocation. The face and extremities, if the paroxysm continues many seconds, become purple; the head is thrown back, and the spine bent: at length a strong inspiration takes place, a fit of crying generally succeeds, and the patient falls asleep. The paroxysm may occur often in the course of the day: but it is most apt to take place on first awaking, or on exposure to causes of irritation, or when vexed, about to cry, or startled by any cause.

5. This affection may continue to recur for some months, if neglected, until at last the extremities are also affected by spasm, or convulsions become general. When it appears upon waking from or during sleep, or upon.
cereal irritation. Although the early state of the affection may be connected with, or sympathetic of, the irritation of teething merely, or of disorder of the alimentary canal, still it may become, after its continuance, or in its more advanced states, very manifestly associated with disease within the cranium, such disease being more evident as this affection proceeds.

8. The diagnosis of this affection has been well stated by Werny and Schmahl, and still better by Mr. Reyley. It may be confounded only with the spasmodic form of croup, with which, as I have stated, it has been, even recently, confounded by some writers of pretension. It differs from spasmodic forms of croup, in its being excited by the passions of the mind, and causes of momentary irritation, and by the irritation of distant but related parts; it occurs chiefly in those who are disposed to convulsive affections; its attacks are intermittent, distant, and irregular, and are relieved chiefly by means which impress the nervous system; it has no precursory signs, but attacks suddenly and unexpectedly; there is neither fever, cough, nor pain; catarrhal symptoms form no essential part of it, and it presents, after death, no traces of irritation in the respiratory passages; while spasmodic croup depends upon cold, damp air, and sudden atmospheric vicissitudes; and the fits of difficult breathing in it are attended by cough, the symptoms gradually subsiding, or being more quickly relieved by the accession of vomiting; it presents remission in the day, with exacerbations in the evening and night, and generally terminates with a glaring expectoration, &c. (See Croup, § 14.)

9. C. Causes.—The more remote causes are not very manifest. Infants and young children are most disposed to it. Dr. Hamilton considers it peculiar to the period of cutting the deciduous teeth. Dr. Clarke thinks that it seldom occurs after the third year. Mr. North says that the earlier symptoms generally appear between the third and seventh month, and that the disease seldom occurs after the appearance of the teeth. I have rarely met with it after the third or fourth year. The numerous instances I have seen, and I have had as many as three cases under treatment at the same time, have been generally between the third month and third year of age. It may doubtless occur at a more advanced age; but most of the cases which have been said to have occurred from four to seven or eight years of age, have been cases of the non-spasmodic forms of croup.

10. Children who are hereditarily predisposed to cerebral affections; who are of a serousful diathesis; and who are insufficiently nourished, or live in a close or unwholesome air; those brought up by hand, or who are delicate during the early months of existence, or are reared with difficulty—whose sutures are long in closing, and whose digestion and assimilating processes are weak and readily disordered, are the most prone to this affection.

11. The pathological states of which it is most frequently symptomatic, or by which it is generally caused, are, functional disorders of the digestive organs, especially the alimentary canal and liver; difficult or delayed dentition, generally with signs of irritation, tumefaction, or inflammation of the gums, or with the appearance of several teeth at the same time; inflammatory states of the membranes of the brain, changes in them or in the cerebral structure, or irritation about or near the base of the brain, or effusion into the ventricles; tubercular formations in the membranes, or within the cranium; enlargements of the glands, or of the thymic gland; and serofululent enlargement or other disease of the cerebral glands, or of the glands at the root of the lungs, whereby the recurrent or other laryngeal nerves are irritated or pressed upon.

12. D. The nature of the disease has lately been the subject of much discussion. It has not been very recently disputed that the larynx itself is entirely free from lesion; that is admitted. The questions are: is this an affection depending upon inflammatory irritation, or irritation of any kind, at the roots or origins of the laryngeal nerves, or communicated to or existing in any portion of them, whereby the muscles which constrict or close the glottis are unduly contracted? is it spasm of these muscles from direct or indirect irritation and sympathy? or is it owing to pressure upon the nerves which actuate the muscles which open the glottis, thereby paralyzing them? The crowing or shrill inspiration, with the struggles to inspire, dread of suffocation, &c., are unquestionably owing to a more or less complete closure of the glottis; but that the closure results from spasm of the constrictors, or that it proceeds from paralysis of the dilators of the larynx, are the points requiring to be proved. The disease may be the result of either morbid condition—either may be considered as sufficient to cause it; and we may even admit that the one condition may produce it in some instances, and the other in different cases. The former of these views, or the opinion that the affection proceeds from irritation at the origin of the nerves, or in the nerves themselves, which supply the muscles constituting the glottis, or from irritation in distant but related parts acting sympathetically upon these nerves, was the one very generally entertained, until Dr. Lay proposed the opposite or latter view.

13. There can be no doubt of the digestive organs or of the gums sometimes evincing disorder in connexion with the first appearance of the laryngeal affection, and without any sign of disorder within the cranium; and there can be no doubt of the chief and primary indications of distress which the infant then manifest in a peculiar way in the head; and it is equally evident, that whatever lesion, either during life or after death, observed in the brain, has often been superinduced by, or has been the consequence of previous disorder, or of the repeated attacks of laryngeal suffocation and the consequent congestion of the brain. I have seen cases in which the brain appeared either primarily or very early affected in connexion with the stridulous inspiration, and yet, after every disorder referrible to the brain had been quite removed, both the suffocating inspiration and the carpo-pedal contractions continued, although in milder grades, and recurred until the digestive functions and secretions were brought to a healthy state, and the child had had the advantage of change to a pure and healthy air.
Views as to the nature of this affection should not be based upon the history of a few cases, but upon that of many, and upon post-mortem examinations. Some cases have appeared to proceed from dentition only, others from disorders of the digestive organs merely, and others from disease of the brain; and yet, upon examination after death, those cases which have manifested even the least amount of cerebral disorder during life have exhibited great congestion and vascular injection of the brain and its membranes, particularly about its base and near the medulla oblongata, sometimes with effusion of serum, in rare instances even of blood between the membranes and in the ventricles, especially the fourth ventricle. In many of such cases there can be no doubt of the lesion within the brain being the consequence of attacks of this affection, and more particularly of the paroxysm which terminated the life of the patient. One argument in favour of the opinion that the lesions observed within the cranium are the consequences rather than the causes of this affection is, that the same state of parts in this situation is generally found unconnected with any obstruction to respiration. In such cases, however, it is difficult to determine whether or not lesions apparently the same are actually so; and it should be kept in mind that, owing to the physical conditions of the parts enclosed by the cranium and spine, congestion or effusion will produce not only pressure in its immediate vicinity, but also counter-pressure in the most remote parts of those enclosed in them.

14. While Mr. Ryland and Mr. North believe that the dependance of this affection upon disease within the cranium is not proved, and while Dr. Marsh seems to think that it may proceed from inflammation of or at the origin of the pneumogastric nerve, Dr. Lev imputes it to paralysis of the glottis, in consequence of the pressure of enlarged glands upon the recurrent nerves in some part of their course. The glands, to the enlargement of which he ascribes the crowing inspiration, are those at the roots of the lungs, both before and behind the bifurcation of the trachea, with others which lie upon the arch of the aorta, and not unfrequently between the carotids and the deep-seated chain of cervical glands, or glandulae concen*at*urate. That these glands are often enlarged in infants and young children, particularly those of a serofibulous constitution, cannot be denied; and that, when thus enlarged, they may occasionally press injuriously upon the recurrent nerves and produce this affection, may be the case; but that it always proceeds from this cause is not in accordance with my experience; for I have seen cases in which no evidence of enlarged glands was furnished either during life or after death; and, besides, the affection will often altogether other case, and may proceed upon two or more causes, or upon having recourse to means which could either but little affect the state of these glands, or not affect them in so short a time. The recent experiments, however, of Dr. Reim (Ed. Med. and Surg. Journ., vol. xlix.) have shown that the superior laryngeal nerve is almost entirely a sensory nerve, and that the recurrent is almost exclusively motor, supplying both constrictor and dilator muscles; and that severe dyspnoea, amounting to suffocation, may arise from irritation and compression of the inferior laryngeal nerves, or the trunks of the pneumogastrics; for when both, or even one recurrent nerve was irritated, the arytenoid cartilages were approximated, so as in some cases to shut completely the superior aperture of the glottis. When the recurrent nerves are cut and compressed, the arytenoid cartilages are no longer separated during inspiration and their movements are so completely passive that they are carried inward by the current of entering air, which they consequently impede, while they are separated again by the expiratory blast.

15. My own observations of this disease lead me to infer: 1st. That it may proceed from direct or reflected irritation merely—the primary source and seat of such irritation being either in the gums or in the alimentary canal, or about the base of the brain or medulla oblongata; 2d. That the frequent result of attacks of this affection is to develop whatever disorder may primarily exist within the cranium, and to occasion inflammation, or congestion, or effusion in this situation; 3d. That irritation commencing in either of the three quarters just assigned may be sometimes propagated to the recurrent nerves, and expressed through them in the muscles of the larynx; 4th. That the carpo*pedal contractions or more general convulsions which are frequent complications or associations of this affection, are often merely contingent, and, although they may proceed from the same source, may nevertheless arise from different sources of irritation; 5th. That when the laryngeal affection is thus associated, there is greater reason to believe that the parts about the base or centre of the brain are more especially implicated; 6th. That, even in those cases where enlarged glands exist and press injuriously upon the recurrent or other nerves, it is quite as likely that they irritate as that they paralyze these nerves; 7th. That the effects observed to follow an enlarged thymus gland, about to be noticed, although illustrating the influence of enlarged glands in producing this affection, do not prove that the influence is more that of pressure than that of irritation of the laryngeal nerves; 8th. That enlargement of either the thymus, or the bronchial glands, or the glandulae concen*at*urate, may act injuriously by pressing on the veins, and thereby preventing the return of blood from the head; congestion, effusion, and pressure of parts within the cranium resulting therefrom, and giving rise to the affection of the larynx, by either irritating or paralyzing the laryngeal nerves.

16. E. Closure of the Larynx by enlarged Thymus Gland.—Thymus Asthama of Korr.—Mr. Hooopp, of Kilmarnock, first directed attention to closure of the thymus gland, and its influence in producing morbid closure of the glottis, with suffocation, and pressure of the veins returning the blood from the brain. This memoir, although little attended to at the time of its publication, is one of the most important that has appeared in recent times, and contains the particulars of nine cases in which the appearances were observed after death, with several important pathological inferences. (See Elib. Journ. of Med. Science for Jan., 1827, p. 39.) More recently (1830) the subject was
treated of by Kopp, Hirsch, and Dr. Montgomery; still, Mr. Hood's memoir is the most full and circumstantial which has hitherto appeared on the subject. A few cases of the disease have been seen by me since my attention was directed to it by this writer; and three of them were examined after death, the appearances being altogether the same as those described in Mr. Hood's paper. The enlargement of this gland is apparently of a serous nature, as it is sometimes connected with a serous enlargement of other glands. It may, however, be the result of simple hypertrophy and inordinate distention of its substance by vascular congestion, favoured by constitutional peculiarity and over-feeding. In some cases the gland is denser, redder, and more fleshy than natural. Occasionally it exudes a milky fluid when divided; and, according to Mr. Hood, a cream-coloured or pariform fluid. In two cases this writer found abscess and ulceration of the gland, and, in one instance, it has contained tubercular matter, or a substance resembling cheese. When the enlargement has induced a congested state of the brain, probably with some degree of serous effusion within the cranium, owing to its pressure on the veins in the top of the chest, it may be expected that surprise, sudden excitement to cry, or bodily efforts will bring on attacks of this affection by aggravating the morbid state and rendering the gland more liable to terminate its existence. If now the child be able to make an inspiration, the functions are soon restored, and in a short time it recovers its wonted health and spirits. An attack of this kind is attended by the utmost danger; yet, by adopting means for promoting health, the child may never have a return of the complaint. In the second form the child still retains its usual plumpness, but the flesh is soft and flabby, and the countenance somewhat pale, and, on crying, quickly becomes pale and livid. On awakening out of sleep, or beginning to cry, the infant seems incapable of making an inspiration, the face becomes livid, and there is an appearance of alarming convulsions; but generally these symptoms suddenly cease on taking the child up. The same kind of fits may be brought on by feeding, dressing, crying, &c., or by whatever exerts or irritates it. At first the attacks are seldom, but they become frequent as the disease makes progress. Yet it occasionally happens that the child improves in every respect for weeks or months, and yet it suddenly expires in an attack. In all such cases the veins of the meninges are found after death loaded with blood, with more or less serous effusion between the membranes and in the ventricles. The veins of the neck and top of the chest are much distended by the pressure of the enlarged gland, and the heart is void of blood or coagulum. In a third class of cases which Mr. Hood has noticed, the voice is altered just before and after the fit, and has a grumpy sound, which is not heard during the height of the attack, for then respiration is altogether suspended. He considers the complaint to be much modified by derangement of the stomach, or by intestinal irritation, or by difficult or painful defecation.

18. It is very difficult to distinguish these cases from those which Kopp has so beautifully described above (§ 13–15); and it is probable that many of those attacks which have been referred to this disease within the cranium, or to dition, disorder of the alimentary canal, and to serous glands irradiating the recurrent nerves, have been instances of the disease caused by enlargement of the thyman gland. The symptoms, particularly as respects the stridulous inspiration, the threatened suffocation, and the occasions and recurrence of the attacks, are very nearly the same; and I may say that most of the cases which I have seen since the publication of Mr. Hood's paper would have been considered cases of laryngeal affection from the more remote causes of irritation, if that paper had not appeared; which paper I believe to have originated the views of Lely, Kopp, and others. Still, all cases of laryngeal suffocation, appearing spontaneously in children, do not proceed from enlargement either of this gland or of any other, for undoubtedly some cases arise from the causes noticed above (§ 13, et seq.) and, in these, the glands of the neck and top of the chest are either unafflicted or not materially affected. Indeed, it is not yet fully shown whether or not the symptoms are caused more by the pressure of the enlarged glands upon the veins, and the consequent congestion, pressure, or counter-pressure of the parts at the origin of the laryngeal nerves, than by the direct effects of these glands; they are very nearly the same; and I may say they proceed from the former condition, they are the consequences of the superinduced state of the base of the brain, and they may appear whenever the same state of parts arise either primarily, or from other causes.*

* [According to HAgusT, Sir Astley Cooper, MECHEL, CLOQUET, MULLER, and HORNER, the weight of the thyman gland at birth averages about 120 grams, or about an ounce. MICHEL states that it often weighs 360 grams in a large fetus, born at the full period. The reviewer of HAgusT's paper, in the Medic-Chirurgical Review, for April, 1834, gave the weight of the gland at birth between 2 and 3 drachmas, or varying from 120 to 180 grams. MICHEL remarks, that it increases in size till the end of the first, and sometimes to the end of the second year, and in the third year, as in the grown-up, or in the fully-grown person. If this be true, allowing its normal weight at birth to be 200 grams, and the commencement of its growth at the third fetal month, and in the end of the third year, it must be 356 grams; or 618 grams, if weighed 240 grams at birth, gaining in the former case, and in the latter 34 grams per month. Of course, however, an estimate of HESSEX describes the gland as continuing to grow to the end of the first year after birth; while from the first to the third year it gains in weight, and in the first year, or expectation increases, and diminishes; but from the third to the eighth or tenth year it decreases in size, and gradually wastes away to the tenth or twelfth year. If, however, it be reduced to half, or to any fraction, the small ligamentous remains that degenerate into a kind of reticular substance. The same writer states that he never saw a case where the thyman gland existed at the time of puberty. CLOQUET, MECHEL, and others, give nearly the same account of its growth and disappearance. In opposition, however, to this, we have the authority of Dr. Krause (MULLER'S Archives, Heft 1, 1857), who states that he has found thyman in almost all individuals between 20 and 30 years of age, and very often larger than.
may, however, be inferred to exist when the infant is gross, pale, flabby, and scrofulous; the

The semiology of this affection has been fully described by our authors, and we have seen the mode of it by Kopf, Hirsch, and Montgomery exclusively to enlarge ment of the thymus; by Levy to hypotrophy of the cervical glands, and by Sir J. Thomson to the

In a monograph on the thymus gland (Am. Jour. Med. Sci., N.S., vol. 3, 1855, 1855), we have also attempted to show the extreme incompatability of this affection being caused

by enlargement of this structure, to which we would refer the reader. M. Billard, whose autopsie examinations of children have been more numerous than those of any other writer, remarks: "The thymus gland is susceptible of being affected with certain diseases, during the short space of its transient existence. I have never been able to observe any peculiar symptoms belonging to these affections; but, on the bodies of children, I have seen it in two instances, much tumefied, very red, and extremely tender. I have also noticed inflammation, which, perhaps, might lead to its suppuration or disorganization." The French pathologists, generally, question the existence of a disease called thymic angiomatosis, as illustrations of partial evolutions of the thymus, which have served as the

From somewhat extensive observation, we are satisfied that the disease in question may be caused by gastric or cerebral irritation, central or reflex, as by teething, as maintained by M. Billard, Dr. Hofmann, and Dr. Wightman. The enlarged cervical glands remain to be proved that it is ever cause by enlargement of the thymus. It is, moreover, to be borne in mind that irritation, whatever set up in children, is always exerted upon the thymic and cervical glandsy and thymus, of the thymus, from its anatomiccal relations, must necessarily result from lesions of the circulatory and respiratory organs, and hypotrophy of the thymus, from its anatomical relations, must necessarily result from lesions of the circulatory and respiratory organs.

In a monograph on the thymus gland (Am. Jour. Med. Sci., N.S., vol. 3, 1855, 1855), we have also attempted to show the extreme incompatability of this affection being caused

by enlargement of this structure, to which we would refer the reader. M. Billard, whose autopsie examinations of children have been more numerous than those of any other writer, remarks: "The thymus gland is susceptible of being affected with certain diseases, during the short space of its transient existence. I have never been able to observe any peculiar symptoms belonging to these affections; but, on the bodies of children, I have seen it in two instances, much tumefied, very red, and extremely tender. I have also noticed inflammation, which, perhaps, might lead to its suppuration or disorganization." The French pathologists, generally, question the existence of a disease called thymic angiomatosis, as illustrations of partial evolutions of the thymus, which have served as the
when the attacks are severe, suffocative, and unattended by any marked evidence of head-affection, or of disorder of the alimentary canal; when there is distention of the veins in the neck; when the lower part of the neck, between the inferior attachments of the sterno-mastoid muscles, appears full or tumid; when the top of the sternum seems elevated or pushed out, and when there is dulness on percussion under the sternum, particularly its upper portion, and on each side of it. Fullness of the veins about the head and neck, without any obvious cause, or an unusual increase of that fulness when the head is somewhat low, should excite a suspicion of the existence of paralysis. This form of the disease is most common in children from a few weeks old to the age of two or three years; but it is not infrequently seen in those of four or five years of age, and it may even occur in grown-up or aged persons.

20. F. The prognosis of stridulous affection of the larynx should be stated with much reservation and caution. A child that has once had an attack should be considered in a precarious state until it has recovered, and instances of the disease existing any time after the period of first dentition has passed, the risk increases with the severity and frequency of the fits, and when they are associated with the carpo-pedal contractions or general convulsions. If the affection proceed from enlargement of the thymus or other glands, the danger is also greater than when it seems to depend upon dentition or disorder of the digestive organs only. If it appear in the course of disease within the cranium, particularly of meningitis and hydrocephalus, it is generally fatal, although I recently attended a case of this kind which recovered. The most favourable circumstances are, a sound constitution, the attacks being slight and rare; the absence of affection of the brain, and of scrofulous disease of the thymus or other glands; and the ability to have change of air, especially to the seaside.

21. G. Treatment.—The intentions with which the treatment of stridulous laryngeal affections should be conducted are, 1st. To avoid the occasions or exciting causes of the paroxysms; 2d. To remove the morbid conditions on which they depend; and, 3d. To endeavour to prevent the paroxysm from being followed by dangerous or fatal results. The propriety of avoiding the occasions and causes by which a return of the fit is produced is so obvious as to require only the most cursory notice. Every source of excitement and irritation, both moral and physical, should be guarded against; and efforts of all kinds, especially straining at stool, ought to be avoided. Sudden surprises, and disturbances from sleep, excitement of the temper and passions, as well as all muscular efforts, should be shunned; and all the secretions of the stomach and other glands ought to be freely promoted, without exhausting the powers of life.

22. b. The removal of the morbid conditions on which the paroxysms depend is obviously the most important indication. This should be attempted only after a careful examination of symptoms, especially those connected with the head and scalp, with the gums, and with the stomach and bowels. Sources of irritation in the chest, particularly in the top of it, and in the neck, should be carefully inquired after.

a. The frequent occurrence of stridulous affections of the larynx with dentition ought always to suggest an instant examination of the state of the gums; and if fulness, redness, dryness, or heat of them be present, or any other indication of irritation, and especially if the salivary flux, which usually attends dentition, be suppressed or scanty, a free division of the gums in the situation of the advancing teeth, and a recourse to sialogogues of a mild kind, should not be delayed.

23. c. If signs of disease within the cranium either have preceded or accompany the laryngeal affection, the treatment must be directed with a strict regard to the nature and intensity of such disease. The accession of carpo-pedal contractions, of general convulsions, or of strabismus, does not prove the existence of inflammatory action of the brain, for the paroxysms of laryngeal suffocation, by interrupting the return of blood from the brain, may have occasioned congestion, irregular circulation, or even serous exudation into the cranial cavity, which may give rise to these symptoms. However, inflammation may exist, and be accompanied with those and with other phenomena, especially in its advanced stages. Of themselves, these symptoms indicate the necessity of relieving the oppressed brain and restoring the healthy balance of the circulation in this quarter; but these ends cannot be attained by trusting to bleeding only, or even chiefly, whereby the powers of life are often overreached. The morbid state of circulation in the brain. Bleeding, however, is generally required, but it must be resorted to according to the state of vascular fulness and power, and be aided by purgatives, alteratives, diuretics, cold affusion on, or frequent cold sponging of the head, and derivatives, according to the features of individual cases.

24. γ. If the stomach and bowels are disorderly, stomachic purgatives, conjoined with alteratives, and given so as to act regularly and moderately, are required. Flatulence and acidity, which commonly are present in these cases, should be removed by prescribing alkalies or absorbents in conjunction with aperients and tone-
ies. Small doses of calomel, or the hydrargyrum cum creta, may be given with calcined magnesia, or with the dried sub-carbonate of soda and rhubarb or jalap; and a mild tonic infusion may be presribed, with a little of the sesqui-carbonate of ammonia, and of some carminative spirit. But chief reliance should be placed on change of air, on exercise out of doors, on cold sponging the head and general surface, and on cold salt-water bathing, when the patient can bear the shock of the bath, which should be cautiously and gradually varied to the warmest that can be tolerated on the scalp, or of enlargements of the glands of the neck, should lead to examination of the state of the lower part of the neck and of the top of the chest, particularly in scrofulous, cachectic, gross, and unhealthy-looking children; and although in these disease may also exist, either in the digestive organs, or within the cranium, or in both these quarters, still, enlargement or scrofulous changes of the more deep-seated glands, interrupting the return of blood from the head, and irritating the recurrent nerves, may be a chief or a concurrent cause of the laryngeal affection. In such cases, as well as in those where the thymic gland is apparently enlarged, strict attention to the state of the secretions and excretions, the exhibition of mild and tonic aperients and alteratives, small doses of the iodide of potassium, with liquor potassae, and sarapis, change of air, especially to the seaside, an appropriate diet, and warm clothing, are the means chiefly deserving notice. An ointment with iodide of potassium may be employed externally, but the judicious use and combination of this substance as an internal medicine render it the most deserving of confidence in these cases. The preparations of quinine and of iron, especially the iodide of iron, and the compound steel mixture with liquor potassae, are also of service, especially in cachectic, flabby, and pallid children; but as respects patients affected with any form of laryngeal affection in large towns, no means are so effectual as change to a pure, temperate tried dry air, especially in scrofulous constitutions, and without such change all other remedies may fail.

26. c. The removal of the attack seldom becomes the office of the physician; for the fit is usually short, and if it were not so, death would generally very soon result. The child should be held up, and somewhat forward; and if respiration does not instantly follow, cold water may be sprinkled over the face, or it may be affused over the head, while the lower part of the body is plunged in warm water. If these measures fail, the shoulders and back may be slapped with the open hand or with a wet napkin, and stimulating salts may be held near the nostrils; but these are then rarely of avail. In those cases of laryngeal affection where the inspiration is made partially, and with a crowing and stridulous noise, and is not altogether prevented, and consequently where there is time to exhibit an emetic, one should be given forthwith, conjoined with a little camphor; and a warm bath, or the semicliniam, may likewise be resorted to. I have seen, however, the emetic fail to act in these cases, although it was given in a sufficiently large dose, owing to the opposition of the brain by the interruption to the return of blood from it; but, upon resuming to the affusion of cold water upon the head, the emetic effect was produced.

27. If none of the measures just proposed is attended with success, recourse to the operation of tracheotomy has been suggested by Dr. Porter and Mr. Ryland. It certainly, however, is not justifiable, as the former of these writers has stated, as long as respiration is carried on even with the greatest difficulty; for in almost every case in which the rima glottidis remains so large as to allow of a partial transmission of air, the affection is not very severe, and the child will struggle through it. "But if," he remarks: "the child is to all appearance dead, and if the practitioner is called to him within any reasonable time, he should then, with the least possible delay, endeavour to inflate the lungs and restore animation by whatever means appear to be the speediest, and of these, perhaps the most preferable will be tracheotomy." Dr. Marsh states, that Dr. Johnson had seen a child, in a state of suffocation, caused by this disease, recovered from apparent death by the instantaneous application of artificial respiration.

28. ii. Suffocative Laryngeal Affection in Adults.—Croup-like Respiration in Adults.—Spasm of the Glottis in Adults. This affection, as it occurs in grown-up persons, proceeds from three principal sources: 1st. Tumours of any kind pressing upon or irritating the laryngeal nerves, or pressing upon the veins; 2d. Inflammation or irritation of adjoining parts, as of the pharynx, epiglottis, oesophagus, &c.; and, 3d. Sympathy with the state of more remote parts, as in cases of hysteria and of irritation of the sexual organs, or spinal nerves.

29. A. Tumours of various kinds, small abscesses, and scrofulous depositions in, or enlargement of glands, may form in the immediate vicinity of the larynx and trachea, or between them and the oesophagus, and occasion fits of suffocation or stridulous or croup-like respiration. Morgagni, Rush, and others have recorded instances of this kind, and I have observed them. Bronchocele, aneurisms of the arch of the aorta, or of the arteries innommatum, and enlarged or scrofulous glands at the top of the chest, sometimes produce a similar effect.

30. a. Bronchocele, particularly in nervous and hysterical females, is very frequently attended by attacks of stridulous or croupy respiration, or fits of suffocation, especially upon mental emotion or physical efforts; and this is the more especially the case about the periods of menstruation or when any irregularity of this discharge exists, as often observed in bronchocele affecting persons of this sex.—b. Scrofulous and suppurring glands, particularly those which are much enlarged, or contain purulent or scrofulous matters, in the vicinity of the trachea or larynx, act in the adult in a similar manner to that mentioned in cases of children (§ 14, et seq.). In a case on which I was recently consulted, a cluster of glands at the root of the lungs were remarkably large and infiltrated with tubercular matter, so as to form a very constant tumour, producing not only more or less dyspnea, owing to its pressure on the trachea, but also fits of suffocation, in one of which the patient expired. This case closely simulated one of aneurism of the arch of the
aorta, owing to the size of the tumour and to the pulsation of the aorta being communicated to it. I have taken, in other laryngeal affections caused by a fungoid tumour—a true fungus tumorales—attached to the posterior aspect of the top of the sternum.—c. Of the influence of occasional tumours in producing attacks of this affection no proof need be offered, as such instances are of frequent occurrence, and instances of them have been published by Lawrence, Fletcher, and others.

31. B. Inflammation of adjoining parts, as of the pharynx, or of the esophagus at its upper part, sometimes is attended by spasm of the glottis, particularly in nervous females. Such by terical females. In these, even the irritation of the pharynx or of the epiglottis, caused by the ascent of acid eructations in the course of indigestion, or of the globus hystericus, or of flatulence in connexion with hysteria, sometimes produce similar attacks. The irritation occasioned by an elongated uvula, either upon the epiglottis or upon the rim glottidis, has had the same effect in some cases. (See Treat, Diseases of.)

C. The irritation of the sexual organs, or of the spinal nerves, is occasionally connected with this affection, which then assumes the form of irregular hystera, and in such circumstances an attack is often produced by cold, or slight inflammatory action in the respiratory passages, which, from its severity and recurrence, may be mistaken for acute or chronic laryngitis, if the various nervous and hysterical symptoms attending it be overlooked. In cases of this kind, an attack may be brought on by violent mental emotions, especially if the digestive or respiratory organs be in an irritable state at the time; but it seldom occurs unless the uterine functions be also disturbed, as indicated by either a disordered state of the cata menia or by leucorrhoea. (See art. Hystera, § 31, 37.) It should, however, be always kept in recollection, that cases in which there is some degree of inflammatory action and much spasm are often met with in females, particularly those liable to hystera. I have seen several cases of this description, which required a treatment appropriate to their mixed nature. Severe attac ks of spasm of the glottis are very apt to occur in the course of hooping-cough or bronchitis, when either of these occurs in nervous or hysterical females, and will readily be aggravated by a too lowering treatment.

32. D. Treatment. It is obvious that the treatment of these affections should depend entirely upon the pathological conditions producing them.—a. When proceeding from tumours of any kind, or from small abscesses, or serofe- gious enlargements of glands, the iodide of potassa, taken with sarsaparilla, are the most efficient means which can be resorted to; and are especially useful when the affection is caused by bronchocele. If hysterical symptoms be present, the iodide of iron may be employed, or the foregoing medicines may be given with any of the preparations of valerian or of camphor. It is obvious that the dependence of this affection on aneurism, or on malignant tumours, almost precludes any hope of cure, and admits only of temporary alleviation.

34. Where inflammatory irritation of the pharynx, or upper part of the esophagus, is attended with spasm of the glottis, means must be employed to remove the inflammation, and these will generally, also, prevent the occurrence of the spasm. After such depletions as the nature of the case may require, much benefit will result from the use of a linctus containing, in a lubricating and an emollient vehicle, a small quantity of the nitrate of potash, or of the hydrochlorate of ammonia, with a little vinum speciacoamiae, and any narcotic or sedative tincture or extract; and, if the spasms continue, a rubefacient embrocation may be applied at the root of the throat. The following have been often prescribed by me with almost instant relief, the embrocation being applied around the throat on flannel, until much heat and redness of the skin are produced.

No. 281. R Potassii Nitritatis, 5j.e. (vel Ammonii Hydrochloratis, 5j.e.); Mucilag. Ac. Arachis; Sarps Tohustani, 3,3 j.e.; Vini Ipecacuanhae, 3j. ; Touch. Hysocyami, 5j. ; Cetacei, vel Pulv. Traganthi, q. s.; et secondum tentem linctus a quo parvissima quantitas linii oesophagi, adhibita, ne laesuram oesophagi, evocata utenda.

No. 282. R Linimenti Camphoros Compo.; Linimenti Terebinthinae, 5j. ; Olei olive, 5j. ; Olei Limonis, et Olei Canthari, 2,5 j. ; Mus. Frat Embrocatione, non disturbando.

35. c. The Hysterical or nervous form of spasm of the glottis is almost instantly relieved by having recourse to the above linctus et embrocation. If these fail, which is rarely the case, camphor may be given with a narcotic, with the extract of belladonna, of opium, of hembane, &c., or with a full dose of Dover's powder. The preparations of valerian with ammonia are also of use. When the affection of the glottis is connected with inflammatory irritation, either in the bronchi or at the base of the pharynx, perseverance in the linctus and embrocation, varied according to circumstances, will generally remove both the one and the other. The disorder of the uterine functions, or the morbid conditions connected more immediately with the hysterical affection, will next require attention, particularly with a view of preventing a return of it. (See Hystera, Treatment of.)

iii. ATOMIC AND PARALYTIC STATES OF THE LARYNX.

Classif.—IV. Class, III. Order (Author).

36. Defin. A partial or complete loss of voice and speech, owing to an atomic or paralytic state of the nerves of the larynx.

37. This affection is generally symptomatic, but it is occasionally primary or ideopathic, as when it is caused by an exertion of the voice much beyond the power or tone of the parts: it is, however, then rarely or never complete. The term aphonia has often been employed synonymously with mutitas or dumbness, with which loss of voice, or aphonia, has thus been confounded. But in dumbness, or mutitas, the voice exists; it only cannot, owing to the aboli tion of the sense of hearing, be modulated into articulate or certain sounds. In aphonia, the voice is either totally or at least, the power of articulating existing when the voice is partially retained. In rare instances, however, the partial loss of voice is attended by a loss
of the power of articulation, and, in this case, the powers of deglutition are also more or less lost. Aphonia, in various grades, may arise from a great variety of circumstances, and of morbid conditions, which may be arranged under the three following heads: 1st. Functional or nervous loss of voice; 2d. Catarhal aphasial; 3d. Loss of voice from inflammations of the larynx and its consequences; 4th. Aphonia from tumours of various kinds in or near the larynx; and, 5th. Aphonia from disease, or injuries, at the origin, in the course of, and affecting the laryngeal nerves, so as to paralyze them.

38. A Functional or nervous loss of voice may be said to be a more or less complete abolition of nervous power in the muscles of the larynx, independent of inflammation, or of organic disease of adjoining or of related parts. The primary state of this form of aphonia is generally caused by debility, and excessive efforts of voice, or inordinate exertion of the vocal organs. It may likewise result from overwhelming emotions of the mind, from sudden moral or physical shocks, from chills caused by sudden exposure to cold, or by drinking cold water, and from masticating narcotic plants in mistake. More frequently, however, it is merely one of the very numerous modes in which hysterica in its irregular form manifests itself, and is then generally connected with irregular, difficult, or suppressed menstruation, with uterine irritation, &c. (See Herrarian, 61.) In these circumstances, the paralyzed state of the muscles of the larynx may be attributed to an irregular distribution of nervous energy, connected either with exhaustion or with derivation to distant parts. This form of aphonia may be of very short or very protracted duration. It may recur frequently, or only at distant periods. It may also be only partial, or altogether complete, and among the most difficult affections to remove.

Catarhal aphonia is of frequent occurrence, particularly in females. It is probably connected with congestion of the mucous membrane of the larynx and epiglottis, and impaired action of the laryngeal muscles. In its more complete and prolonged states, it is also partly owing to nervous or hysterical disorder, cacharath exciting and aggravating the functional affection. Catarhal aphonia is usually accompanied with relaxation of the uvula, and catarhal congestion of the posterior nares and pharynx, with an atonic condition of the adjoining part, which is extended to the larynx.

40. C. Inflammation, its consequences, and other organic changes, as tumours, &c., seated in or near the larynx, occasion, as shown in other places, more or less complete aphonia. In the purely inflammatory states, the injection, thickening, tumefaction from effusion of serum in the connecting cellular tissue, and the impaired as well as embarrassed action of the muscles, always attending inflammation of their surrounding and connecting tissues, sufficiently accounts for the hoarseness or aphonia which accompany them. When edema of the larynx, or when ulceration, or any other of the consequences of common or of specific inflammations exists, so as to injure or to destroy, more or less, the mechanism by which voice is produced, then no farther agency is requisite to account for the phenomenon. The same organic lesions, which I have shown above (28, et seq.) to be occasionally causes of spasm of the larynx, may also, particularly when they mechanically impede the motions of this part, or when they paralyze its nerves, produce aphonia. Tumours of any kind, or abscesses, will have this effect, when situated so as to act in either way.

41. D. Lesions within the cranium, when they disorganize, paralyze, or otherwise implicate the organs of the laryngeal nerves, or similarly affect them in their course, will cause complete aphonia, generally also with loss of the power of articulating, and sometimes also of deglutition. In these cases, congestion, effusion, or other changes of an organic or of a sclerous kind have taken place at the base of the brain, near or in the medulla oblongata; or counter-pressure, caused by effusion of blood or of lymph, or by sclerous or other tumours in the vicinity, or even lesions of the dura mater or bones of the base of the cranium, may have produced this effect. Aphonia from these changes either attends, follows, or even precedes apoplectic, paralytic, or epileptic seizures, and may generally be considered a very unfavourable circumstance, as patients thus affected rarely continue long exempt from a fatal seizure.

42. In some cases of this kind, inarticulate sounds may be uttered, the power of modulating the voice and of articulating being lost. I was called upon, some years ago, to visit in consultation a gentleman who several months previously had lost the power of articulating any sound, however simple. The movements of the tongue were nearly abolished, and the power of deglutition, unless substances were conveyed over the root of the tongue, was lost. These were the only paralytic symptoms, and he was, in every other respect, in good health, and without any sign of cerebral disease. Treatment having proved ineffectual, my attendance, after some time, and altogether too late, I learned that he died suddenly some months afterward. Somewhat similar cases of palsy, affecting only the muscles of the larynx, pharynx, and tongue, have been observed by me in children; but they have generally been preceded by some acute cerebral affection, or by convulsions. In every case death has taken place suddenly, and, in those cases where inspection afterward was allowed, organic lesions were found about the medulla oblongata, or at the base of the brain, and consisted either of those alluded to above (41), or of softening of the cerebral structure.

43. E. Treatment.—The plan of cure should entirely depend upon the evidence furnished as to the existence of either of the morbid states to which aphonia has now been referred.—a. If the loss of voice result only from relaxation or atony of the vocal chords, owing either to debility or to over-exertion, gargles containing capsicum, a warm rubefacient embrocation around the throat, and the heating and application of camphor with mineral acids, or other tonics, will generally be of service. If it be connected with hysteria, the same means as now advised, and the preparations of valerian, camphor, ammonia, iron, &c., may severally be employed, according to the state of the uterine functions and constitution of the patient. In the more obstinate of the nervous and hysterical cases of
aphonia, electricity has been advised; and in these I have found the pyrethrum, or other stimulating substances, used perseveringly, as nitroglycerine, of great benefit. Occasionally an active emetic, consisting of ipecacuanha, decoction of senega, and some preparations of squills, has proved of service, particularly when followed by a stomachic purgative, and the tonic and stimulant remedies just mentioned.

44. b. When aphonia is cattartical, the emetic, and subsequently a stomachic purgative, diaphoretics, stimulating gargles, and embrocations, applied to the throat or around the neck, are generally of service. If it presents ulceration, or ulceration of the larynx; from destruction of the cartilages, or from other consequences of inflammatory action, or of syphilis, the means advised for these lesions when treating of the several forms of laryngitis are then required.*

45. c. If aphonia arise from scrotulous glands, tumours, or other lesions, paralyzing the laryngeal nerves, or mechanically obstructing the movements of the larynx, the internal use of tincture of the nard of galbulinum, with liquor potassae, or Brandt's alkaline solution and sarsaparilla, may be tried, and aided by such other means as the peculiarities of the case will suggest.

46. d. When aphonia proceeds from disease within or near the base of the cranium; when it appears to usher an attack of apoplexy or palsy, or attends upon, or follows an apoplectic or epileptic seizure; when it seems to depend upon vascular congestion, effusion, or some organic lesion, the treatment must be remarkably various. Consult the nature and state of the disease of which it is a symptom. If it precede and seem to threaten an acute attack, vascular depletions, purgatives, and derivatives are indicated. If it follows such an attack, the above alteratives, permanent derivatives, and drains, &c., particularly setons, issues, or open blisters, are requisite.

47. Defin.—Pain, soreness, constriction, and tenderness in the region of the larynx; epiglottis swollen and erect; breathing shrill and suffocating; voice hoarse, sharp, and lastly suppressed; short, painful, and convulsive cough; great anxiety and restlessness, with fever and occasional syncope of the head.

48. This disease was first noticed with precision by the second Monro, Home, and Cheyne, and subsequently by Farre, Bailey, Black, and others. The varieties which it presents in practice have been particularized by Cheyne, Cruveilhier, Bretonneau, Batte, Trousseau, Belloc, Kylan, and others; but we are still without a correct arrangement of these varieties, in relation either to each other or to the complications in which they are very often presented to our observation. Before I describe the varieties of laryngitis which I shall arrange the arrangement of which I shall adopt.

49. 1st. CATARRHAL OR SLIGHT LARYNGITIS, which often attends common colds and sore throats, and is characterized chiefly by cough and hoarseness of the voice. It generally subsides in the course of a few days, and often without the aid of medicine; but, in faulty or cachetic constitutions, or in the highly inflammatory diathesis, it may pass into some one or other of the following varieties.

50. 2d. Acute LARYNGITIS may appear as other inflammations, either primarily or consecutively, and present certain forms depending upon diathesis, previous disorder, and epidemic influence. It may be sthenic, as when it occurs in a previously healthy constitution; or asthenic, when it affects weak or cachetic habits, or appears in connexion with some other malady.—A. Sthenic acute laryngitis may be, a. Primary and simple; commencing in, and limited chiefly to the larynx and epiglottis, and attended by acute inflammatory fever. It may be consecutive, and complicated with inflammation of the fauces, tonsils, and pharynx; or of the trachea and larger bronchi, &c., as in sporadic and epidemic group (Diphteritis); luminous exudations forming on the inflamed surface, and the attendant fever being of an inflammatory or sub-inflammatory character. —B. Asthenic acute laryngitis may be, a. Primary and simple, with the effusion of serous or of a sero-puriform matter in the sub-mucous tissue of the larynx and epiglottis, the attendant fever being less acute, and the constitutional powers impaired.—B. Secondary and complicated, as when it occurs consecutively upon scarlatina, smallpox, erysipelas, or malignant sore throat, low fevers, &c.

51. 3d. CHRONIC LARYNGITIS, which may be either primary or consecutive of the acute, or of disease of related parts.—a. Simple chronic laryngitis, limited chiefly to the larynx and epiglottis.—b. Complicated chronic laryngitis, associated with disease of the lungs, generally of a tubercular or scrofulous nature, or with chronic bronchitis.—c. Specific or phthisitic laryngitis, attended by secondary syphilitic symptoms, or with the venereal cachexia. These are the several forms of simple and complicated laryngitis, which will be found arranged at the head of the next page.

52. i. Description.—A. CATARRHAL LARYNGITIS is generally slight, and often attends catarrah, particularly when the catarrhal irritation extends from the fauces to the larynx. It may be viewed merely as an extension of the affection of the mucous surface of the throat, thence to the larynx, and frequently also to the trachea and bronchi on the one hand, and along

* [In the New York Jour. Med. and Colarteral Sciences, vol. iv. p. 248, may be found a report by Dr. J. E. Taylor, of New-York, of twelve cases of aphonia, treated by cauterizing the larynx with the nitrate of silver (40 grs. to 2 gr.), after the manner recommended by Troussseau and Bellon, by means of a sponge attached to the end of a piece of whalebone, bent to an angle of about 80 degrees. This was pressed directly into the larynx, saturated with the solution, by bringing forward and depressing the tongue by means of a curved, broad spatula. In three instances, three applications were sufficient to effect a cure; two were materially benefited; three cases of laryngeal pathos were only partially relieved. Dr. Horace Green, of New-York, has discovered and several cases of cures of this affection, by the employment of the same mechanical means. We have known several chronic cases cured by the repeated application of galvano-magnetism to the larynx.]
the oesophagus on the other. It is characterized by the usual catarrhal symptoms, by hoarseness or partial loss of voice, and cough, which is at first dry, but may become productive of mucus or more copious expectoration as the complaint proceeds. There is either little or no attendant fever, or fever of a slight remittent form. This variety may pass into the acute, but it much more frequently is followed by the simple or complicated states of chronic laryngitis. It more commonly, however, disappears spontaneously, or after treatment.

53. **B. Acute Laryngitis** is a most dangerous disease in all its forms; but more especially in the asthenic complicated form. The particular character or state which it may assume depends upon the habit of body, temperament, and previous health of the patient; upon the existing epidemic influence, and upon the nature of the disease on which it is consequent, or with which it is associated. It is a formidable malady, as respects the suddenness of the attack, the alarming and distressing nature of the symptoms, the rapidity of its progress, and the frequency of its fatal issue. Its occurrence in the course of other diseases, and the fact of its being the cause, in many instances, of the great danger and fatality of these, render it a subject of great interest. Viewing it in all its relations, it may be divided (§ 50) into the sthenic, or truly inflammatory, or as it affects a person in previous health, and the asthenic, as when it appears in the cachectic or in the course of other maladies.

54. *a. Sthenic acute laryngitis* may appear in various circumstances; it may be—

1. The common and simple throughout; or

2. Consecutive and complicated. It is of importance that it should be considered in each of these forms, and with due relation to the other affections by which it may be preceded, associated, or followed; and this will become the more evident when the more complicated states of the disease come under consideration; for several maladies in which laryngitis often forms a most dangerous part have been frequently described without the occurrence of laryngitis, as in the extension of disease to the larynx, either in a sthenic or an asthenic form, has constituted the chief interest and risk to the patient attending them.

55. *a. Simple acute laryngitis* occurring primarily, or in a constitution capable of manifesting the sthenic or true inflammatory state of vascular action, frequently appears with some degree of sore throat, difficulty of swallowing, chills or slight rigours, followed by symptomatologic inflammatory fever. Soon after the commencement of the attack a dull pain or soreness is felt in the upper and interior part of the throat, with a sense of constriction, and tenderness when the larynx is pressed. The voice is harsh, hoarse, or sharp, and there is a slight, frequent, short cough, without expectoration. The fauces are generally red or inflamed, and when the tongue is pressed downward and forward the epiglottis may be seen erect, swollen, and red. At this stage of the disease the larynx is not strictly inflammatory, the pulse being full, quick, and strong; the skin hot and dry, the face flushed, the tongue white and sometimes tumbid, and thirst urgent.

56. At a more advanced stage, and as the termination of the inflamed parts diminishes the aperture of the glottis, the voice becomes small, piping, whispering, and ultimately suppressed; the breathing difficult, inspiration being sibilous, shrill, prolonged, and laborious; the larynx is drawn downward with great force on each attempt to inflate the lungs. The cough is stribulous, convulsive, or strangulating, and attended by scanty, viscid, and transparent expectoration, and by attacks of spasm of the glottis threatening suffocation, which are occasionally induced by difficulty of swallowing, owing to the imperfect closure of the glottis by the swollen and inefficient state of the epiglottis. The eyes almost start from their sockets; the countenance becomes pallid and anxious; the pulse feeble, quicker, and less uniform, and the surface of the body cooler. The constitutional phenomena now indicate imperfect aération of the blood in the lungs, the lips assuming a more leaden or livid hue, and the tongue a darker colour. More or less fulness or swelling may be observed in some cases around the larynx and in the course of the trachea. The patient is now apprehensive, restless, sleepless, and desirous of embracing any means of relief, feeling that he is on the point of suffocation.

57. In the last stage, respiration can hardly be performed; the voice is gone; the pulse is weak, small, and intermitting; the lips are livid, the face pale and leaden, and the surface cold or clammy. The patient sits upright with open mouth and outstretched neck, grasping objects around him to assist the laboured inspirations. In this stage, he sometimes dozes, but soon starts up in the utmost agitation, gasping and struggling, and in many cases sinks in a state of gradual asphyxia, if he be not carried off in one of the spasmodic attacks of suffocation attending the cough, or following attempts at swallowing in the advanced stage of the malady.

58. The course of the disease generally presents the three stages indicated above, when it is not interrupted by treatment. These stages may be viewed as the first, early, or inflammatory stage; the second, or developed stage; and the third stage, or period of exhaustion and asphyxia. The duration of this form of laryngitis varies from eight to twelve hours (Armstrong and Cheyne) to several days. The more usual
LARYNX AND TRACHEA—INFLAMMATION OF—SHTENIC.

duration, however, is from two to five days. It very rarely is longer than a few days, unless the disease pass into the chronic form. The more completely acute laryngitis is limited to the larynx, the shorter, in general, is its duration. Cases are recorded by Rush, Tachéron, Porter, and others, in which the inflammatory appearances were found limited to the larynx, and a fatal issue ensued within twenty-four hours from the commencement of the attack.

59. 3. Consecutive or complicated sthenic laryn-gitis is characterized chiefly by the extension of the inflammation from the fauces, tonsils, and pharynx, on the one hand, to the larynx; and more rarely from the trachea upward to the larynx on the other, as in sporadic cases of croup. In all such cases, the inflammatory action is chiefly superficial, and is attended by an exudation of albuminous lymph on the internal surface. The signs of danger in acute fever, the exudation in the tonsils and fauces, and extends to the respiratory passages, it has been termed "Diphtherite," from δέφθαρα, pellis, exuvium, or "Angine Convulsivum," by M. Bretonneau, who wrote on this subject, and confounded this form of angina—the "Angina Membranacea" of the older writers—both with Cynaehic Maligna and with Sporadic Croup; and in this he has been followed by several of his contemporaries. One part of his mistake has arisen from inattention to the characters of the attendant fever, and to the superficial manner in which the local affection has been viewed. Attention to the following facts will more fully explain the source of this very egregious mistake: a mistake fraught with danger as regards the appropriation of the means of cure.

60. Inflammations of the throat frequently occur, both as sporadic and as epidemic diseases; they may be simple, or they may be the chief characters, and result in dangerous, or even fatal consequences. In many instances, and particularly when they are epidemic, they are accompanied with an exudation of lymph on the inflamed surface; and whether the inflammation commences in the tonsils and soft palate, or in the pharynx, or whether it assumes a sthenic or an asthenic character, owing to the nature of the constitutional disease of which it is a part, and the circumstances connected with the patient, it is more or less prone to extend itself through the various passages leading from the pharynx; and when the larynx and epiglottis thus become affected, the disease then assumes a different and a much more dangerous character, death sometimes taking place in a few hours. In all cases, when the inflammation extends from the fauces, tonsils, and pharynx to the respiratory passages, the local appearances and the character of the attendant fever indicate the nature and tendency of the malady. In sporadic and intermittent cases, both the local appearances and the constitutional affection indicate an acute and sthenic disease, an albuminous exudation, or a firm and continuous coating of albuminous lymph, forming on the inflamed surface, and the attendant fever being inflammatory or sub-inflammatory.

61. In other epidemics, and even in a few sporadic cases, but more commonly when the affection of the throat accompanies the acy-
nance is now pale, leaden, and often livid, particularly during the fits of suffocation which occur, and the pulse small and intermitting.

64. The duration of the disease is various. The morbid action may continue in the tonsils, palate, and posterior part of the pharynx for six or seven days before it extend to the larynx; but, after it has reached this part, death may take place in twenty-four or forty-eight hours, either from a paroxysm of suffocation, or in the slower mode of asphyxia noticed above (§ 57) as often terminating the more simple form of the disease. In some cases, the laryngeal disease follows more rapidly upon the affection of the throat; and, in a few, it seems almost coetaneous with this affection. In these cases, especially, the inflammatory action extends not only to the trachea, but frequently also to the larger bronchi, as demonstrated by post-mortem examinations, and as more fully shown in the article Croup (§ 13, 33).

65. Consecutive, att:henic laryngitis is sometimes a complication of the more serious forms of scarlatina, measles, and small-pox, particularly in certain epidemics. But when it is thus complicated or associated, it generally assumes a less sthenic character, and approaches, in some cases at least, and especially in the constitutional affection, the asthenic or the next form to be noticed. In these associations the local affection varies considerably, particularly as respects the appearances of the albuminoid exudation, which may be scanty, partial, or almost absent. (The local symptoms vary much in the nature of the primary malady and state of the patient. In some cases, especially in those consequent on angina maligna, there is not only much diffused swelling of the parts, but also an exudation of soft, dark lymph, which concretes imperfectly into crusts or patches, and these irritate the larynx and epiglottis, especially when they become partially detached. Infiltration of the sub-mucous cellular tissue, with swelling and softening, also takes place; the infiltrated and softened areas appear as a diffusive, or sero-sanguinolent, or of a dark colour, from the presence of blood globules in it. The colour of the inflamed parts depends partly upon the character of the infiltrated fluid, upon the state of the lymph thrown out upon the diseased surface, and upon the grade of intensity or malignity marking the constitutional as well as the local malady. The affection of the throat in these cases, particularly when it extends to the larynx, is attended by vital cohesion of the sub-mucous tissues, and by a soft or less tenacious state of the lymph diffused upon the affected surface, which, in some cases, membranous, but in others pultaceous, assuming a gangrenous-like appearance, from its colour and softness, and from the odour exhaled. In the more malignant cases, the crusts or patches of lymph become darker and more foul, owing to the exudation of dark blood, or of a bloody ichor from the inflamed surface, when they are being detached from it. In this form of the disease, the states of vascular action and tone, and the condition of the blood, which is always more or less altered, prevent the formation of a firm concretion on the inflamed surface, and give rise to the morbid and gangrenous-like exudations.

LARYNX AND TRACHEA—Inflammation of—Asthenic.
characterizing it, as more fully shown in the articles Scarlet Fever and Throat.

69. When the larynx is consecutively affected in these asthenic or malignant cases, the progress of the disease generally is fatally accelerated. The breathing becomes laborious or convulsive; the inspiration difficult and prolonged; the voice croupy, whispering, or suppressed; cough frequent, sibilative, and harsh; the veins of the neck distended; the throat and laryngeal region tender or swollen externally, and tender to the touch. In this state, sunken eyes, pallid countenance, dilatations of the nostrils, threatened suffocation, restlessness, anxiety, and distress are rapidly followed by a leaden or livid countenance; by convulsions, especially in children, or by coma and death. In many of these cases, as well as in the more asthenic complications, the morbid action invades the trachea to a greater or less extent, but generally in a much slighter degree.

70. C. Chronic Laryngitis.—Pethis La-
ryngis.—Under this head have been comprised a number of chronic affections and alterations of the larynx, which are often associated with changes in either the epiglottis or the trachea, or even in both. These affections are frequently complicated still further with other maladies, especially with those of the lungs, and with chronic constitutional diseases. They may be, 1st. Primary, simple, or the chief affec-
tion; or, 2d. Consecutive and symptomat-
ic. They are commonly inflammatory at their com-
 mencement; although the character of the inflam-
mation may be either catarrhal, or acute, or asthenic, or specific.

71. a. Primary and simple Chronic Laryngitis.—A comparatively slight form of inflammation, or, rather, a state of catarrhal irritation, may af-
fect the mucous membrane of the larynx for several weeks, or even for many months, and produce merely hoarseness, a frequent husky cough, with sore mucous expectoration, and a sense of soreness at the top of the person’s palate. This affection may be limited to the larynx, or be associated with relaxation of the uvula, or with indications of a similar irritation in the faucae, pharynx, and trachea. It is most com-
 mon in persons exposed to cold and wet, and in the intemperate, and generally follows a neg-
lected catarrh, or repeated catarrhal attacks. This form of chronic inflammatory action may exist for a considerable period without produ-
cing further change than thickening of the mu-
cous membrane; and, if only temporary, it is but occasionally gives rise to farther changes, es-
pecially to ulceration, to softening, to serious or soro-puriform infiltration, and several other les-
sions about to be noticed.

72. The more severe states of chronic laryn-
gitis may commence in the above catarrhal form; they may even follow the acute attacks; but much more frequently they appear with hoarseness, and with a dry, husky cough; and are considered as catarrhal only, until they are followed by disorganization and serious constit-
tutional disturbance. They are thus insidious, not only in their primary and simple forms, but also, as will be noticed hereafter, in their con-
secutive and complicated states. The symptoms which require the closest observation are those connected with the voice, the cough, the respi-
ration, the sensibility of the part, the physical signs referable to the chest, and the expecto-
ratior. The voice is variously altered. At first the defect of the voice is apparent only when speaking loud, or when varying the tone; but it generally becomes more and more crack-
ed, until its healthy tone is quite lost. Hoarse-
ness is then always present, and is, in the more catarrhal and slight cases, loose, mucous, and deep; but in the more severe and prolonged instances it is notoriously stridulous, dry, and squeaking, or whispering. In the worst at-
tacks it is more and more affected until it is altogether lost. The cough is, in the early sta-
ges, short, dry, and hacking; but in the latter stages, and when the glottis is incapable of be-
ing closed, it is loose, continuous, and hawking or peculiar, as noticed by MM. Trouessaret and Belloc. The respiration is usually affected sooner or later in the course of the malady. Difficulty of breathing frequently occurs in the night, and on any physical exercise, and is characterized by spasms of the glottis. In pro-
portion to the mechanical impediment to the passage of air, and to the degree of edema of the glottis attending the disease, are the dysp-
nea, and the hissing and stridulous noises on respiration, increased. After the dyspnea be-
comes permanent, or amounts to orthopnea, death generally takes place in fifteen or twenty
days. The sensibility of the larynx is seldom very acutely affected, although it is always slightly increased. In one half the cases, pain is not but occasionally complained of; still it is felt, with a sense of soreness or tenderness when the la-
rynx is handled or pressed, or rubbed against the spine. The morbid sensibility of it is evinced chiefly by the effect of cold air upon it, and by the readiness with which cough is excited by this or by other causes.

73. The expectation is at first scanty and mucous; but as the disease advances to disor-
ganization, or becomes more intense or acute, it is mucous-puriform, sanguine, or streaked with blood, and is accompanied with copious perspira-
tive and rropy. Purulent expectation sometimes relieves the difficulty of breathing; and when this is observed in connexion with pain and soreness in coughing, and with hoarseness or loss of voice, ulceration may be inferred to have taken place. As the ulceration and disor-
organization proceed, dead or ossified portions of the artenoid and criocoid cartilages, or cal-
carceous substances formed in the larynx, are sometimes expectorated, and more rarely they fall into the bronchi and lungs, causing irritation, and consequent inflammation in the parts where they lodge.

74. Difficulty of swallowing is occasionally felt, particularly when the epiglottis is more or less implicated, or when irritation extends to the pharynx. In these, paroxysms of cough and suffocation are induced by the attempts at deglutition, and by portions of the substances taken passing into the glottis. The physical signs indicating either the exemption of the bronchi and lungs from disease, or the exist-
ence of disease also in these parts, are much obscured by the impediment to the circulation of air through the larynx, and more dependance may generally be placed upon percussion than upon the respiratory murmurs in evincing this exemption. At almost any period of the prog-
ress of chronic laryngitis an acute state of inflammatory action may occur, generally with more or less edema, or sero-mucous infiltration of the sub-mucous tissues, and terminate the life of the patient in a very short period; and this may take place almost at any stage of the disease, either previously or subsequent to ulceration. In simple or idiopathic chronic laryngitis, death is occasioned either by this occurrence, or by the paroxysms of orthopnea, caused by spasm in addition to edema, by disease of the cartilages and other lesions, or by the suffocative paroxysms induced by the passage of mucus into the diseased larynx.

75. b. The complicated and consecutive states of chronic laryngitis are very much more common than the primary and simple. The most frequent of these complications is that with tubercular phthisis. M. Louis has remarked that upward of one fourth of the cases of this malady were complicated with chronic laryngitis, this latter being the consecutive affection. It may also be associated with chronic tracheitis, with ulceration in the trachea and large bronchi, and with chronic inflammation of the pharynx, but the association is rarely thus limited, being generally extended also to the lungs. When chronic laryngitis extends to the trachea, or when chronic tracheitis extends to the larynx, and laryngo-tracheitis is thus present in a chronic form, tenderness and soreness are often felt in the course of the trachea; and, in some instances, I have observed great swelling of the throat along the whole tube; but in all these the lungs were also diseased. This swelling may be followed by the trachea arising from the existence of ulceration in the internal surface of the tube, and from the edema or infiltration of the cellular tissue external to the cartilaginous rings.

76. The epiglottis may be inflamed and ulcerated without the larynx itself being materially affected, although the epiglottitis is often implicated when the larynx is diseased. M. Louis states, that of eighteen cases of inflammation and ulceration of the epiglottis, the larynx and trachea were free from disease in six. Of these latter, pain, more or less severe, was felt by four in the superior part of the thyroid cartilage, or between this cartilage and the os hyoideus. The pain was compared to that of a sore, to a pricking sensation, or to a heat of the part. In some cases it had lasted a month or two, but in others it had occurred but a few days before death. In these cases, although the pharynx was healthy, deglutition was difficult, fluids sometimes being thrown upward. In other cases, however, some twelve patients had ulcerations at once in the epiglottis, larynx, and trachea, complained of dysphagia, pain, and occasionally regurgitation of fluids by the nose.

77. It has been shown that simple chronic laryngitis is generally attended by great mechanical obstruction and stridulous breathing; but when the laryngeal affection is consequent upon, or complicated with pulmonary disease, the obstruction in the larynx is commonly much less, and stridulous breathing is hardly remarked. This is owing to the circumstance of primary chronic laryngitis giving rise to more edema, or infiltration of the sub-mucous tissues, than laryngitis consequent upon pulmonary tubercles. In this latter the inflammatory irritation and the consequent ulceration is more superficial and less obstructive to respiration than the former. In both acute and chronic laryngitis, the vesicular murmur becomes feeble in proportion to the obstruction, as shown first by Dr. Graves and Dr. Stokes; and in severe cases it can hardly be perceived, the feebleness or absence of this murmur being equal in all parts of the chest. In order to ascertain the presence of lesions of the lungs in cases of chronic laryngitis, more reliance may be placed on percussion than on the stethoscope. Where the mechanical obstruction is but slight, as Dr. Stokes remarks, this instrument may be used with exactness; but even in cases where the lung is fully and freely inflated, it will occasionally be next to impossible to determine whether the symptoms proceed from laryngeal disease alone, or from its complication with an affection of the lung.

78. The principal fact to be kept in recollection in cases of chronic laryngitis is the very frequent association of pulmonary disease with it, even when the larynx has been the part seemingly first attacked. There is no doubt that chronic laryngitis is in some cases first developed, and that the lungs become secondarily affected, particularly where a predisposition to pulmonary disease exists; and in these especially the susceptibility of the larynx to causes of irritation is much increased; but both maladies may commence simultaneously, and even proceed pari passu, that of the larynx only being manifest, owing to the nature of its organization; or that of the lungs may have arisen and seem to be consecutive, even while it is consequent with the laryngeal, or even primary. The obscuration of the physical signs of pulmonary diseases by laryngeal affections is so great that the former are generally masked by the latter from those who trust chiefly to these signs, to the neglect of those physiological and rational phenomena which generally accompany even the early stages of pulmonary consumption, and in which the closely observing physiologist or clinician confides more than in the phenomena furnished by the stethoscope. It is only in the far-advanced stages of pulmonary tubercles that the physical signs are manifest, when they are complicated with chronic laryngitis, as shown hereafter (§ 86). It may, however, be concluded, that where there are laryngeal cough, mucopurulent or purulent expectoration, hoarseness or aphonia, semi-stridulous respiration, cyanosis, and hectic fever, pulmonary tubercles exist in advanced stages, whether they are indicated by the physical signs or not; and the inference is strengthened by the occurrence of night perspirations, irritability of the bowels, inervation of the finger nails, and various other symptoms.

79. c. Syphilitic Chronic Laryngitis.—Chronic laryngitis sometimes occurs in the course of secondary syphilis, and it then assumes a specific form, soon passes into ulceration, the ulceration apparently extending from the tonsils and pharynx by continuity of surface to the laryngeal mucous membrane. Hence syphilitic chronic laryngitis is almost always associated with syphilitic inflammation of the tonsils, fauces, and pharynx. Mr. Carmichael considers venereal ulceration of the larynx as the conse-
quence of the phagedenic venereal disease; and he believes that the ulceration always propagates itself at its edges by continuity of surface from the faucæ to the pharynx, and thence to the larynx.

80. ii. Appearance after Death. — A. In the acute forms of laryngitis, the lesions observed on dissection vary with the character and complications of the disease. — a. In the sthenic and simple forms, the mucous and sub-mucous tissues of the larynx are not only red and injected, but also swollen or thickened; and these appearances may be confined chiefly to the larynx, or extended to the upper part of the trachea. The epiglottis is very red, swollen, or thickened, or swollen and erect. The folds of the glottis, and the cellular tissue extending from the epiglottis to the glottis, are red and swollen from infiltration of serous lymph, or even of pure lymph, patches of which are sometimes found on the mucous surface of the larynx and the inferior surface of the epiglottis. In cases which have not proved very rapidly fatal, a sero-puriform fluid, or even pus, escapes when these parts are divided. Ulceration is more rarely met with in the sthenic laryngitis, or when the disease has been consequent upon inflammation of the throat, with albuminous exudations — or upon angina membranacea — a more or less complete and consistent coating of albuminous lymph is found in the pharynx, the larynx, and, to a greater or less extent, along the trachea; and often, in some degree, also in the large bronchi. The exudation, however, is either scanty, or consists of semi-consistently thin matter in the lower part of the larynx, and in the bronchi.

Occasionally, the false membrane formed in the larynx seems to have been partially detached, and is loose and ragged, or is altogether removed. The mucous membrane and sub-mucous tissues are red and injected, and frequently, also, more or less swollen.

81. b. The asthenic form of laryngitis is attended by a serous infiltration of the sub-mucous cellular tissues, causing great oedema and swelling of the parts. In many cases, the mucous membrane itself being but slightly injected, and in some cases, the folds of the glottis are so infiltrated with serous or sero-puriform fluid as nearly to close its aperture. In many of these, the epiglottis is but slightly altered; but in others, the part close below, or at the root of the epiglottis, and at the anterior and upper part of the larynx, are most infiltrated, the former being, in some instances, separated from the latter by the effusion in this situation. In the complicated states of asthenic laryngitis, particularly in the associations with scarlet fever, measles, small-pox, erysipelas, or with diffusive inflammation of the cellular tissue in the vicinity, the sub-mucous tissues of the larynx and epiglottis are often infiltrated with a dirty, sero-puriform matter, or with a foul serum and lymph, which fills the ventricles, and surrounds the vocal ligaments, and sometimes extends to the cellular tissue at the root of the tongue and external to the larynx, and even to the adjoining parts. In these more malignant cases, all the tissues are more or less softened and discoloured; and the alterations frequently extend to the pharynx and faucæ on the one hand, and to the trachea on the other.

82. ii. In chronic laryngitis, the structural lesions are numerous: 1. The mucous membrane is red in patches, and exhibits a granular appearance, even when it is not ulcerated, owing to the formation of its follicles: it is redness, apparently, thickened; but this change is seated chiefly in the sub-mucous cellular tissue, and causes enlargement and imperfect mobility of the parts, with partial obliteration or linear contraction of the ventricles of the larynx. 2. Severe, piritiform, or tuberculous infiltrations of the cellular tissue, and of the internal laryngeal muscles, either with or without softening and atrophy of these muscles and of the ligaments, are often observed, or thickened, thickening, or ulcerated, and the generation of the muscles which move the cartilages of the larynx, and contractions of the ligaments, are frequently met with. These lesions account for the loss of voice in this disease.

4. Purlent collections, or small abscesses in the sub-mucous cellular tissue, particularly in the ventricles and around the cricoïd cartilage, are seen in a few cases. 5. Ulcerations of the mucous and sub-mucous cellular tissues occur in various forms and situations, and take different stances: thus in chronic laryngitis. The ulcers sometimes are small and round, and penetrate only the mucous membrane; occasionally they are large, irregular, and superficial, with purulent secretion on their surfaces. In some instances they are still more extensive, and, in the syphilitic laryngitis, accompanied with watery excessences. Ulcers are not infrequently found in the ventricles, particularly in cases of phthisis, and are extremely ulcerated, or deep and irregular. The arytenoid, and even the cartilages of the other cartilages, are occasionally destroyed by ulceration, but chiefly in young subjects. In most instances, and in older persons, ossification takes place in the cartilages before the ulceration reaches them. Ulcers are most commonly seen between the vocal chords and the

[Note: The text is cut off after this point, and the last line is incomplete.]
epiglottis, but they are often found in other parts of the larynx, and in the laryngeal surface and edges of the epiglottis, and more rarely at the lower part of the larynx and commencement of the trachea. 6. In some cases, ulcerations, varying in size, form, and depth, are found in the trachea, especially its upper part; and in one instance I found a fistulous opening into the esophagus. The ulcers are chiefly in the musculo-membranous portion, especially when the affection of the larynx and trachea is complicated with ulceration of the pharynx. 7. Ossification of the cartilages is generally observed in the more prolonged cases. The osseous matter is irregularly deposited, generally on the surface of the cartilages. The cricoid and thyroid cartilages become naturally ossified in advanced life; but MM. Trouseau and Belloc have shown that chronic laryngitis of two years’ duration produces the same change in young persons, irritation accelerating those changes to which the tissues are naturally liable at the course of time. Instances of acro-
crosis of the arytenoid, cricoid, and even of the thyroid cartilages, have been recorded by Law-
cence, Porter, Cruveilhier, Otto, Ryland, Andral, and others. MM. Trouseau and Belloc found this lesion in more than one half of the cases of laryngeal phthisis which they ex-
amined. They describe the cartilages to be deformed of their perichondrium, and of a dull, dirty hue. The sequestrum of dead cartilage is not readily thrown off, and the cellular tissue surrounding it gives the aspect of an infected purulent pus. These purulent collections often open and discharge their contents, sometimes with dead portions of the cartilages, or with ossifit deposits, or with various portions of the ossified cartilages. The opening and dis-
charge of these matters usually take place in the larynx, but in rare instances they have occurred into the esophagus, or outwardly through the integuments of the neck in still rarer cases. These mortified portions of the cartilages, as well as curvus portions of the ossified cartil-
ages, and phosphiatic concretions in the diseased larynx, are sometimes discharged without any preceding or attendant abscess, and merely as a consequence of ulceration. When their es-
cape from the larynx is impeded or attended by much spasm, or when they cause much irrit-
ation on being detached, they act as foreign bodies, and occasionally produce suffocation. They may even fall into the trachea, and pro-
duce effects such as are mentioned when treating of foreign bodies in the larynx and trachea.

9. The epiglottis is often enlarged, thickened, or swollen; frequently, also, it is ulcerated; chiefly, however, in the inferior surface, and at the edges, in connexion with ulceration of the larynx and disease of the lungs. In the syph-
ilitic form of the disease, the ulceration ex-
tends from the lingual to the laryngeal surface, and sometimes destroys the whole of the epig-
Iottis. In less common cases, it is contracted and shrivelled, and more rarely expanded and thickened. 10. Besides the above, calibrau ve-
gutations, warty excrescences, tubercles, and, more rarely, cancer and hydatids of the larynx have been remarked; and some of these lesions have been seen extending to the epiglottis. 11. The trachea has been observed to contain morbid secretions proceeding from ulceration of its internal surface, or from disease of the bronchi or lungs. It is sometimes remarkably thickened from deposition of lymph in the sub-
mucous cellular tissue, and in a few instances a similar deposition is observed in the cellular tissue external to the cartilaginous rings. Red-
ess and injection of the internal surface of the trachea, and ulceration as above mentioned, are commonly associated with tubercular ex-
cavations in the lungs, and are most frequently observed in its posterior or membranous part. In some cases, these changes of ulceration par-
ticularly, are confined to, or most remarkable on one side of the trachea, which invariably corresponds to the diseased lung; or, if both lungs be diseased, to that most affected. 12. In a remarkable instance which occurred to my friend Mr. Worthington, of Lowestoft, sever-
al of the rings of the trachea were absorbed, and, in consequence of the fibrous structure be-
ing deprived of its antagonizing power at that part, the canal was constricted so remarkably as hardly to admit a quid, and as to suffocate the patient. 13. Tumours of various kinds, ab-
scesses, aneurisms, &c., have been found pressing upon the trachea, and even on the larynx, and causing not only permanent obstruction to respiration and spasm of the glottis, but also morbid secretions from the internal surface of these passages, and partial destruction or per-
foration of their parietes.

83. The lesions just described will, in the vari-
ous stages and grades of their development, sufficiently explain the phenomena of acute and chonic laryngitis. When Infiltration of the sub-mucous cellular tissue obstructs the pass-
age of air into the lungs, or when the exuda-
tion of albuminous lymph upon the surface of the larynx produces the same effect, respira-
tion, voice, and speech are more or less im-
peded, and the various morbid phenomena con-
cerned with these functions are developed. When a thickened granular, or superficially ul-
erated state of the mucous membrane of the larynx is present, the muscles and ligaments be-
ing impaired, and the mobility of the parts of the vocal apparatus is not materially affected by infiltration of fluids or other lesions, respira-
tion is not impeded, but hoarseness, and alter-
ation of the tone of voice, are present. When the muscles and ligaments are diseased, and when the subordinate parts of the apparatus are incapable of the requisite motions, aphonia is more or less complete.

84. iii. Diagnosis.—A. Of the Acute.—The stridulous and difficult breathing; the prolonged inspiration, the larynx being always drawn downward most forcibly during the act, as first pointed out by me in the article Croce, and the reference made by the patient to the top of the windpipe as the source of his distress, are sufficiently distinctive of the nature of the disease.—Abscesses in the vicinity of the larynx may be mistaken for acute laryngitis; but ex-
amination of the upper part of the throat, and the partial or general swelling and tenderness observed externally, the confined motion of the larynx, particularly from side to side, and the difficulty of moving the jaw, will indicate the nature of the affection. Spasm of the glottis may be mistaken for laryngitis; but it rarely affects adults, and only hysterical persons. In these, however, a slight form of laryngitis, as
that sometimes consequent upon cold and common sore throat, is often attended by severe accesses of spasm, and may be erroneously viewed as hysterical spasm of the glottis merely. I have met with several instances of this association of inflammatory and nervous affections of the larynx, and the importance of recognising their exact nature has been made apparent in all of them. The previous catarrh, or sore throat, the existence of fever, the symptoms referrible to the larynx, especially the stridulous breathing, the hoarseness or aphonia, and the mere exacerbation of the inflammation or feelings by the nervous or hysterical state of the patient, will indicate the association here contended for, and which consists of a slight form of acute laryngitis, presenting violent exacerbations, owing to the nervous temperament of the patient. 85. It has been remarked above (§ 59), that laryngitis is sometimes complicated with tracheitis, the complication taking place in two, or perhaps three ways: 1st. The inflammation may advance upward from the trachea to the larynx. 2d. It may extend from the pharynx to the larynx and trachea. 3d. It may attack both the larynx and the trachea at nearly the same time. In cases of primary or sporadic group, the inflammation appears in either the first or the third of these modes, and is generally at the commencement, or at an early period of its course, a laryngo-tracheitis, often extending, at an advanced stage, to the large bronchi, as shown in the article Croup. On the other hand, that complication of laryngitis which is concurrent of, or complicated with pharyngitis, and which has been called "croup in the adult," "secondary croup," "epidemic croup," &c., commences and extends always in the second of these modes. Between these two kinds of croup, as they have been denominated by several writers, or, rather, between these forms of complicated acute laryngitis, as I have termed them, the distinctions are of great practical importance. Yet they have not been made with sufficient precision. Dr. Stokes has pointed out many of the most important of them, but as some of them have not been considered by him with reference to the characteristics of certain epidemics, I shall modify a few of the distinctions he has adduced.

Distinctions between the chief Forms of Complicated Laryngitis.

Tracheo-laryngitis, or Primary Group.
1. The windpipe first attacked.
2. The local disease the chief cause of the attendant fever. The fever symptomatic.
3. The fever inflammatory.
5. The disease sporadic, and in certain situations epidemic, but never infectious.
6. The exudation of lymph spreading from the trachea to the glottis, or from below upward.
7. The pharynx healthy.
8. Dysphagia either absent or very slight.
9. Catarhal symptoms often necessary to the laryngeal.
10. Complications with bronchial or pulmonary inflammation, frequent.
11. Absence of any characteristic odour of the breath.

Pharyngo-laryngitis, or Secondary Group.
1. The laryngeal affection concurrent of disease of the trachea and fauces.
2. The local disease occurring in the course generally of a constitutional, and most commonly of a febrile malady.
3. The fever sub-inflammatory, adynamic, or languid.
4. Both adults and children attacked.
5. The malady frequently epidemic, and generally infectious.
6. The inflammation, and the exudation attending it, spreading from the throat, or from above downward.
7. The pharynx diseased.
8. Dysphagia common and severe.
9. Laryngeal symptoms occurring without pre-existence of catarrh.
10. Complications with these diseases rare.
11. The breath often characteristically fetid.
12. Antiphlogistic treatment very rarely requisite. Restorative, tonic, stimulating, and other remedies necessary.

86. B. Diagnosis of Chronic Laryngitis.—A peculiar laryngeal cough, a permanent change in the voice, a constant and slight cough, and pain or tenderness in the larynx, generally characterize chronic laryngitis. But difficulty of breathing and pain may be wanting in the early stages of the disease, or may occur only occasionally in the advanced periods. When the laryngeal swelling or constriction is considerable, the difficulty of respiring, and the peculiar sound attending it, are sufficiently indicative of the disease; and, when these are wanting, the stethoscope will detect, as Dr. Stokes has shown, a harshness in the sound of the air passing through the larynx, suggesting the idea of a roughness of surface. When the laryngeal constriction and the laryngeal respiration are slight, or altogether absent, disease of the larynx may yet be inferred as the cause of the cough and other symptoms by the negative indications of the thoracic organs, the sounds of percussion and of respiration being good throughout the chest. In abscess and mortification of the cartilages of the larynx there are laryngeal cough, fetid purulent expectoration, and even hectic, and there may be no disease in the chest; but these cases differ from ordinary phthisis larygea, particularly in the prominence and rapidity of the purely laryngeal symptoms. The difficulty of determining the complication of the disease with pulmonary tubercles in their earlier stages, or true phthisis larygea, should lead to a careful investigation of the history of the case, with the view of ascertaining whether the laryngeal affection was pre-existing, and whether it supervened in the course of the lungs. If it be found that the first symptoms were sore throat, relaxed uvula, difficulty of swallowing, and were followed by those of a laryngeal character, or that a syphilitic taint had existed, there is a great probability that the first morbid action was manifested in the larynx, and that the lungs were unaffected. But if, on the other hand, as Dr. Stokes observes, it is ascertained, that previously to any hoarseness, stridor, or dysphagia, there has been cough without the laryngeal character, particularly if it was at first dry; that the breath has been short; that there has been pain in the chest about the collar-bones or shoulders; that hemoptysis has occurred; that hectic has been observed, although the expectoration continued mucous; and that the patient has emaciated, it is almost certain that the case is in reality one of pulmonary tubercles, in the course of which laryngeal disease has occurred. If, moreover, the patient is of a scrofulous disposition, or has already lost brothers, sisters, or a parent, by tubercular disease, we may be certain that this is the nature of the case, although we can detect no physical sign of pul-
monary tubercles. In examining such cases, a careful comparison of the sounds emitted on percussion by corresponding opposite portions of the chest, and an investigation by successive investigations or at different periods, will show the state of the disease. If, co-existent with laryngeal cough, mucous-purulent expectoration, semi-stridulous breathing, and hectic, with frequent expectoration and tenacious sputum of opposite corresponding portions of the chest, there is almost sufficient evidence of tubercular disease of the lungs. When there are copious mucous-purulent expectoration of considerable continuance, we may infer the existence of suppurating tuberculous cavities in the lungs. When there are dulness on percussion, or cavernous rhonchus in some part of the chest, particularly under a clavicle or sequestral ridge, with copious expectoration, night sweats, emaciation, &c., an advanced period of the tubercular disease is present.

87. iv. Prognosis.—A. In acute laryngitis the prognosis is considered more unfavourable than in any other inflammatory disease by Drs. Cheyne, Bayle, and others. Mr. Bayle states, that of seventeen cases observed by him during six years, only one recovered; but this is much below the average recoveries. Mr. Ryland refers to twenty-eight cases treated by different practitioners, in each instance the patient recovered; but he believes that this proportion conveys too favourable a view of the usual termination of the disease, a greater number of successful than of fatal cases having been recorded. There can be no doubt of the correctness of the opinion given by Dr. Williams, that the prognosis should be very unfavourable, and the more so, the more progressive the difficulty of breathing. When the face becomes pallid, and subsequently livid, and the patient lachrymose, the danger is extant. The complicated asthmatic and chronic forms of acute laryngitis are especially fatal, particularly when they occur in an advanced stage of exaniematous, or epidemic, or malignant diseases. Hopes of recovery may be entertained in the milder forms or states of the malady, and when the breathing becomes less difficult, and is attended by a freer expectoration. The slight catarrhal form is merely a state of catarrhal irritation of the glottis, to which no risk is attached, unless it issue into the acute or chronic inflammatory states. Mr. Ryland found that, of the eighteen cases which terminated fatally, death occurred within the first twenty-four hours in four, on the second day in one, on the third day in five, on the fifth day in one, on the sixth day in one, and on the eighth day in two instances.

88. B. The prognosis of chronic laryngitis entirely depends upon the states in which it is presented for its observation. In its simple and mild forms, a favourable yet cautious opinion may be given; for, although they will generally yield to judicious treatment, exacerbations, edema, or even ulceration, may take place. If, however, even these forms occur in a faulty or serofulous constitution, a much more unfavourable opinion should be formed of the result. If, however, the disease has continued for any time; if it have not been amenable to treatment; if the expectation has been long continuant; and especially if the history and existing state of the case, and the presence of the

syptoms noticed above (§ 86), indicate its connexion with pulmonary disease, a most unfavourable result may with certainty be anticipated. Fetter of the breath and spitting indicate mortification of the cartilages, and is very unfavourable; but in simple laryngitis there is still a chance of the dead portions being thrown off, but there is no chance of laryngeal disease becoming cured. There is an almost certain certainty of excavations in the larynx. In the suphylotic form of chronic laryngitis, if the general health has not suffered much, and if the lungs be sound, the patient may recover; but the chances will depend entirely upon the degree of local lesion and the general state of the frame.

89. v. Causes.—A. Acute laryngitis may directly follow exposure to cold, wet, and currents of air, continued or very great exertion of the voice, and accidental attempts to swallow acid, caustic, or scalding fluids. Dr. Porter observes, that when a person attempts to drink any of these by mistake, a convulsive action of the pharynx and upper portion of the esophagus takes place, and throws the offending fluid out through the mouth and nostrils, under the epiglottis, thus irritating and inflaming this part and the rima glottidis. Drinking boiling water by mistake children who have been accustomed to drink from the mouth of a hot teapot, are the usual instances of acute laryngitis. Hill; the inhalation of very hot air, or of flame, as in some cases of burning, as shown by Mr. Ryland; and the inhalation of very acid vapours, as the strong fumes of ammonia, or of iodine, or the chlorine gases, &c., are also exciting causes of the disease. I attended a case many years ago with a practitioner, which

* (In 193 cases of autopsic examinations of phthilous subjects by M. Louis, he found the larynx ulcerated 63 times, or in somewhat less than one third of the cases; the glottis 35 times in 135 cases; the trachea 76 times in 100 cases; the bronchi 22 times in 49 cases examined. The same pathologist, in the same subjects, that in 213 cases he observed ulcerations in other parts of the body, more especially in the mouth and orifices, and in the respiratory passages. Phthisis, 1845, he repeats, that among upward of 500 nontuberculous subjects, carried off by chronic diseases, and examined by himself, not one presented ulcerations in the larynx or trachea. (Sydenham ed. p. 46.) There are five cases, however, quoted by MM. Trouseau and Bellon, in which death is supposed to have arisen from an affection of the larynx, attended with ulceration of its investing mucous membrane, while the lungs were free from tubercles, M. Vallee, however, as M. Louis, questions the authenticity of these cases. It is, moreover, worthy of remark, that MM. Trouseau and Bellon do not appear to have themselves observed a single case of laryngeal ulceration without pulmonary tubercles. It has been fully established, by the researches of modern pathologists, that the point of junction of the chordae vocales, where they are sometimes superficial, is the most common seat of these ulcerations; next in order of frequency come the chordae vocales themselves, especially at their posterior aspect, the base of the epiglottis, the epiglottis itself, the arytenoids, and lastly, the interior of the ventricles. This accounts for the extreme frequency of aphonia in cases of chronic laryngitis.)
was caused by swallowing a large quantity of mustard, in order to produce an enetic effect after poisoning from opium. The man recovered. In the consequence; 2. Secondary forms above described (§ 63), the disease occurs in the course of Cysanche tonisllaris, of C. pharyngea, and of 3. parotidea; and in a decidedly asthenic form, in the course of scarlet fever, measles, smallpox, erysipelas, and typhoid fevers. It may be consequent even upon glositis, and diffuse inflammation of the cellular tissue of the neck or throat. Mr. Lawrence and Dr. Williams have met with it in the course of an infection of the latter, severe or prolonged courses of mere indigestion, or a laryngitis of the voice. When inflammations of any kind attack the throat, or parts adjoining, their extension to the larynx is favoured by accumulations of morbid secretions and excretions in the abdominal viscera, and by depressed states of the powers of life: a fact of great practical importance, and hitherto insufficiently attended to both in our pathological reasoning and in our therapeutical indications. A laryngitis may arise from the same causes as have been now enumerated; but it sometimes succeeds the acute disease, and much more commonly it follows the frequent recurrence, or neglect, of the slight or catarrhal state of irritation mentioned above (§ 52). Great or prolonged exertions of the voice, particularly by those addicted to the use of spirituous liquors, and the combination of neglected catarrh with intemperance, are the chief causes. Morocculcular courses, the extension of suppitative ulceration from the throat, dust or grosser foreign bodies inhaled or passing into the larynx, and injuries of the throat, also sometimes occasion chronic laryngitis. Persons of a scrofulous diathesis, those liable to cutaneous eruptions, or who have been suffering for a long time the more severe forms of indigestion, particularly cardialgia with acrid eructations, and all disposed to, or already affected by tuberculous disease of the lungs, are especially predisposed to this affection. Its dependence upon pulmonary consumption is most frequent and intimate. It is most common at the middle period of life, or probably somewhat earlier, at least according to my experience; and is nearly equally frequent in both sexes. MM. Trouseau and Bellon think that it affects males oftener than females; Mr. Ryland, that it more frequently attacks the males.

[According to M. Louis, ulcerations of the larynx are twice commoner in females than in males. Thus, of nine cases of ulceration of the epiglottis recently reported (Sydenham ed. of Researches, &c.), eight occurred in males; of 13 cases of deep ulceration of the larynx, two only were furnished by females; and of nine patients affected with similar ulcerations of the trachea, six were males, and in no instance was partial destruction of the rings of the trachea observed in a female.—Loc. cit., p. 43.)

22. vi. Treatment.—A. In the acute sthenic laryngitis, particularly in its primary and uncomplicated form, the treatment should be prompt, early, and decided, in order to arrest the disease before effusion, in any form, or in any situation, takes place. The necessity for having a very early recourse to treatment is shown by the rapid fatalism of some cases (§ 68). The intentions with which remedial means should be prescribed are, 1st. To reduce inflammatory action, and thereby to prevent or decrease the consequences of it usually productive of a fatal issue; 24. If effusion, or infiltration of the laryngeal tissues have taken place so as most dangerously to obstruct respiration, to obviate such obstruction and its consequences; 3d. To promote the removal of such lesions as have taken place.

93. a. The first intention involves a recourse to blood-letting; but a cure of the disease is not to be expected from this means alone, although it should be employed early, and decided upon, and in the manner advised by me in the article Blood (§ 64), so as to make a decided impression on the pulse without producing syncope, and within the first twelve or twenty-four hours from the accession of the disease. After effusion or infiltration has taken place, so as to interfere with the purposes of respiration, blood-letting will be then too late to be of any service. A repetition of the blood-letting, and the quantity of blood thus derived from the amount of the disease, the habit and constitution of the patient, and the effect produced by it. Cupping on the nape of the neck, after the first or second venesection, should not be neglected. By its means a very large or small, but always a definite quantity of blood may be taken, and with a derivative effect. A recourse to leeches is seldom so satisfactory as to cupping, in this disease. After the first blood-letting, a full dose of salome—five or six grains, with three or four of James's powder, and a third of a grain of opium, as advised by Dr. Cheyne—should be given every third, fourth, or fifth hour, until the gums become affected. I have never seen any benefit derived from the application of blisters, and I am sure that I have seen them injurious. Dr. Cheyne properly objects to them. A recourse to strong liquor ammonia, as suggested by Dr. J. Johnson, may be preferable; still it acts only as a vesicant, and, when applied over the throat, it is so near the seat of inflammatory action as to excite its activity rather than to diminish it by derivations. Romberg, Campbell, and others, advise the eroot oil to be externally applied, but it is more appropriate in the chronic form of laryngitis.]

[To show the extent to which blood-letting has been carried in this disease, we may refer to the case of Dr. J. W. Pring—five or six bloods, as detailed by Dr. J. B. Beck, in the 12th number of the New-York Medical and Physical Journal. Dr. F. had complained for three days of soreness of the fauces and thirst, when he was attacked with pain, difficulty of breathing and swallowing, and a sense of strangulation, for which symptoms 152 ounces of blood were abstracted, as follows: On the 17th of November,
1823, vxi; evening, xxxv; 18th of November, xxvi; evening, xxxv; 19th of November, xxvi; evening, xxvi; 20th of November, xxvi; 22d of November, vxi; total, 153 f. For three or four days after Dr. F. was still in a precarious condition, and required a repetition of the blood-letting. Dr. Cheyne, in his valuable essay on laryngitis in the Cyclopaedia of Pract. Med., p. 110, has given cases to prove the inefficacy of blood-letting in this disease, and attempts to point out the circumstances which should lead to the employment of this remedy; the principal of which is that v. s. will not recur so readily to early, while the condition is good, and the blood properly arterialized in the lungs; and that, after the skin becomes dusky or livid, it is hazardous to resort to it.

94. For more than twenty years I have had recourse, immediately after blood-letting and the first dose of medicine, to the application of flannel, wrung out of hot water and freely sprinkled with spirits of turpentine, or with a combination of this substance with camphor, or with camphor and eucalypt oil, around the whole neck and throat. This application, when duly managed and modified as respects its continuance and the combination of substances used, is the most efficient remedy in all the forms, simple and complicated, of acute laryngitis; and, as it does not vesiculate, or at least very slightly, it is not in the way of the operation of tracheotomy, which will rarely be necessary when it has been early resorted to.

It has a remarkable effect in restraining inflammatory action in parts near those to which it is applied, and, by preventing the spreading of the effusions and infiltrations consequent on inflammation. The success of this application will entirely depend upon the decision with which it is employed. Dr. Cheyne objects to the use of tartar emetic in any way, lest it should excite vomiting, and, by throwing matters against the evert and exposed epiglottis, cause violent convulsive irritation; and Dr. Williams, for a similar reason, argues against the propriety of applying keeches on the tonsils, as proposed by Dr. C.

If the irritation of the bites, and of the blood proceeding from them, can hardly be supposed to be otherwise than injurious. The above measures may, although early resorted to, only delay the unfavourable progress of the disease, may fail in arresting the inflammation, and in preventing its consequences from dangerously or even fatally obstructing respiration. It is now that the second intention must be adopted; but the third should not be neglected from the commencement for the removal of the lesions, or consequences of inflammation already produced, should be attempted forthwith; and the means best calculated to attain that end are, also, those best adapted to fulfil the first indication, more especially the free use of mercury, and the application of the embrocation already mentioned around the neck.

95. b. The second intention must be resorted to as soon as the lesions consequent upon inflammation begin to obstruct respiration, so far as to prevent the necessary changes from taking place in the blood. If the swelling is not great, and pallor, with lividity of the lips, appears, blood-letting and the other means advised above will be of no avail, and tracheotomy is then indispensible. It may have been even too long delayed; for it must be performed before the blood is altered so far by the obstruction to respiration as to change its sensible qualities. Dr. Cheyne justly remarks, that if the symptoms be such as to contra-indicate blood-letting, and yet asphyxia is imminent, the operation should be instantly performed. As long as the complexion is good, and asphyxia not threatened, it may be delayed. Mr. Lawrence says that it should be resorted to as soon as the symptoms enable us to ascertain the nature of the disease; and, although this may be too precipitate a recommendation in some particular cases and circumstances not without some risk, it is preferable to delaying it too long. The effect of treatment, particularly of blood-letting and of the application around the throat, which I have advised, should be first observed; and if these do not give relief in a period varying from twelve to twenty-four hours, according to the urgency and peculiarities of the case, tracheotomy should be resorted to. But no precise time ought to be assigned before the operation is performed; for the local symptoms, and the states of the vital functions caused by the laryngeal obstructions, should alone guide both physician and surgeon in respect of it. There are pathological circumstances connected with too prolonged a delay of the operation which should not be overlooked, as they are the most powerful arguments against such delay. These are the increased disposition to bronchial and pulmonary congestion with obstruction to the respiratory function, and with interrupted function of the lungs, circulation, and the fact that these changes, when they reach a certain pitch, often lead to fatal results, although the obstruction to respiration may have been removed previously to the occurrence of any immediate risk of asphyxia. Still the operation may be tried even when asphyxia approaches, as a few instances have occurred of its success at the last extremity; but the engorged state of the lungs and congestion of the bronchial surfaces, which increase with the progress of the local obstruction, generally pass into effusions and infiltrations consequent on inflammatory action, when the respiratory actions are restored by the operation after having been too long delayed. An early recourse to the operation is particularly indicated when laryngitis has been caused by swallowing acrid, or corrosive, or boiling fluids, as the means of cure recommended do not act so rapidly in these cases as in many others, and an early opening into the trachea facilitates the treatment of the injured parts.

96. After the operation, care should be taken not to insert too long a tube into the windpipe, as such a one will excite serious irritation; and equal care should be observed that expectoration be not prevented by constantly expiring through this tube, otherwise the accumulation of mucus or muco-puriform matter in the trachea and bronchi will prevent all benefit from accruing from this measure. The tube, therefore, should frequently be closed after a full inspiration, and the patient told to expire forcibly through the glottis, in order to expel the accumulating matter. Until the obstruction in the glottis is removed by the mercurial treatment, which should be persisted
in until its effects become manifest, active counter-irritants should be applied on the chest or between the shoulders, and the most efficient of these are terebinthine embrocations and blisters. These, and a recourse to cupping, or to dry-cupping on the chest, according to circumstances, will diminish or remove the congestion of the bronchial surfaces and lungs, and the disposition to inflammatory action in these parts, which often destroy patients after tracheotomy had apparently for a time saved them, and which generally arise in the manner just stated, and less frequently are propagated along the respiratory passages as the disease proceeds. In the administration of these, the remedies above alluded to,

[The mustard cataplasm is a very useful application in these cases, as is also a warm poultice in which the leaves or an infusion of tobacco have been mixed, as recommended by Dr. Chapman (Dis. of the Respiratory Organs, Phila., 1845, p. 122); or a segar may be smoked, if the patient is unaccustomed to it. Active purgation has also been highly recommended, and Dr. Reaum relates two cases in females where imminent suffocation was prevented by the administration of colo.

R. O. Tiglii. gtt. iv.; Extr. Col. Comp., gr. xx. M. Div. in pil. iv.; give one every two hours, till copious evacuations are produced.]

Although we regard copious venesection as indispensable in the treatment of acute laryngitis, we believe that mercury is a still more important remedy, and that without it the former would rarely prove successful. We think very favourably of mercurial injection in these cases, as well as mercurial inhalation, and colo.

should be given internally in doses of one grain every hour, combined with extract of gentian, until evident constitutional effects are produced. In this manner we prevent the necessity of the excessive loss of blood, and recovery is consequently expedited.

Dr. Chapman (loc. cit.) is an advocate for the most energetic bleeding in the early stages of this disease, carrying it even to fainting; remarking that, "less extensively used, it is altogether inadequate to an extreme emergency. The only two measures of the disease I have ever cured, or seen cured, were mainly by this energetic course. Washington's death, humanly may be ascribed to his having been so sparingly bled in the very commencement of the attack. The subsequent and larger bleedings were too late, effusion having taken place. He was a very robust man, of a sanguineous temperament, in whom such an inflammatory attack required the freest depletion." (Loc. cit.) After free blood-letting, Dr. C. recommends copious emesis, by colo.

mert, tart. anthemine, and ipecacuanha, promoting its action by the warm bath. The late Dr. Armstrong related emetics, also, as almost a specific in the treatment of this disease, repeating their use as soon as the slightest signs of stricture in the larynx returned. If the disease does not yield, Dr. C. next advises leeches to the throat, then enemolent poultices, and, finally, a blister, with inhalation of the mildest vapours. The tobacco cataplasm here comes in with frequently beneficial effect. If soon as the time has arrived when the directly depleting measures can be carried no farther, Dr. C. recommends recourse to sweating, by the Dover's powder and the vapour bath, continued for several hours. He also places much dependence on the alternative influence of calomel, in combination with opium and ipecacuanha, and, as a last resort, recommends tracheotomy. "By opening the windpipe in due season," says Dr. C., "respiration would proceed in spite of the obstruction of the glottis, the irritated structures restored to quiescence, or, at least, relieved from the existing violent agitation, so exasperating in its effects, and which, by continuance, must produce pulmonary implication, or effusion into the cellular tissue of the larynx itself. From this peril, the danger is in no respect enhanced. The aperture thus to be opened remain open until the inflammation subsides, and the natural passage re-established by the subsidence of the tumefaction, or the removal of other impediments." (Loc. cit.)

In that form of acute laryngitis attended with an edematous disposition, as we often observe in persons of a lymphatic temperament, the loss of blood is rarely beneficial; here emetics, with strong counter-irritants to the throat, and swabbing the fauces, and even the larynx, with the application of moist solutions of silver, or alum, will be found the most efficacious treatment.

97. B. The complicated forms of sthenic laryngitis require a different treatment from that advised in the simple sthenic form. In that complication which is consequent upon, or coetaneous with tracheitis, and which constitutes a very large proportion of the cases of croup, nothing can be added at this place to what has been fully addeduced in that article, from a tolerably extensive experience. When laryngitis occurs, from the extension of inflammation, with albuminous exudation from the fauces and pharynx —is consequent upon angina membranacea—and when the local and constitutional symptoms indicate a more or less sthenic disease, the treatment should be such as may subdue increased vascular action, and be especially and early directed to the state of the fauces and pharynx, in order to prevent the extension of the morbid action from them to the larynx. The means most useful in this form of disease are fully described in the article Throat, Diseases of.

When the larynx becomes implicated, a vigorous recourse to calomel, and the application of the terebinthine embrocation around the neck and throat, sometimes preceded by cupping on the nape of the neck, are chiefly to be relied upon. Venesection is rarely indicated, and as rarely beneficial in this disease, unless in its most sthenic states, and in pithoric and robust persons, where it should be employed with a careful observation of its effects; but the treatment will depend much upon the character of the epidemic. The topical applications of alum, in the form of a paste or otherwise, or of nitrate of silver, or of mercuric acid, as advised for angina membranacea (see art. Throat), are now generally of no avail; and if the former means are inefficacious, tracheotomy must be resorted to, and should not be too long delayed, although a successful result from it is even less to be expected in this malady than where it is performed in simple laryngitis; for there is a much greater disposition of the morbid action to propagate itself from the larynx downward in the complicated than in the simple dis-
ease, and patients are more likely to be carried off by the consecutive bronchitis.

98. C. In the treatment of acute asthenic laryngitis, blood-letting is inefficacious or injurious, whether the disease appear in its simple form (§ 67), or in any of the complicated states (§ 69) noticed above. The means which are most likely to be of any service in any of these forms of the disease, is the mechanical opening with cam-

phor and opium, in large and frequent doses, and the terebinthate embrocation already prescribed, kept constantly applied around the neck, fauces, and throat. In the intervals be-

tween the doses of calomel, camphor, and opio-

um, stimulants, tonics, and antiseptics are often

required to support the powers of life, and prevent the progressive deterioration of the blood. In the complicated asthenic laryngitis attending croupaeh maligia, or any of the more maligntant forms of generally occurs, the use of the calomel is not often of service, as the laryngeal affection generally terminates life before any constitutional effect can follow its exhibition. If, therefore, it be given at all, it should be

prescribed with camphor, or with camphor and

opium, either in the form of powder or linetis, so that it may act upon the fauces and pharynx, and thence upon the larynx. In these complica-

tions, tracheotomy should be performed at an early period. In the case of the laryngeal dissection, if per-

formed at all; but at any period of these the

chances of success from it are very few; for the constitutional disease, and the frequently-attendant association of congestions or asthena-

ic inflammations of the bronchi or lungs, reduce these chances to almost the lowest calculation. In the primary asthenic laryngitis (§ 67) trache-

tomy is more likely to succeed, when early performed, than in any of the complicated states, inasmuch as the infiltration of the sub-

mucous tissues of generally occur, in the larynx. It should be kept in view that this and the complicated states of the disease, being characterized originally by deficient vital power and a morbid condition of the blood, will rapidly become worse in both these respects; and that, if this operation be not resorted to at a very early period, the consequences of delay pointed out above will the more readily suc-

ceed, and the chances of success from it be re-

markably reduced. If purgatives be resorted to at any period of the asthenic forms of laryn-

gitis—and they will be required in many cases—-they should be combined with warm, tonic, and stomachic substances, and their operation be promoted by stimulating and antispasmodic enemata. Or enemata may, in many instances, be confided in chiefly, in order to evacuate the bowels. Spirits of turpentine with castor oil, sometimes with common salt—or with cam-

phor, asafoetida, &c., according to circumstances—are the most efficacious, and most appropriate to the states of the disease."

"[Dr. Cheyne has stated, that the case of General Washington in 1799, of inflammation of the larynx, is the best well-marked instance of this disease on record. We quote Dr. Craik's report of the same as made at the time.]

"Some time in the night of the Tuesday, the 10th of Dec., 1799, having been rapacious in the preceding week, General Washington was attacked with an inflammatory affection of the upper part of the windpipe, called, in tech-

ical language, laryngeal congestion, accompanied with a violent aggravation, accompanied with some pain in the upper and fore part of the throat, a sense of structure in the same part, a cough, and a difficult rather than a pain-

ful deglutition, which was soon succeeded by fever and a shock, and a disease of the lungs. Mr. Belloc, calling himself Dr. Jackson, presenting himself to the gentleman, in an air of importance, declaiming to himself the disease, and relieving itself to the general, he possessed a pledger in the neighborhood, who took from his arm in the night twelve grains of his own gold dust, and by any means be procured on the family to send for the attending physician till the following morning, who arrived at Mount Vernon at seven o'clock in the morning, discovering the ease to be highly alarming, and foreseeing the fatal tendency of the disease, two consulted physicians were instantly called for, who arrived soon after a, two, three, and the other at four o'clock in the afternoon. In the mean tine were employed two pretty copious bleedings, a blister was applied to the part affected, two moderate doses of calomel were given, and an emesis was induced, which operated on the lower intestines, but all withou-

out any perceptible advantage, the respiration becoming still more difficult and imperfect. On the arrival of the first of the consulting physicians, it was agreed, as there were yet no signs of accumulation in the bronchial vessels of the lungs, that the lungs should be opened and two hundred grains of calomel were given, succeeded by repeated doses of caustic tartar, amounting in all to five or six grains, with no other effect than a copious discharge from the bowels. The powers of life were gradually renewed more particularly by the food of the body; blisters were applied to the extremities, together with a cupatism of beer vinegar to the throat. Speaking, which was painful and breathing, more beginning, now became practicable; respiration became more and more contracted and imperfect, till half past eleven on Saturday night, re-

taining the full possession of his intellect, he expistted without a struggle. He was fully impressed at the begin-

ning of his complaint, as well as through every succeeding stage of it, that it was not mortal, submitting to the several exertions made for his recovery rather as a duty than from any expectation of its efficacy. He con-

sidered the inflammation of the windpipe, upon which he was inflicted, and the disease, and several hours before his death, after repeated efforts to be understood, succeeded in expressing a desire that he might not suffer with further interruption. During the short period of his illness for the wonder-

ful time in the arrangement of such few concerns as required his attention with the utmost serenity, and anticipated his approach to the grave with every expression of the equanimity for which his whole life had been so uniformly conspicuous. The violent aggravation with which this case con-

cluded the inflammation of death, was his special instruc-

tion; the pain in the upper and fore part of the throat, the sense of structure in the same part, and the labour of respi-

ration, should be relieved when the inflammation was made the cause of the trouble, and the part of the throat affected. The difficult deglutition arose from the state of the tonsils, in which, probably, the inflammation commenced. The

inflammation did not descend into the bronchial vessels of the lungs, where, had they been attacked, the difficulty of digestion, or the state of the tonsils, in which, probably, the inflammation commenced. It may be inferred, therefore, as will be apparent from the sequel, that this was a genuine specimen of laryn-

geal affection."

This account is dated Alexandria, Virginia, Dec. 21, 1799, and signed by Dr. James Craik, attending physician, and Dr. Elisha D. Dick, consulting physician.]
100. General **blood-letting** is sometimes required in this form of the disease, and chiefly in plethoric and robust persons at the commencement of the disease, or when the chronic symptoms become aggravated into a more acute state. Local depletion by *cupping*, or by *leeches* applied to the sides of the neck, below the level of the larynx, are, however, more frequently used, particularly when the weakness of the larynx is felt, and they should then be employed with decision. If the disease has been consequent upon suppression of the menstrual or hemorrhoidal discharge, leeches should be applied to the tops of the thighs, or to the anus.

101. External *derivation* or revulsion is more beneficial than vascular depletions when the disease has been of some standing, a recourse to which should only be had in certain circumstances. Various means of derivation have been advised, and each has been in vogue for a time. First the tartar-emetic ointment was employed, especially in this country; and then moxas were recommended, on the Continent particularly. Afterward, friction with cerotin oil were advised, and various liniments and embrocations containing liquid ammonia. Besides these, blisters, the liquor ligni, or the terebinthinate of mercury, &c., were resorted to; and there are few of these which have not given temporary ease in a few cases, or have either been of no avail, or aggravated the malady in others. The general error was, that they have been applied either over or too near the larynx—too close to the seat of irritation to derive from or subdue it; and hence, from their proximity, rather administering to its duration than arresting it. These, if employed at all, should be applied at a distance from the larynx, as on the Miles or nape of the neck, or top of the sternum, as advised by me in the article *Croup* (§ 45). The only application that can be prescribed with advantage on the throat itself is the terebinthinate embrocation mentioned above; and the inhalation of the fumes from it, especially when their escape is moderated by a covering external to the flannel with which it is applied, is generally beneficial. A caustic, mezeroon, or peau-issue, setons, or open blisters, or the terebinthinate of mercury, &c., is produced by means of tartar-emetic ointment, and kept freely suppurating or discharging, in the nape or sides of the neck, or at the top of the sternum, are the most deserving of notice of the various modes of procuring a continued purulent discharge.

102. Most British physicians have recommended a mild *mercurial course*, in order to fulfil the first indication of cure; and in a few principles, it has been successful, although a more severe course, and the consequences connected with it, have in some instances even caused the disease, especially in those exposed to atmospheric vicissitudes and in the intemperate. MM. *Trousseau* and *Belloc* adduce several cases of the success of a general mercurial treatment, even when the disease was not of a syphilitic species, and state that many cases truly desperate were cured by giving mercury to, or a purgation. When the practice is determined upon, calomel may be given, triturated with sugar, in small or moderate doses, and in the form of linctus or electuary, so that it may come in contact with the pharynx and epiglottis; and its use should be persisted in until the mouth becomes slightly affected, or salivation is produced. A diminution of pain, or of constriction of the larynx; an improvement of the voice, and a looser and easier cough, indicate the good effects of this course. If it fail, or cease to be further beneficai, a recourse to the application of morose with the form of *linchis* or *elethery*, or in similar semi-fluid vehicles, is occasionally of service. Those which are demulcent and cooling are commonly to be preferred; and I have generally employed various sirups and mucilages containing small doses of nitre, or of hydrochlorate of ammonia, and of camphor or of benzoin, with narcotics and sedatives, according to the peculiarities of the case; taking care not to offend the stomach, or to disorder any of the several digestive processes. If these means do not afford decided benefit, the liquor potassae may be given, with small doses of a solution of the iodide of potassium, and with camphor and narcotics, either in the form of mixture or linctus. The inhalation of vapour or steam imbued with the fumes of camphor, turpentine, narcotics, balsams, &c., as already advised by me for the chronic forms of *Bronscuris* (§ 98), is sometimes of service, and is, as just remarked, one of the sources of the benefit afforded by the terebinthinate embrocations recommended to be applied to the neck and throat in this disease. *Narcotics* are generally useful in allaying irritation and cough. The extracts of *belladonna* and *stramonium* may be added to the warm-fluids used for the purposes of the inhalation of their steam, or they may be applied by friction to the anterior part of the neck. The salts of morphia may also be employed externally on the back or nape of the neck.

103. The above treatment will generally remove the primary form of chronic laryngitis, if it have been adopted before extensive ulceration or destruction of the cartilages has taken place; and will sometimes be successful even in the specific or syphilitic form of the disease; but, when these lesions exist, slight hopes can be entertained from any mode of cure. MM. *Trousseau* and *Belloc* have introduced the *topical plan of treatment*. They observe that whenever inflammation becomes chronic, and affects only a circumscribed part of the economy, it commonly resists the most extensive and active general treatment; and that, on the contrary, it is almost always modified by topical treatment, whatever be the means. This, to a certain extent, explains the difficulty with which internal local diseases are cured, compared with those which are external. They consider it, therefore, obvious, that if by any means local applications could be made to the mucous membrane of the *larynx* without interrupting respiration, many cases might be cured which are considered incurable; and this they believe that they have done.

104. The inspiration of dry or moist vapors has been recommended in *phthisis laryngea* and in other affections of the respiratory apparatus; but those which have been employed, and often too empirically prescribed, have been either too acrid, stimulating, or concentrated; and not being confined in their operation to the l-
LARYNX AND TRACHEA—Inflammations of—TREATMENT.

801

rynx, but acting upon the respiratory surfaces generally, have proved more injurious than beneficial. The action of these cannot be limited; and hence those only which I have advised above, and in the article Broncho (chronic inflammation of), and which are balsamic, aromatic, emollient, and narcotic, and cannot injure the lungs, should only be employed. MM. Trouseau and Béclot consider themselves to those which I had advised in the above article long before the publication of their work; but they recommend still more active and more strictly topical means, consisting of both liquid and dry applications.

105. The liquid applications used by these writers consist of solutions of nitrate of silver, corrosive sublimate, sulphate of copper, and per-nitrate of mercury. They prefer, however, the solution of nitrate of silver, from the application of which no inconvenience has arisen. The solution of corrosive sublimate, of the strength of from one to eight grains to the ounce of distilled water, they found to be very serviceable in some cases of syphilitic ulceration. The solution of nitrate of silver, in the large proportion of from one to two parts in four parts of distilled water, they apply to and behind the epiglottis, by a small roll of paper bent at its moistened end, or with a small piece of sponge, fixed to a rod of whalebone, bent, at an angle from the sponge, at an angle of 80 degrees. The patient's mouth being opened wide, and the tongue pressed down, the sponge is passed to the top of the pharynx; and as soon as it reaches it, a movement of deglutition is produced, which carries the larynx upward, at which movement the sponge is brought forward and squeezed under the epiglottis, and the solution freely enters the larynx. Convulsive cough, and sometimes vomiting, ensue; but the application causes no pain.

MM. Trouseau and Béclot have another means of effecting their object. To a small syringe, like Anel's, a canula, at least five inches in length, and curved at its free extremity, is attached. The syringe is filled three fourths with air, and one fourth with a solution of the nitrate of silver. The canula is then introduced into the posterior fauces, opposite the larynx, and the piston being rapidly advanced, the liquid, mixed with the air in the syringe, falls in a fine shower on the superior part of the larynx and epiglottis. The patient is immediately seized with a violent fit of cough, which, however, need give no alarm. He is then immediately directed to gargle his throat with water aerated with muriatic acid or salt water, which decomposes that portion of the solution which is not combined with the tissues.

The practice of cauterizing the larynx, as recommended by Trouseau and Béclot, has received the sanction of Sir Charles Bell, and Cusack, of Dublin, by both of whom it has been practiced. It is also recommended by Williams, Stokes, Vance, and others, as a mode of treatment possessing peculiar efficacy. It was early introduced into this city by Dr. H. Green, who has employed it, together with constitutional remedies, with considerable success in many cases of chronic laryngitis, even when complicated with tubercular disease of the lungs; and Dr. Taylor, as already remarked, has reported several cases of aphonia and laryngitis cured or materially benefited by its use.

In many cases, there is good reason to believe that the bent probang and sponge is carried directly into the larynx, though in other instances the operator is probably deceived. It is now abundantly established that a foreign body may be pushed into the larynx without producing much, if any, coughing, or sense of strangulation. Dr. Taylor recommends that, instead of carrying the probang to the back part of the larynx, and then waiting for the larynx to be elevated, as recommended by Trouseau and Béclot, the instrument should be carried sideways over the base of the tongue, the sponge looking to the right side; and, as the tongue is requested to be protruded, the epiglottis becomes erect, and, as the larynx is elevating, the sponge, if not too large, is brought to a level with the superior opening, and passed directly into the larynx, and the fluid expressed by the quick contraction of the posterior muscle of the larynx, which contraction is distinctly perceptible to the fingers of the operator, and with a slight motion, or the request to protrude the tongue, the probang is removed with case. The operation is made especially easy when the epiglottis can be distinctly seen and felt, the root of the tongue not deep nor broad, or thick and elevated, nor the tongue loose; while in others the tongue is so very long as to preclude the epiglottis from being distinctly felt; and, again, so deep is the larynx in other cases that it cannot be reached with the finger. Nor must we forget the difference in the size of the opening of the larynx, that we may judge what kind of instrument we are to use in each case. The strength of the solution may vary from 20 to 40, and even 60 grains, to the ounce of water.

Dr. Green has reported (Ibid., vol. iv.) several cases of chronic laryngitis, which, he states, were "permanently cured" by this local treatment, although it is worthy of note that he used constitutional remedies, at the same time, in every case, as iron, the balsams, cubeba, &c.

"During the last six months," says he, "upward of 50 cases have come under my care, and, in the treatment of these cases, in more than 500 instances have topical remedies been introduced below the epiglottis into the laryngeal cavity. In many instances, where chronic inflations of the throat have existed for years, and have been attended with ulceration, with hoarseness, and in some cases with complete aphonia of many months' standing, the parts have been restored to a healthy condition, and perfect vocalization established." With respect to the practicability of entering the larynx in this manner, it is to be borne in mind that the epiglottis, or valve to this opening, except at the moment of deglutition, is adherent by virtue of its own elasticity, retained in a vertical position, and that foreign bodies frequently find their way accidentally into the larynx and trachea. Baron Larrey states (Rel. Chir. de l'Armee d'Orient) that, in attempting to pass the elastic tubes, for the purpose of conveying liquid nourishment to the stomachs of soldiers who, from wounds of the neck, were unable to swallow, "the tube often went into the larynx instead of into the oesophagus," and that, when this happened, "the mistake was not discovered

II. 101
by any particular sensation about the glottis." Ryland, also, in his treatise on "Diseases and Injuries of the Larynx," says that "an elastic sound, introduced into the larynx, does not give rise to any peculiar sensations that will indicate the occurrence with any degree of certainty" (p. 241). We have also known the tube of the stomach-pump accidentally passed into the larynx, without exciting any marked irritation. In the 23d volume of the Medical-Chirurgical Transactions of London, 1840, is a paper by Sir Cesar Hawkins, on the "Diagnosis of Foreign Bodies in the Larynx," in which cases are mentioned of foreign bodies, as pieces of bone, &c., being lodged in the laryngeal cavity, without exciting cough or other symptoms of irritation.

In employing the nitrate of silver for a lotion, it is important to use that which comes in crystals, and not in the cylinder form, as the latter is often found to contain a portion of uncombined nitric acid, which is of an irritating nature. With respect to the propriety of resorting to this local method of treating diseases of the larynx, we should say that where, from general and physical signs, we have reason to believe that the lungs are not seriously diseased, it would be advisable to use local applications to the larynx, after the manner above recommended; but where there is tubercular disease existing, the most that can be expected from the treatment is temporary relief. (See N. Y. Jour. of Med., vol. iv.)

Chronic laryngitis has attracted considerable attention of late years in this country, from its supposed frequent occurrence among clergymen. Dr. Chapman, while he admits that it is often met with among this class, observes that he "knows nothing in their habits or occupations to dispose them more to such attacks than various other classes of people, and especially the members of the professions of law and medicine. When the disease attacks clergymen, Dr. C. supposes that it first invades the fauces, and extends afterward to the windpipe." (Lectures on Diseases of the Thoracic and Abdominal Visera, Philadelphia, 1841, p. 119.) Dr. Clymer, also (Williams "On Dis. of the Respiratory Organs," Philadelphia, 1845, p. 129), remarks, that "the vocation of the clergy has been thought to render them peculiarly liable to this disease, especially in this country, and that has, in consequence, been called the 'clergyman's sore-throat.'" This peculiar susceptibility from the nature of their pursuits may be doubted. The disease, in fact, to which they, in common with others, seem particularly liable, is a chronic pharyngitis, and is popularly known as bronchitis. On inspection of the pharynx, its lining membrane will be found to be injected, and the follicles greatly enlarged, and resembling split peas. We have examined this subject at some length in the N. Y. Literary and Theol. Review for 1838, to which we refer the reader. We believe that chronic laryngitis, in its cases of derangement of the digestive organs, leading to malnutrition, and that the most successful treatment will generally be found that which restores them to a healthy condition. Elongation of the uvula, with congestion of the vessels of the fauces and bronchi, is for the most part dependant on some of the forms of indigestion, and is to be removed by directed remedies to the original disease. With respect to other treatment, we can add nothing to the very satisfactory account of our author. The reader will do well to consult Dr. Chapman (loc. cit.) on this disease, as well as Bell and Stokes' Lectures, &c.

106. Applications in the form of powder to the larynx have likewise been recommended by MM. Troussseau and Bellloc. Among these may be mentioned, in an inverse ratio to their power, the sub-nitrate of bismuth, alum, acetate of lead, sulphate of zinc, and subnitrate of copper. Calomel and red precipitate also produce remarkable results in cases of ulceration, whether syphilitic or not, of the mucous membrane of the larynx. All these, excepting the sub-nitrate of bismuth, which may be applied pure, ought to be mixed with finely powdered sugar or sugar-candy in variable proportions, according to their activity: calomel with twelve times its weight of sugar; red precipitate, sulphate of zinc, and sulphate of copper, each with thirty-six times that of lead; and acetate of lead with seven times its weight of sugar; and nitrate of silver with twenty-two, thirty-six, or seventy-two times its weight of sugar. The last is said to be most successful in erythematous laryngitis, with erosions or ulcerations. The powders should be impalpably fine; the least roughness or perceptible fragment of a crystal occasions such cough as expels the powder. The powder is put into one end of a reed or glass tube, and the other is carried back as far as possible into the mouth. After a full expiration, the patient closes his lips around the tube and inspires suddenly and forcibly through it, some of the powder being thereby carried into the larynx and trachea. The cough, which the powder excites, is advised to be restrained as much as possible, so as to prevent a too speedy expulsion of it. This mode of applying these powders may be resorted to twice, or even oftener, daily, according to the nature of the case; but the mercurial powders should not be thus employed, unless the patient be applied oftener than twice or thrice a week.

107. Applications to the pharynx are often beneficial in chronic laryngitis; for it is well known that this disease often originates in the mucous membrane of the throat (see article THROAT), especially in the tonsils, fauces, &c., and extends to the pharynx, and thence to the epiglottis and larynx; and that it is often caused by enlargement or relaxation of the uvula, often in connexion with other affections of the throat. Caries even of the teeth may affect the pharynx and larynx. In such cases, the treatment should be directed to the primary affection. An elongated uvula should be shortened, and suitable gargles prescribed. Besnati extols gargles of alum and sulphate of zinc. MM. Troussseau and Bellloc prefer the nitrate of silver, and, when angina pharyngea coexists with chronic laryngitis, they touch, two or three times a week, the tonsillar arch of the palate with a pencil of nitrate of silver, or a solution of the same; or they apply a powder consisting of six or eight grains of the salt to about a drachm of powdered sugar. A strong solution of corrosive sublimate, or of sulphate of zinc, fulfills the same intention. Even when the mucous surface of the posterior fauces or pharynx is not affected with inflam-
sary irritation, the same means have been useful in chronic laryngitis.

108. b. The second indication, viz., to improve the general health, is generally required, and, without attention to be paid to it, the local measures above advised may be employed in vain. The means which should be adopted in order to attain this end ought to vary with the circumstances, and especially with the origin and complications of individual cases. When indications of irritation are observed in the throat or pharynx, or when the uvula is elongated, the digestive functions will be rarely found un- disordered. These should be improved by mild tonics and purgatives, and by stomachic aper- eutics and alternatives. The compound steel mixture with liquor potasse, or the iodide of potas- sium with liqueur potassae and sarsaparilla, are among the most suitable medicines that can be resorted to with this intention, after the secre- tions and excretions have been evacuated. A residence in a mild, equable, and congenial climate, strict attention to diet and regimen, and the use of mild chalybeate and debubrient mineral waters, will very materially assist other means of cure. When the laryngeal affection is dependant upon an early stage of pulmonary tuberculosis, these will be especially requisite, par- ticularly change to a warm, mild, and equable climate.

109. In the syphilitic form of the disease, the constitutional cachexia must be removed, as already hinted at, by a mild mercurial course, or by a course of iodine and sarsaparilla, [dulcamara, or yellow dock.] In this species, gar- gles, or the local application to the larynx of solutions of [sulphate of copper, sulphate of zinc, nitrate of silver, or] corrosive sublimate, and the exhibition of this substance internally, in the form either of pills or of solution, until the system is affected, or conjointing it with tonics, sarsaparilla, &c., are sometimes very advantageous.

110. c. The third indication, or the relief of urgent or dangerous symptoms, is often called for in the course of the disease. Several of the means already mentioned, and recommend- ed to be conjoined with other remedies, in- tended to answer the first intention, as the internal and external use of narcotics, anodynes, and demulcents, particularly stramonium, belladonna, &c. (§ 99, et seq.), will be required to fulfill this indication. Still, however skillful the treatment may be, these and other combina- tions of means may fail to prevent, or acci- dents may occur to produce impending suffocation. In cases where the epiglottis is so ul- cerated or otherwise injured as not sufficient- ly to protect the rima glottidis, articles of food or foreign bodies may become entangled in, or may pass the larynx into the trachea; and these, or threatened suffocation from other cir- cumstances, as from the sudden inflation or abscess of the sub-mucous tissues, may require treatment of a more specific character. When such cases are re- sorted to, and a canula of sufficient diameter introduced, the affection of the larynx should be treated in a suitable manner, care being tak- en, in the way above advised (§ 96), not to al- low secretions to accumulate in the trachea so as to interrupt respiration. When the organ is capable of performing its functions, the canula may be withdrawn, and the wound will soon afterward heal. If the disease of the larynx be of such a nature that the air cannot pass through the glottis, the canula must be con- tinually worn. MM. Troussseau and Belloc adduce an instance of its having been worn for ten years.

111. Females suffering under chronic laryn- gitis often experience violent exacerbations of cough, and laryngitis as a consequence, a distressing suffocation. In these cases, especially when occurring in hysterical temperaments, the application of the terebinitine embrocation around the neck, or a belladonna plaster or ointment, and recourse to an enema of spirits of turpentine with castor oil, and sometimes with camphor or asafetida, will generally re- move the attack.

112. IV. Foreign Bodies in the Larynx or Trachea.—The consideration of this subject in connexion with diseases of the windpipe has been neglected by all writers on these dis- cases, excepting Dr. Stokes and Mr. Ryland, although numerous instances of this accident, and minute accounts of the consequences pro- duced by it, are on record. A somewhat par- ticular notice of this subject has, however, been taken by Pelletan, Louis, and Porter. The situations in which the foreign body may remain, or into which it may pass, are: the rima glottidis itself; the ventricular laryn- x; the trachea; and the bronchial tubes, particularly the right. It may, from the efforts of coughing, be forced upward into the trachea or larynx, thence to return again to its former position. † The much greater fre- quency of the passage of the body into the right than into the left bronchus, has been imputed by Dr. Stokes, not to the greater diameter of the right than of the left tube, but to the manner in which the trachea divides to form these tubes, the septum at the bifurcation not being in the median line, but proceeding to the left of

* [There are numerous cases on record, where tracheoto- my has been successfully performed, both in acute and chronic laryngitis; as in Lond. Med. Gazette for March 6, 1814; Lond. Med. Gazette, Aug. 7, 1845.] The acute form of the disease, should evidently be performed, if possible, while the patient's strength is yet entire, and be- fore the system is poisoned beyond recovery by the lungs congested. † In the Montreal Med. Gaz., 1814, is an account of a successful case of tracheotomy, for the removal of a paper-stem from the trachea of a boy four years of age. We may remark, that tracheotomy possesses decided advan- tages over laryngotomy, in case of laryngitis, as the trachea is rarely involved in the disease, and an incision through the unhealed incision of the larynx, and the subsequent introduction of a canula, necessarily adds to the existing irri- tation. With respect to the use of a canula, Mr. Liston says, there is no agent on which operations of foreign bodies can be employed whenever it is necessary to provide for the fre- quent change of the canula. —Lond. Med. Gazette, 1814.

† [Mr. Bartlett relates a case (New-York Jour. of Med., 1815), where a piece of bone was expectorated, which was supposed to have been lodged in the bronches 60 years previous. In the Glastrum's Retrospect, part iii. London, 1837, it is recorded a case of spontaneous expulsion of a piece of bone from the larynx four years after it had lodged there. In the Dublin Jour. of Med. and Phys., an instance is mentioned of a boy, where a piece of wood had been swallowed by a boy and passed into the trachea, whence it was spontaneously expelled, five weeks after. Dr. Lofts remarks, 'He Lafcadio Heiles has a case where the covering remained in the air-passages for eight months, when it was coughed up, and the pulmon- ary symptoms which accompanied it. Dr. Dobson relates a case of an ear of grass remaining in the air-passages seven weeks, giving rise to severe bronchitis; it was then ex- pectorated, and the patient recovered. Many other similar cases are on record, where foreign bodies have remained for a long period in the larynx, or air-passages, and then expelled (spontaneously, when recovery took place.)
it, so that a body falling through the trachea will most readily pass into the right division.

113. When the body has passed into the air-passages, various results are observed: 1st. It may be expelled forcibly through the glottis, after a period of time varying from a few moments to many years. 2d. It may produce death by suffocation, from its being impacted in the larynx. 3d. It may cause acute inflammation of the whole lung, owing to its lodgment in the principal bronchus, and the patient die before abscess is formed, or after an abscess has formed in the lung. 4th. It may occasion symptoms of consumption, from which the patient may recover with the discharge of it, or from which he may die. These very different results arise chiefly from the various grades of organic sensibility of the bronchial tubes in different persons, from the state of predisposition to disease in the lungs, and from the size, nature, and form of the foreign body. In some cases, remarkable pain is produced by it; in others, extensive disease takes place without any pain.

114. It is remarked by Dr. Stokes that facts are wanting to throw light on the occurrence of pain, but that the chief cause of distress, most probably, will be found to reside in the degree of mechanical obstruction produced by the foreign body, the distress being always found to be great in proportion to the feebleness of murmur in the affected lung. Thus, if a smooth body, such as a bean, enters the bronchus, and so obliterates the tube as totally to prevent the entrance of air, the distress is extreme, the patient being suddenly deprived of the use of half of his lungs; while, on the other hand, an irregular body, as a tooth, may exist long in the same situation, with comparatively little distress, because, though to a certain extent obstructed, the tube is not impermeable. This writer observes, that in the great majority of cases in which chronic consumption was produced, the foreign body was of an irregular form. The patients escaped rapid death because the air-passage was not completely obstructed, and their disease exceeded from the long-continued irritation caused by this body.

115. A. Diagnosis of Foreign Bodies in the Windpipe.—When any substance remains impacted in the larynx the symptoms are at once most violent, distressing, and strangulating, the breathing being croupy, pain in the larynx most severe, the cough most incessant, and attended by paroxysms of suffocation. The violence of the symptoms will depend much upon the degree of mechanical obstruction and the nature of the body causing it. The foreign body may, owing to these circumstances, produce almost instant death; or it may be expelled after a shorter or longer period; or it may fall into the trachea or bronchus, and, after an interval of comparative ease, be succeeded by a return of the laryngeal symptoms, or by acute or chronic inflammation of the lung. Hence cases of this accident may be divided: 1st. Into those in which the foreign body has remained, from the first, entangled in the larynx; 2d. Into those in which having passed this part, into the trachea or into a bronchus, it is driven upward from the trachea, to be temporarily caught in the larynx, again to descend into the trachea or bronchial tubes, producing alternations of suffering and comparative ease; and, 3d. Those in which the foreign body, having passed into the trachea or bronchus, produces either acute disease with severe suff ering, or more chronic inflammation with slight or consumptive symptoms.

116. a. In the first of these cases, the sufferings are those stated above (§ 115); or they may be of a less severe character, as when the body is lodged in the ventricles of the larynx, where it may remain for a considerable period, but not without producing inflammation and its consequences. M. Pelletan instances the occurrence of a button-mould having fallen into the larynx, where it caused severe cough, and occasional attacks of suffocation. The trachea was opened, but although the button was felt, it could not be extracted until the necrotic cartilage was divided, and then it was taken from the left ventricle of the larynx. A soldier, after drinking water from a pool, was suddenly seized with symptoms of suffocation, and died while preparations were being made for tracheotomy. A leech was found in the right ventricle, and obstructing the glottis. The severity of the cough may occasion, in accidents of this nature, so great disturbance of the cerebral circulation as to produce apoplexy, or convulsions, according to the age of the patient; and death may follow from this circumstance after the foreign body has been removed.

117. b. In the second class of cases, or in those in which the body passes into the trachea or bronchus, and is occasionally driven up, on expiration, against the larynx, or is caught in it, the greatest variety of symptoms may be produced, and intervals of case may take place. When fever appears, it is consecutive upon the local irritation, and the paroxysms of cough are a state of incomplete relief. A fragment of a body being driven into the larynx, or by its being impacted into a principal bronchus, so as to suddenly deprive the patient of one lung. From the secretion of mucus consequent upon the irritation caused by it, a rattling takes place in the throat. As the disease proceeds, respiration becomes stridulous, but the sound, according to Mr. Porter, is never so loud or so harsh as in croup. M. Louis has noticed the occurrence of emphysema above the clavicles. M. Lescure has adduced a case in which the lungs were emphysematous throughout. I have met with emphysema above the clavicles in one case of this kind, in a child about eight or nine years of age. Dr. Stokes considers it a rare symptom. The following case by this physician is interesting, and illustrative of this subject.

118. A gentleman, aged twenty, in previous health, while conversing in the act of eating a piece of cheese after dinner, suddenly fell from his chair, and in a state of insensibility. A fragment was speedily passed into the oesophagus on the supposition that a foreign body had lodged there, and in a few minutes he partially recovered. The attack recurred soon after with great violence; the face was congested, and the breathing spasmodic and stertorous. He was then freely bled, but no improvement followed. A loud rattling in the throat was heard,
the patient tossed himself on the bed, and threw his arms about so as to expand the chest as much as possible. All the muscles of inspiration were in violent action, and the surface of the body became pale and cold. Suspicion of asphyxia from tracheal obstruction being entertained, a stethoscopic examination was made. The chest sounded everywhere clear; but the vesicular murmur could scarcely be perceived in any portion of the lungs, the feebleness being equal and universal, and it is to be assumed that the patient made the most violent efforts at inspiration. A loud sonorous-rattle, every moment increasing, was heard in the trachea, while the slight dilatation of the chest, compared with the respiratory efforts, clearly pointed out some obstruction in the windpipe. The failure of treatment calculated to relieve the brain, and the evident secretion into the trachea, as shown by the loud rattle at the top of the sternum, were strongly indicative of the symptoms not having been caused by spasm of the glottis, but by a morsel of food pressed into the trachea. Tracheotomy was now performed, and a crucial incision made through the tube; and on the angular portions between the incisions being removed, a mass of putrid matter was forcibly ejected through the opening, with instantaneous and complete relief to the symptoms. Respiration became easy, the expansion of the lungs full and audible; the patient breathed through the glottis, and quite recovered.

[It is not unusual for individuals to become choked by morsels of food or other substances being lodged in the pharynx, at the entrance of the glottis. Here pressure should be made on the abdomen to prevent the descent of the diaphragm; a forcible blow should be made by the flat hand on the thorax. The effect of this is to induce an effort similar to that of expiration; the larynx being closed, oesophageal vomiting takes place, and the morsel is dislodged. But if this plan fails, the pressure should be kept upon the abdomen, the finger introduced into the throat, and the same smart and forcible blow made on the thorax as before. By the irritation of the fauces, the cardiac is opened, and by the blow on the thorax (firm pressure being made on the abdomen) an effort similar to that of expiration with a closed larynx is made, and a direct vomiting occurs, and the morsel of food is carried away. (Williams.) If the body has passed into the trachea, and symptoms of suffocation are urgent, tracheotomy should be instantly performed. Some time since we were summoned to visit a fine girl of ten years of age, who was seized with symptoms of suffocation and strangling while at dinner. Having satisfied ourselves that the foreign substance was not in the pharynx, we immediately proposed to open the trachea, but the parents peremptorily refused to have the child's throat cut, to use their own language, for the purpose of saving its life. Remonstrance was useless, and in ten minutes respiration had entirely ceased. Post-mortem examination disclosed a solid piece of beef blocking up the trachea, about midway from the glottis to the bifurcation.]

119. It may be mentioned here, that substances may pass into the trachea, during deglutition, through an ulcerated fistulous opening between the trachea and oesophagus, generally in the membranous portion of the former. Of this I have met with one ease, and similar instances have been recorded by Zeviani, Van Dieveren, and others. In these cases, the ulceration, terminating in perforation, may commence in either canal, but generally in the trachea, and is almost always preceded by tubercular cavities in the lungs. In these cases, the symptoms are not materially different from these just noticed, or to those about to be mentioned in connexion with the passage of foreign matters into the bronchi. This occurrence takes place chiefly in the last stage of tubercular phthisis, complicated with ulceration of the trachea and larynx.

120. c. In the third class of cases, or those in which the foreign body passes into a principal bronchus, and occasions either acute disease and severe suffering, or chronic consumptive symptoms (§ 118), the particular lesions, as well as the symptoms which result, are very diversified. These are chiefly, 1st. Acute or chronic inflammation of the trachea, or of the trachea and larynx; 2d. Acute inflammation of the bronchus in which the body is lodged; 3d. Bronchitis with haemoptysis; 4th. Acute pleuro-pneumonia; 5th. Abscess of the lungs; 6th. Asthmatic symptoms; 7th. Acute or chronic phthisis.

121. When the foreign body is thus situated, the consequences, and the symptoms attending them, are very diversified in different cases, according to its situation and form. The diagnosis depends on a careful examination of the history and symptoms and physical signs of the case. Generally, the sudden occurrence of irritation in a large bronchus, commonly the right, in a patient who had presented no previous sign of thoracic disease, is evidence that a foreign body had passed into it. The situation of the foreign body is often pointed out by local pain, but not constantly, even when this body is of a irregular form and irritating nature. The physical signs depend upon, 1st. Its situation; 2d. The degree of obstruction it presents to the entrance of air; and, 3d. The amount of irritation it occasions. If it remain in the trachea, these signs are more obscure than when it is lodged in one bronchus; for, in the former case, the respiratory murmur is obscure in both lungs, but in the latter it is obscure in one lung only; the obscurc being in proportion to the degree in which it obstructs the passage through the bronchus. Hence the murmur is greatly lessened, or altogether extinguished, in the lung whose bronchus is thus obstructed, while the sound on percussion remains the same, and the opposite lung presents the puerile respiration. If, however, the obstruction of the bronchus continue for a considerable time, without the foreign body being dislodged, or driven upward into the trachea, congestion or inflammation of the obstructed lung may take place, the air in its cells be absorbed, and that side of the chest become dull under cussion, especially when compared with the other side. Hence the suddenness of the irritation, the existence of it before the appearance of constitutional disturbance, and the completeness of the bronchial obstruction in a whole lung, should be viewed as indicative of the occurrence in question, and lead to a more
minute examination of the history and state of the case.  

122. B. Prognosis.—Whatever may be the effects produced by the foreign body—and these will depend not only upon the physical properties of this body, but also upon the peculiarities of the individual—these effects do not always cease upon the removal of it. However, this circumstance ought not to prevent the institution of measures for removing it; as, when it is removed, the means, which the manifestations of the effects produced by it, will then more readily be followed by beneficial results. The issue, it is obvious, will depend upon various circumstances; upon the various consequences noticed above; upon the nature, size, and situation of the foreign body; upon the local and constitutional disturbance produced; and upon the removal or presence of this body; it has, however, been unfavourable in a large proportion of cases. 

C. Of this accident depends upon the bulk of the obstructing body. In most instances tracheotomy should be resorted to early; particularly when the body is large, is lodged in the trachea or larynx, and when it is moveable from a bronchus into the trachea. If it be firmly lodged in a bronchus, and have caused the lesions usually consequent upon it when impacted in this part, little hopes can be entertained from the operation. Emetics have been recommended, but they rarely succeed unless the body be of a small size. If it be large, it may be forced upward during vomiting; and caught in the larynx, and produce suffocation. Owing to this reason, Dr. Stokes argues against having recourse to emetics, and advises an early resort to tracheotomy. I believe, however, that there is less risk from the use of emetics, or of an emetic, than he infers; but I agree with him in advising a recourse to the operation early, and before inflammatory action is developed. On this subject, the reader will consult with advantage the works of Mr. Ryland, Mr. Porteous and By Dr. Stokes, and the other writings referred to in the Bibliography and References.  

[A very interesting case is related by Mr. Brodie (Clinical Lectures, Lond, Lancet, 1844) of the celebrated English engineer, Mr. Brunel. ]

"This gentleman," says Sir Benjamin Brodie, "in playing with a child, flung a half sovereign into his mouth, and it slipped down the wind-pipe. In the first instance it produced sickness, and as he drew his breath, previously to vomiting, it descended into the bronchus, and occasioned coughing every now and then. When his head was placed down, it could be felt rolling along the trachea. We attempted to remove it by placing him on a moveable platform, so that his feet were up and his head down, nearly at right angles. The half sovereign descended, and stuck in the glottis, so as nearly to choke him. We therefore determined not to repeat this experiment till we had got an opening in the trachea, which would act as a safety-valve. We made an opening, some few days afterward, below the thyroid gland; but the half sovereign was not coughed up, as a cherry-stone would have been, because it was too heavy. We made some attempts to use the forceps, but found it so dangerous that we desisted. When he had recovered from the effects of this operation—in the mean time, passing a probe every now and then—we again placed him on a moveable platform; his back was struck with the hand, and the half sovereign escaped from the bronchus. He could feel it rolling along the trachea till it came to the glottis; and now, instead of sticking there, it passed through, just as you would roll it through the dead body, and came out of the mouth. There was no spasm of the glottis, and the absence of it was to be attributed to the operation on the trachea. In blood which came out with the half sovereign, which had evidently passed in from the external wound; and where blood went in you may be sure that the air went in also."—(Loc. cit.) A similar case is related in "Brathwaite's Retrospect," part xi., where an English shilling piece was removed from the larynx by inversion of the body. The patient, a man, was placed with his shoulders against the raised end of a high sofa, and then, being seized, by three powerful men, by the loins and thighs, he was rapidly and violent. The tumour was removed from the head into the dependant position; and after a shake or two, the larynx, at the same time, being moved rapidly from side to side, the shilling passed into the mouth, and fell upon the floor. Not the slightest cough nor dyspnoea was produced; the patient was perfectly free from uneasiness, and there was a marked change in the character of the voice. He had not the slightest subsequent bad symptom.]  

124. V. Of Tumours external to, and compressing the Windpipe. —Some notice has been taken of these, in connection with the production of spasm of the glottis (§ 28, et seq.); it is, therefore, unnecessary to add more on this subject than to enumerate the kinds of tumour that may affect either the trachea or larynx, particularly the former. The effects of tumours upon the windpipe may be mechanical only, or chiefly vital, or resulting from their influence upon the nerves of the tube, or upon the circulation through the veins of the neck; or both mechanical and vital. The tumours may be injurious in these ways, either with or without compression of the tube, so as to diminish its caliber, much of the effects produced by them depending upon their situations, their influence on the nerves and blood-vessels, and the sensibility of the patient. When they are situated above the sternum or clavicles, they are less likely to occasion injuries or urgent pressure on the trachea than when they are developed under the sternum or upper portion of the chest. If the tumour be situated under the sternum situation are, abscess of the neck; enlargements of the lymphatic glands; bronchocele; tumour consisting of aequous cysts sometimes developed in the vicinity of the thyroid gland, but not affecting it, and described under the name of hydrocele of the neck by Mainoir and Ollier; aneurism of the carotid or thyrdo arteries; and solid or malignant tumours of the neck. These may form without materially compressing or displacing the trachea, owing to the yielding nature of the parts external to them and the trachea. But those tumours which are formed under the sternum, and are more deeply seated, are generally productive of more distress, by affecting the trachea in these modes in a severer manner. They not unfrequently rise above the sternum, but their

1. Deyon.—Dusky red or livid tubercles of various sizes on the face, ears, and extremities; thickened or rugous state of the skin, a diminution of its sensibility, and falling off of the hair, excepting that of the scalp; hoarse, nasal, or lost voice; oze

na; ulcerations of the surface and extreme feator.

2. Considerable confusion has arisen from not distinguishing this disease from elephantias, or elephant leg, on the one hand, and from the squamous lepra, or lepra Greceoram, on the other—diseases perfectly distinct from each other. As regards the tuberculous cutaneous sealy diseases, especially the lepra and psoriasis of Willan, were deemed leprous and received into the hazaretos. The circumstance of the description in the books of Moses of several forms of cutaneous disease as being leprous, and the applicability of parts of that description to the above squamous affections, have contributed to this confusion. In order to simplify the subject, it will be preferable to consider the true leprosy of the Middle Ages entirely apart from the chronic sealy eruptions just mentioned; and to view the lepra of Willan, as M. Scheidel has done, as a species only of psoriasis, more especially as the appearance, nature, and treatment of both these squamous diseases are very nearly the same. I shall here briefly describe tubercular lepra, as it appears to have prevailed during the Middle Ages, and down to modern times in Europe, and as it is occasionally met with at the present day in some warm and Eastern countries; and afterward notice certain modifications of it observed in various countries. I have viewed the scaly lepra as a species of psoriasis.

3. Description of Tubercular Lepra.—

Several writers state that physical and moral languor and depression often precede the appearance of the disease in the skin. Occasionally the spots and tubercles characterizing the disease appear in the skin with febrile symptoms; but the attack is more commonly very gradual and slow. Patches of the integuments are generally changed in color and hue; and a darker hue before the development of the tubercles. The spots become even deeper in color than the skin in the dark races; and yellowish, or reddish, or livid, shining, and slightly elevated in whites. These spots are irregularly disseminated, and look as if they were full of oil, or covered with varnish (Abans). They are occasionally quite insensible, but more frequently feeling is not quite absent in them, although they may be compressed without pain. At first, sometimes, they are more sensible than the surrounding skin; but this state, and the redness attending it, subside by degrees; the flush being followed by a tawny or bronze color. The spots, after being stationary for a period of various duration, are always succeeded by tubercles, some of which are cutaneous, others are seated in the cellular tissue underneath. The cutaneous tubercles are small, soft, round, reddish, or livid, varying in size between that of a pea and an olive. They appear on every part of the face, particularly the nose and ears, and on the legs, but in rare instances they have occurred on the legs only. Commonly in a few years they spread over the whole body, although they are more numerous in some parts than in others; and the malady becomes more and more marked. Of all places, the face is most affected and most deformed by it. The visage is puffed; the skin of the forehead is beset with tubercles, and marked by numbers of deep transverse furrows. The superciliary ridges are swollen, furrowed with oblique lines, and covered by nipple-like projections. The hair of the eye-brows and the cilia are lost. The lips become thick and shining; the chin and comb of the ear enlarge, and are thickly covered with livid tumours. The lobe and axis of the nose are generally even more distorted than the eyebrows; the nostrils are irregularly dilated, and the cheeks are swollen. The whole of the features, enlarged and distorted by the puffing of the subcutaneous cellular tissue and by the tubercles, present a frightful deformity.

4. Arrived at this stage, tuberculous lepra sometimes remains stationary for a very considerable period. The skin then seems principally impregnated, the chief functions being but little disturbed. The time which elapses between the appearance of the first tubercles and the development of those which succeed them varies exceedingly. Frequently they are rapidly evolved; but they never acquire a very large size. Subsequently, commonly after some years, the greater number of these tubercles inflame, and either suppurate or are resolved. Ulceration, according to M. Raver, is preceded by an acute inflammatory state, during which the tubercles and the surrounding integuments become hot and red. The tubercles, which are ulcerated, sotken and discharge a languid pus, that dries up speedily, and forms adhering brown or blackish scabs, which rarely rise above the level of the skin. Sound cicatrices are formed under these scabs in rare instances.

5. When the disease appears before the age of puberty, the growth of the beard, and of the hair upon the genitals and axillar, is often prevented or checked. In some, however, the beard only is wanting. In adults, the beard, and the axillary and pubic hair occasionally, but very rarely the hair of the head, are lost. Frequently the sensibility of the skin is somewhat impaired; sometimes it is at first increased, occasionally not changed. As the disease advances, it is often very much impaired in the extremities, especially the lower. The tubercles on the upper extremities follow the same course as that above described. They are less numerous than on the face, and appear chiefly on the outer and posterior surfaces of the elbow. The thumb is often swollen, but is rarely the seat of tubercles; it is commonly livid, with less of the bronze cast than other parts of the body. The lower extremities and feet are similarly, but generally more severely affected. The hollow space of the sole is filled up by the swelling of the cellular substance, giving the feet a flat appearance. The tubercles of the buttocks are large, those of the soles are flattened. Ulceration of the tubercles of the legs is always slow of healing. The phalanges of the toes occasionally sphecatate, especially when the disease is complicated with serious internal lesion, and is tending to a fatal termination. The trunk of the body is seldom the seat of tubercles,
6. The mouth, the fauces, uvula, tonsils, pharynx, and nasal fossae are often studded with tubercles of a smaller size than those of the skin. A longitudinal band of tubercles frequently extends from the superior incisor teeth backward, along the roof of the mouth to the uvula. The lingual veins are sometimes varicose. The pituitary membrane is generally inflamed, and secretes a sero-purulent fluid, the inflammation occasioning pain of the frontal sinuses, and ultimately caries of the cartilages and tuberous bony elements of the nose. The voice becomes hoarse, nasal, and is finally lost. The eye-sockets and parts of the eyes are affected, but these are enlarged, deformed, livid, and studded with tubercles. The sense of smell is early impaired, and soon altogether lost; especially when the pituitary membrane ulcerates and discharges a profuse fetid secretion. The eyes are not materially affected, beyond the loss of the cilia. The sense of taste is not impaired. The pharynx becomes covered with tubercles, but the esophagus is seldom thus affected. The stomach and bowels generally perform their functions regularly, unless they be disturbed by active mediocres.

7. The organs of locomotion are generally much enfeebled. If the disease has commenced before puberty, the patient continues weakly, and gradually becomes deformed; but if manhood has been attained before this invasion, and the person is fully developed, the affection of the muscular system approaches, and proceeds slowly and gradually with the progress of the disease. The influence of the malady upon the generative organs is rarely precisely determined. According to some writers, the evolution of these organs is always arrested by it when it occurs before puberty; and it causes them to fall into a state of atrophy when it appears after this period. Pallas states, that the Tartars affected with the malady show a distaste of sexual intercourse. All the patients M. Raym saw had the genital organs well developed; and none of them was tormented by the libido increpilis, mentioned by some authors as a frequent concomitant of the disease.

8. Terminations.—Tuberculous lepra is seldom seen in Europe; hence its morbid anatomy has been imperfectly studied. But the most exact accounts which have been furnished concur in showing that persons who are the subjects of it are almost always carried off by acute or chronic inflammations of the respiratory organs and passages, and of the digestive visera; and less frequently by low fever. It is often the end of the disease, and has been found enlarged; the intestinal tubercles ulcerated, or about to become so; and the mesenteric glands enlarged and tubercular in persons who have died of the disease. Small cavitaries have also been observed in the intestines. The liver and spleen have not been materially altered. A thickened state of the mucous folds of the larynx, tubercles on the vocal chords, occasionally ulcerated, and frequently containing much pus, and small ulcers of the mucous coat of the trachea, have been found after death, and account for the affection of the voice during life. The lungs generally contain crude or softened tubercles scattered through them. Three patients examined by M. Raym had the lungs thus affected. Others who have died at an advanced period of the disease have shown distinct marks of pneumonia. The organs of circulation, and the nervous centres, present nothing remarkable. In a coloured man, which I saw examined after death from this disease, the heart was smaller and softer than natural.

10. II. Maladies allied to Tubercular Leprosy.—The leprosy of Iceland, as described by Dr. Holland and others; that of the Faroe Islands, noticed by de Beers; the cases which occurred in the Shetland Islands, and mentioned by Drs. Edmundson and Simpson; those observed by Dr. Herbst and Dr. Adams in Africa, as well as those still met with in Africa and in the East and West Indies, are identical with the disease now described, the leprosy of the Middle Ages. There can be no doubt of the disease being somewhat modified by endemic influences, and by modes of living and other circumstances proper to the individual, even in the same locality; but several maladies very distinct from it have been confounded with it, although its tubercular character offered a sufficient distinction between them.

11. I. Lepra Taurica.—Leprosy of the Crimea.—L. of the Cossacks.—Pallas, Guettier, and Martius have described this disease, which, they say, was introduced by the Russian troops engaged in the war against Persia into the Crimea. The description given of it by Von Martius shows that it is identical, in its accession, course, progress, phenomena, and terminations, with true tuberculous leprosy. It is therefore unnecessary to occupy my space with an account of it. The same remark applies to the leprosy of Holstein, as described by Doctor Streve.

12. II. Lepra Anæsthesiaca.—This is supposed to be the Baras of Armenia, and has been observed by Winterbottom, Robinson, and myself. It is characterized chiefly by remarkable absence of sensibility not only from the extremities, but also from the general surface, and by the comparative smoothness of the skin, and frequent absence of a tubercular state of the inguinal glands. It is probable, however, that these are merely modified, or extreme cases, in which the anesthesia and ulceration of the extremities are the prominent phenomena, and the tubercular changes less manifestly produced, or at a more advanced period of the malady. It is likewise very probable that the several diseases which were considered as leprosus in remote ages, among the Jews, and in more recent times in Eastern and intertropical countries, were more or less closely allied to it by not being in these ages, and even in modern times, several squamous and cachectic maladies assumed a more invertebrate and irremediable form, in consequence of the nature of the food used by their inhabitants, and that these maladies are not only remarkably modified from the states now presented by them in highly civilized countries, but, as respects some of them, are also thereby rendered specifically different.

13. When we consider that the use of salt was by no means general in some countries during the early and Middle Ages, that this substance was procured with difficulty in many countries, and is still scarce and valuable in several, even at the present day; that all kinds
of animal food, even the richest and coarsest, flesh-meats and fish, were often eaten in a ran-
cied or semi-potual state; that they were rarely cured otherwise than by smoking, or by dry-
them in the air; that in many countries most of the food used during the greater part of the
year was preserved in this manner, and that vegetable food was in most of them but little
employed; that periods of scarcity, or of want of 
vegetable substances or of grain, often
heightened the injurious influence of unwhole-
some animal food; that the clothing worn next
the skin was generally woolen, and retentive of
the secretions from the surface, thereby ir-
ritating and contaminating the integument.
Of personal cleanliness were very imperfectly
adopted, it will not appear surprising that
chronic cachectic maladies were of frequent
occurrence in the ages and countries thus cir-
cumstanced; that they assumed various forms,
with the nature and combination of the diver-
sified causes producing them; and that they
have changed their forms with changes in the
intensity and concurrence of these causes.

The Lepra anasthesica has been described
by Dr. Argy, and by Mr. Robinson, and their accounts of it agree in many re-
spects with what I have seen of it in Africa. It
commences in spots or patches, which are of a
somewhat lighter shade of colour than that of
the adjoining surface in blacks, and of a tawny
colour in whites. These patches appear first
in the feet, hands, legs, and arms, and seldom
on the face and trunk until a more advanced
period. They sometimes seem slightly prom-
inent from the shrinking of the several tissues of
the skin; and they are shining, rough, and ap-
parently wrinkled, from minute indented lines;
but the wrinkles do not run into the surround-
ing skin. The hairs—if any have previously
existed in the seat of these patches—fall out,
or cease to grow in them. The patches are
insensible, and extend slowly over the legs and
arms to the trunk, until the extremities, and
sometimes also the greater part of the surface
of the body, are more or less affected, and de-
prived of feeling. The affected surface is un-
persurable, but neither itch, nor painful, nor
swollen. As the disease advances, the pulse
becomes slow and soft, and the bowels consti-
pated. The toes and fingers are benumbed, as
if with cold, shining, slightly swollen, and stiff.
The soles of the feet and palms of the hands
present hard and dry chaps; and a furfura-
ecous matter is deposited below the nails, rais-
ing them and causing ulceration around them.
The legs and forearms next swell, and the skin
becomes rough and chapped. Ulcers form on
the metacarpal and metatarsal articula-
tions in the lines of flexion, and afterward in
the corresponding parts of the articulations
of the larger joints. These ulcers enlarge and
spread, and the fingers and toes drop off.
The lobes of the ears, the alae nasi, and the lips
are in some cases thickened and enlarged, and
ultimately ulcerated, discharging a thick viscid
matter. As the malady is proceeding to this
stage, tubercles form in many instances in the
skin of the limbs, face, and sometimes of the
trunk. As the small joints are penetrated by
ulceration and fall off, so they heal up, and
others are attacked in succession, until the
limbs are deprived, one by one, of their ex-
tremities. The voice becomes hoarse and gut-
tural, and ulceration sometimes attacks the
throat, but in a less degree than in the more
prominently tuberculous form of the disease.
Oc-
casionally the extremities, cicatrized stumps,
and portions of the skin are thickened, tuber-
culated, or ulcerated. Food is taken with an
appetite, and slowly digested. The intellec-
tual as well as the vital functions are impaired
and benumbed. The patient is apathetic, and
merely vegetates; yet he often lives for many
years in the slighter or earlier stage of the
malady, or even in the state of mutilation char-
acterizing their advanced stage. At last he
is carried by feverish relapses.

15. The above account, which is chiefly from
my own notes, is somewhat different from that
given by Dr. Wintebottom, which, however,
is confused and imperfect, and evidently owing
to his having described as varieties different
stages merely of the same malady. Mr. Rob-
inson has also, judging from my own observa-
tion, and from the accounts given by Dr. Ains-
lie, described as a distinct species what ap-
pears merely by a modification of the dis-
case, in which the anæsthesia, and the falling
off of the fingers and toes, were the most prom-
inent phenomena. He, however, admits that
tubercular changes sometimes show themselves
in the course of the anæsthetic variety. This
is agreeable to my own observation. As the
cases which I saw in several parts of Africa
were modified, according to the stages of the
malady, some approaching more closely to the
anæsthetic, others to the tuberculous, I believe
that there are two forms of the disease insensibly
passing into each other. Mr. Robinson mentions
the occasional occurrence of the chief charac-
teristics of both varieties in the same patient;
and Dr. Ainslie remarks, that he never met
with a case of genuine leprosy which was not
distinguished both by want of feeling in the
extremities, and by tubercles. Both modifica-
tions are equally prolonged, and both make
more rapid progress in the poor, ill fed, old,
and debilitated, than in the rich, well fed, and
young.

16. iii. JEWISH LEPROSY.—The term Berat
seems to have been applied by Moses gener-
cally, and to have included, 1st. Book, a
form of the disease not rendering the person affect-
ected by it unclean; 2d. Berat lebena, bright white
berat; and, 3d. Berat echva, dusky berat, spreading
in the skin. The second and third species he describes as being called Tsorat, venom or
malignant, and as contagious. The form of
Berat, called Book by the Hebrews, seems to
agree with the Lepra vulgaris of Willan. Dr.
Good considers the third, or Berat echva, to be
the same with the Lepra nigrans of Willan
and Bateman. It may be so, but there is no
further proof of this than of its being the tu-
berculous or true leprosy of the Middle Ages.
The second variety, or the Berat lebena, is prob-
ably the Leucor, of lepore, the Greeks, and the
third species of Vitalgo of Celsus.

17. The Jewish leprosy has been assimilated
by other diseases. Bartholinus, Leclerc,
and others associate it with tuberculous elephantiasis. HILLARY and Adams think that it was the Francobas of Africa. LORRY and several others regard it as a distinct malady. It is impossible to form, from the scanty accounts furnished us, a just idea of the disease. It is, however, not unlikely that the term leprosy was applied by the Jewish priests to various cutaneous affections, particularly those which were of a chronic, self-contaminating, or contagious nature; and it is probable that Francobas was one of these, as well as other inverte cutaneous maladies arising from the modes of living, the habits and circumstances of the Jews at that time, and of the Egyptians, and that these maladies have changed their characters, owing to changes in the nature and combinations of their exciting causes.

18. iv. The RADENSKY, a disease very prevalent in Norway, has been considered by many as a variety of tuberculous leprosy, from its very close resemblance, in many of its symptoms, to that malady. But in the article on that disease I have shown it to be generically distinct, that its characters, course, and terminations are quite different from that leprosy of the Middle Ages. This is still more especially the case with PELLAGRA (which see).

19. The speadaskhed, a disease prevalent in the district of Bergen, in Norway, has been confounded with radesyege; but, from recent researches, it is fully proved that it is identical with the leprosy of the Middle Ages, or elephantiasis of the Greeks—w ith the leprosy still existing in Norway and in Eastern countries, and hence quite distinct from the radesyege. The disease has been applied indiscriminately to the elephantiasis of the Greeks, the lepra of the Arabians; to the leucex of the Greeks, the hcra of the Arabians, or the leprosy of the Jews; and to the slighter scaly affections to which the names lepra and psoriasis were given by the Greeks and moderns. It seems extremely probable that other diseases, perfectly distinct in their natures from one another, and from those alluded to, were often included under the generic denomination of leprosy, provided that they possessed the general characteristics of inverte, or a disposition to self-contamination, or to propagate themselves by contact with the morbid matter secreted by them. This seems to have been the case, especially among the Jews and Eastern races. From the very precise accounts furnished by the writers of the Middle Ages, particularly subsequent to the Crusades, the term leprosy was applied with tolerable precision to the elephantiasis of the Greeks—to the tubercular—disease. The monks THEODORE, LANDRANC, BERNARD GORDON, DE CHAULIC, GILBERT, JOHN OF GADDESEN, and several others have described this malady, as it occurred during the 14th century, with more precision and minuteness than any modern writer. As Dr. J. Y. SIMPSON remarks, in his very learned paper on leprosy and leper hospitals, the details which they, and some other writers of that period, have given of the chief characters of the disease are altogether similar, and the symptoms are precisely the same which distinguish the Greek elephantiasis. They also enter most minutely into all the local and constitutional symptoms, with the view of fully distinguishing the disease; and they point out the mode in which a suspected person ought to be examined before the existence of a malady which is to consign him to a leper hospital should be decided upon.

21. It seems, however, that the precision thus hitherto cultivated by the earlier of the Middle Age medical writers was subsequently departed from; for, during the fifteenth and sixteenth centuries, all cutaneous eruptions of an obstinate character, or attended by ulcerations, were deemed leprous and received into lazaret houses, which were extremely numerous throughout all Europe, particularly in countries bordering on the Mediterranean. At the present day the term leprosy is restricted by the medical men of this country, particularly to those varieties of squamous affections, which the Greeks denominated lepra (lyppa); while, in Continental countries, and in the East more especially, it has been applied to the elephantiasis Graecorum, the tubercular leprosy, or lepra Arabum. I have already stated my reason for removing the seyly lepra, or the lepra of the Greeks, and of WILLAN and his WAY (to the term leprosy), to which it properly belongs, and of restricting the term leprosy to the tubercular disease, the elephantiasis of the Greeks, the lepra of the Arabians, to which this term was strictly applied by the writers of the Middle Ages, and by most of the later writers, although several other cutaneous affections, besides the tubercular leprosy, were received into the leper or lazaret houses in more modern times. It is probable, however, that the strictness of diagnosis observed during the thirteenth and fourteenth centuries depended on the circumstance of the seclusion of the leprous being enforced; while, subsequently, persons suffering under chronic maladies supposed to be allied to leprosy were allowed to enter, for the advantages of medical treatment, those leper institutions possessing the characters of an hospital, and where medical treatment was resorted to.

23. GUY DE CHAULIC, the celebrated surgeon of the fourteenth century, assigns the following six symptoms to the leprosy or lepra nostrilis malady. "Rotundity of the ears and eyes; thickening and tuberosity of the eyebrows, with falling off of their hair; dilatation and disfiguration of the nostrils externally, with structure of them within and festivity of the lips; voice raucous and nasal; festivity of the breath and of the whole person, fixed and horrible satyr-like aspect." John of GADDESEN remarks, that "no one is to be adjudged a leper, and separated from mankind, until the figure and form of the face are actually changed. Hence, ulceration of the feet, or foul seething, must not be considered as arguing the presence of leprosy, nor nodosities, unless they appear on the face, and with the aforesaid conditions." GLANVILLE,
LEPROSY—DIAGNOSIS OF—CAUSES.

another English author, who wrote in the fourteenth century, "De Proprietatibus Rerum," states, according to the translation of the Vicar of Barkeley, that leprous persons "have reddle wheakes and pimples in the face, out of whom offene runne blood and matter; in such the noses swelten and ben grete; the virtue of smelling faileth, and the brethe stynkth ryte foul." The infectyd are uncleane, spotted, gloyn, and gyttyrye; the nostryls ben stopyly, the wasen of the voys is rough, and the voys is horse, and the here falls." No recent, or even modern writer, has distinguished this malady with greater precision than the above early authors. The definition of Sauvages is perfectly diagnostic of the malady: "Facies deformis tuberculosis cutaee, azema, raucoelo; cutis Elephantia, crassa, ucutiosa; in extremis artasbus anaesthesi.

24. B. The difference between it and Elephantia—the Elephantiasis of the Arabs—is very wide. This latter is not a tubercular malady, and commences in the lymphatic veins and sub-cutaneous cellular tissue, and not in the skin itself, this latter structure being only consecutively altered. (See art. Elephantia, or Elephantiasis of the Arabs.)

25. C. The differences between tubercular leprosy and tubercular venereal affections are, chiefly, the appearance of leprosy in Europe very long before the venereal disease, the characters which are peculiar to each. The blotsches and tubercles of leprosy are of a shining, brownish tint, of an oily look, soft, tawny, irregular, distinct, separated by fissures, and attended by a general puffiness, loss of hair, and occasionally by much insensibility of the skin. The tubercles of syphilis are red or livid, hard, developed in the substance of the corion, clustered together; not insensible, generally consequent upon venereal ulcers, and not attended by loss of the hair, of the parts which they affect.

26. IV. Causes—M. Rayer remarks that, first observed in Egypt, then in Italy during the time of Pompey, leprosy subsequently extended, and has since been seen in the four quarters of the globe. It spread over the whole of Europe like an epidemic during the Middle Ages, especially about the period of the Crusades. Since the commencement of the 17th century, this malady has gradually disappeared from the countries of Europe, and is now confined to intertropical regions. It is more common among the poor than the rich; in the indigent, and in strangers after residence in a warm country. It has been described by Pococke as it occurred in Asia Minor; by Prosper Alpinus, Desgenettes, and Laerrey, in Egypt; by Bruce, in Abyssinia; Marsden, in Sumatra; Marshall, in Ceylon; by Robinson and Anslow, in India; by Bergeron, in Ceylon; and by various writers in St. Domingo, Martinique, New-Orleans, the Isle of France, coast of Africa, &c. From these localities enjoying a warm, humid, and variable climate, M. Rayer concludes that such a climate is favourable to the development of the malady. But it was as prevalent in northern as in warm countries during the Middle Ages; and, although it has almost entirely disappeared from the former of these, it is probable that cases may still lurk in some European localities, the descendants of those who were subjects of the malady. The disease was prevalent in the Faroe Islands as late as 1676, when it was accurately described by Deses, and its causes assigned with greater truth than by any modern writer. It continued also to occur in the Hebrides and in the Shetland Isles long after it had entirely disappeared from the southern parts of Britain; and Mr. Burney mentions his observing it in the Shetland Isles in 1700; and as late as 1742, the Island of Papastour continued to be the place assigned for the exclusion of those affected by it. In 1736 and 37, this island contained five persons affected with this malady; and an account of it was drawn up by the Rev. A. Fiscen at that time, and is in the possession of Mr. Barclay. It has been recently published by Dr. Simpson, and it contains an extremely accurate description of this disease. In 1772 and 76, there was one case in this island; and in the account furnished by Mr. Rannie, session clerk, mention is made of a leprous woman in 1778, who died in the fields before a house could be built for her; that about the same time there were leprous persons in the district of Wasness, and that the son and daughter of a man were infected and sent to the hospital at Edinburgh. In 1779, a young man, a native of these islands, was a considerable time in that hospital, affected with this malady, which appeared in 1809, Dr. A. Edmonston met with a case of it.

27. The exciting causes of this malady, once the most generally diffused, the most surely and slowly fatal, and the most permanent of all those which have prevailed at any time in the human species, are veiled in obscurity. It appears to have been prevalent for several centuries; and although it may not have been, for a considerable portion of that time, so common as syphilis and chore, which now, it in succession, yet it was more certainly fatal and dangerous than they to the posterity of those who became the subjects of it. That it was believed to have been contagious, is proved by the strenuous efforts made to seclude the diseased, and prevent their communication with the healthy. In the account, above alluded to, of the Shetland lepers, it is mentioned that the disease is found by experiment to be very infectious, and seems also to run in the blood, most people that have taken it without infection from another having been related to three families in the isle. It affects any age or sex, and young persons bear it longer than those of a more advanced age, some having lived ten years under it, others only two, some four, some six, &c.; but none ever recover after the symptoms fully appear.

28. The Rev. L. J. Deses, whose curious and rare work is now before me, assigns what appears, as I have already hinted (§ 13), to have been the chief causes of this malady, that is the cause of the leprosy to be the air and the diet; for here is a pretty cold and moist air, which usually causeth the scurvy to those that lead a solitary life, and this hath a great affinity with leprosy. Besides, the meat of all, specially of the poorer sort, is half-rotten flesh or fish, all their nourishment in summer being likewise fresh fish and sweet milk, without any salt; wherefore he that is not of a strong and good complexion, may easily have his blood cor-
rupted, the sickness gnawing itself through the body before it breaketh out, and when any one is so infected, he may easily give it to another that is of the same complexion with the sick;" 

"It has also been taken notice of, that two living together in marriage, though the one be found infected, they live together as before as long as one doth but murmur of it, till the magistrate doth separate them; and yet the sound remaineth uninfected, whereas another is often taken with the disease by a very little conversation."—(P. 312, 313)

29. **Dr. Ainslie** expresses a doubt of the contagious character of the disease; but he admits, with all others who have professed to investigate the matter of this malady, that it is hereditary. On this subject, Dr. A. Edmondston remarks that this disease is hereditary, "and has been transmitted to successive generations, without extending itself to individuals living under the same roof, or even to all the offspring of the same parents; nor does it seem to propagate itself by infection, unless in those cases where a matter is generated and discharged from the sores. This is the certain medium of communication, and an attention to this circumstance has given rise to contradictory views of its nature."

I believe that there is much truth in the latter part of this quotation; I quite agree with this opinion of my late friend. He adds, at another part, "that it was propagated by contagion cannot admit of a doubt. We have seen that it prevailed very generally in the Shetland Isles, about sixty-five years ago, and all the inhabitants were deeply impressed with a conviction of its contagious nature; and the history of the disease but too well confirms the accuracy of the opinion."

30. The investigations of Mr. Stewart, at Tranquebar, where tubercular leprosy is very prevalent, has induced him to give the following as the results: 1st. That women are less liable to this malady than men; 2d. That it is hereditary; 3d. Its being contagious is extremely problematical; 4th. That every leper, suffering from an advanced stage of the malady, demands whether he is capable of propagation of his species; 5th. That a fish diet is found to render every symptom worse; 6th. That poor living, want of cleanliness, mendicant misery, and exposure to cold and damp, are but too constant attendant of this dreadful affliction.

31. From my limited observation of this malady, chiefly in Africa, as well as from other sources of information, I believe that it owed its origin principally to the use of smoked, wind-dried, and semi-puritrd or rancid flesh meats and fish, and of rancid oils; to the want or disuse of salt; to the use of unripe, or spoiled, or mouldy grain; to the want of vegetable productions as articles of diet; to inattention to personal cleanliness; to the nature of the clothing; and to the contact of the matter discharged from the leprous sores, when the disease was far advanced, and when the matter came in contact with the skins of those who were already predisposed to it by the modes of living alluded to, and by want of cleanliness.

32. V. **TREATMENT.** Much good may be done by avoiding the presumed causes of the malady. The cure, when the disease is fully advanced, is hopeless; but in the early stages it may be either entirely removed, particularly if it have yearly commenced, or if the malady is confined to the extremities, or it may be arrested for many years in its progress. The Arabian physicians trusted chiefly to mercury. Dr. HILLARY avoided mercury, and prescribed sarsaparilla. Dr. TOWNE thought that antimonials afforded the greatest relief, and that mercury aggravated the disease. I believe, however, that the bi-chloride of mercury, given with the compound tincture of bark, or with the compound decoction of sarsaparilla, so as to produce alternation, and in such a mixture, is really of great service in the early stage of the malady. Dr. AINSLIE always endeavoured first to improve the health by nourishing diet, cleanliness, and exercise; and afterward to act upon the disease by a cautious use of the bi-chloride of mercury and warm baths, supporting the frame at the same time by generous living. He also mentions the mineral acids and the combination of antimonials and aromatics with approbation. The Hindoo physicians commonly prescribed barberry, or an extract of it, as a powerful remedy for this disease; but Dr. AINSLIE was disappointed in his trials of it. Of all the alternative and deobstruent remedies, he adds, employed by the native practitioners of India, none is of equal repute with the concrete milky juice of the Asclepias gigantea, given with sulphur, and continued for some weeks. Dr. Heberden states that he cured a patient in five months, by means of a mixture of an ounce and a half of powdered cinchona and half an ounce of powdered sassafras root, made into an electuary with sirup, the patient taking the size of a nutmeg twice daily. M. Rayer supposes, however, that a recourse to these and other tonics, as arsenic, &c., is apt to kindle the internal inflammations, which often carry off leprous patients.

33. Although I saw several cases of this disease in different parts of Africa, my residence in any one place did not exceed three or four months. I had not, in consequence, opportunities of observing the effects of treatment. But a few years ago I was consulted by a physician who had resided for some years in a warm climate and treated cases of this malady in all its stages. He had had patches of a tawny colour on his extremities, with thickening of the corion, and enlargement of the hair bulbs and follicles, and loss of the hair of the parts. The patches were slightly insensible; and the sensibility of the toes and feet was somewhat impaired. When I saw him, he had been the subject of the affection during sixteen years; and, at an early part of the treatment, the patches in the upper extremities had nearly disappeared; but those in the lower continued, the highest being situated in the flexures of and little above the knees. He attributed the disease to contagion, and said that he fully recollected the occasion of his infec-

## References

LEPROSY—subsequently had recourse to sulphur fumigating baths, and to various medicated warm baths. His pulse was slow, spongy, and weak; the impulse of the heart weak; and the complexion pale and unhealthy. The patches in the lower extremities had been stationary for about ten years; but, during that time, a few tubercles had formed in them, had broken, and, after continuing to discharge an ichorous matter, had healed up. The nails of the toes and of the fingers were affected as above mentioned. He complained of dyspeptic symptoms. I first prescribed for him the carbonate of potash, in decoction of bark, and, subsequently, a decoction of potassium perchlorate, with quinina potassa, in the compound decoction of sarsaparilla. After this course was continued about six weeks, the above symptoms began to disappear, and within three months his skin and lower extremities were quite clean. Three years afterward there was no return of the malady. This case was evidently one in which the anaesthesia was the most prominent phenomenon. Notwithstanding the success of these means, I believe that, in the far advanced stages of the malady, the prognosis of Holler—"Confirmata leprafricanus non curatur" (De Morb. Intcr., p. 64)—may be viewed as just.

[Leprosy in Mexico.—One of the forms of leprosy above described would seem to be not an uncommon disease in Mexico. Kendall, in his Narrative of the Texan Santa Fe Expedition (vol. ii., p. 220), thus speaks of the lazarios, or lepers of hospital San Lazaro: "The appearance of the unfortunate lepers is loathsome and hideous to a degree that beggars description. It makes its appearance in dulled eruptions on different parts of the face and body of the victim, and these eruptions are never perfectly healed. The limbs of many, and more especially the hands, at first appear to be drawn and twisted out of all shape. Gradually the nose and parts of the feet are carried away, while the features become distorted and hideous. The voice assumes at times a husky and unnatural tone, and again the doomed patient is capable to articulate except in a shrill, piping treble. With many, when near the last stages, all powers of speech are lost, and vainly do they endeavour to make known their wants by sounds which belong not to this earth of ours. Death steps in at last to relieve the poor creatures of their sufferings; and to them, at least, it would seem that the visit of the grim tyrant must be welcome." Mr. Kendall farther states that there were some 60 males, and more than that number of females, and that an inordinate passion such as the simple of San Lazaro, when he was there, that he cannot say whether the disease is contagious or not; that there is little doubt of its being constitutional and hereditary, being never entirely eradicated from the blood. He thinks the climate has some effect in engendering and keeping alive the disease; says that the common belief among the lower classes is, that it is communicable by contact, and expresses the opinion that the only risk a person runs of taking it is from touching the person of one afflicted with it in its worst stages. It seems that when a person is known to be a leper in Mexico, he is at once sent to this hospital, where he remains till death, for we are told that "none ever recover from the horrible disease" (p. 222) "If all the Mexican inmates of San Lazaro," says Mr. K., "were afflicted with leprosy, and we were told that such was the case, there must be three or four different species of the disease. The faces of some of the lazarios were covered with blotches and eruptions, while their hands and feet were unmarked. Others, again, had complexions exceedingly fair and unblemished, yet their feet and hands were distorted or decayed. Some of the victims of the dreadful scourge were covered from head to foot with sores and ulcers hideous to look at, and then there were two or three cases, wherein the malady ran its course without any other marks of the disease than the loss of a nose. But the most singular case of all was that of the old Spaniard, whom I have previously mentioned as continually smoking his cigarritos. His flesh appeared to be entirely gone—dried up—his skin turned to a bluish purple—and his whole appearance was so strangely changed and distorted, that he more resembled an animated mummy than aught else. I cannot compare him with a leper, however, for he retained, while his actions and conversation convinced us that he was a well-informed and gentlemanly man."—(P. 241.)

Leprosy in New Brunswick.—In the year 1844, the attention of the Canadian government was called to the existence of leprosy at Traacadie and Neque, in the Province of New Brunswick, near the Bay of Chaleur; and a commission was accordingly appointed, consisting of Drs. Key, Skenne, Toldary, and Gordon, to investigate its nature and origin. The following is extracted from their report to the Canadian Parliament: "The disease is the Greek elephantiasis—the leprosy; not the elephantiasis of the Arabs, but the leprosy of the Middle Ages; the leprotuberculeuse of the French, or tubercular leprosy, which raged over nearly every district of Europe from the tenth to the sixteenth century. It is the decided opinion of the gentlemen comprising the commission that the disease is contagious; and, so far as they could ascertain, no person in the above districts who contracted it ever cured. It is also their opinion that it has no affinity to serofula; and the idea very prevalent that it is owing to the poor diet of the French settlers, and their filthy habits generally, is not correct, for they found it existing in some of the cleanest dwellings and most respectable families. It has spread very rapidly during the last year. They discovered upward of 20 cases, all of which can be traced up to one quarter. They have every reason to believe that there is a still greater number; but not having power to search, and the inhabitants showing a great disposition to withhold information, or to point out the parties labouring under the disease, they could not make so minute an inquiry as they otherwise would have done, or as they were desirous of doing." Dr. Boyle, of St. Johns, has also investigated the disease (Lond. Med. Gaz., 1841), of which he has given an interesting account. Dr. B. agrees with the commission that the disease is tuberculosis elephantiasis of modern pathologists; the juzam of the Arabs, and the lepra Gracorum of the Middle Ages; but he regards the disease as non-contagious, and goes into a long statement of facts.
to prove this position. He, however, thinks the disease is hereditary, traces its existence back to 1827, numbering some 20 cases and 12 deaths since that period, although he is of opinion that it was introduced into the province much earlier.

In Norway, in the Gazette des Hopitaux, for April 4, 1844, is a short account of a memoir presented to the Academy of Sciences, by M. Danilezsen, physician to St. George’s Hospital at Bergen; from which it appears that this disease has prevailed epidemically for half a century upon the coast of Norway, and that, out of 200,000 habitants, 1200 had been attacked. In the great majority of these cases, the patient was much more or less offensively affected, the face, hands, and legs covered with blisters and tubercles of a livid, brownish colour, and some of them in a state of ulceration.

We are not aware that the disease has ever been noticed to any extent in any part of the United States, although sporadic cases have been occasionally observed, as in a young girl a few years ago in the State of New-York, in whom no hereditary predisposition existed. —

(Worcester, On Diseases of the Skin, p. 231, Philad., 1845.)

In Norway, the Leprosy of the Greeks, in Athens, thus speaks of a patient whom he was invited to visit:—"I examined with great care and minuteness, he heard the history of his symptoms, and saw the disease for myself, as it now affects his throat. I ascertained that the affection commenced, in its primary stage, in the parts as those on the hands, against the altar, and that the ulcerative appearances in each bore a striking resemblance, both in that stage and in the most advanced, to the leprosym of the Greeks, which I can attest to from the case under my inspection. The primary ulcerations, as well as those in the throat, were harder, and with edges more callous, elevated, and irregular, than usual in the Leprosy of the Greeks, as also I have seen occasionally in the cases of our own country. The same character of ulceration was visible in the throat of this patient; and, immediately upon looking into it, I remarked to Dr. R., that this was certainly a form of leues, to which opinion Dr. J. gave also his full concurrence. It passes through the same stages as ordinary leues, from the throat to the skin, and, lastly, to the bones. I am therefore of the opinion, from what I saw, that the leprosym of the Greeks is a more formidable, and apparently a more chronic disease; but the ulcers, as far as I could satisfy myself, are to be attributed to the same parentage. If the leprosym of the patrarch of old was the same disease as the leprosym of Greece, and was always accompanied by the first and last stage, it can be considered as the same as the leprosym of Egypt, it is my opinion that the ancient leprosym is the great progenitor of them all, and that climate, habits of life, constitutions, and difference of race make all the modifications it has assumed in different countries and ages. I come to this conclusion without any feeling or wish to remove the odour which is unhandsomely thrown upon our country, of having given birth to so loathsome a malady. These convictions are the result of careful observation and mature reflection during my journeys in Egypt, Greece, and the East. We have no doubt, in our minds, that when the ancient leprosym and modern leues shall be more closely studied and accurately compared, their identity will be acknowledged. I do not wish to express my opinion of the Scriptures as the same as the present leprosym of the East, the question is narrowed down to small limits, and the infallible evidence of their analogy, that Eastern nations hold a leues person in the greatest detestation and abhorrence, inasmuch that they are made outcasts of society. They are
Leucorrhoea—

Symptoms of.

1. Symptoms of Leucorrhoea.

2. Leucorrhoea, in every form, and in most of the circumstances in which it occurs, is merely symptomatic, either of functional, inflammatory, or organic diseases of the female organs, or of disorder of the general health. It is unnecessary, therefore, at this place, to attempt to give a full account of the several states in which it appears in practice, as its chief symptoms are the forms necessarily comprised in the article under the principal diseases of the vagina and uterus.

4. Leucorrhoea may occur at any period of life from earliest infancy to advanced old age; but it is most frequent between the ages of 15 and 50. In childhood and early infancy discharges from the vagina and vulva are not infrequent, and are commonly the consequence of irritation or inflammatory action; the mucous membrane of the genitals partaking in the phenomena, and all the membranes to be irritated or inflamed at this period of life, and to furnish a copious mucous or muco-puriform secretion. About 45 years of age the disease becomes less frequent, and after 50 it is seldom observed, unless as a symptom of organic lesions of the uterus.

In childhood the discharge proceeds from the vagina and pudenda, and is a simple and primary disease; in old age it is chiefly from the uterus and vagina, and is generally symptomatic. During the period of uterine activity, it proceeds from either the vagina, or the internal surface of the uterus itself, or from any two, or all, of these situations; and is more frequently a consequence of pre-existing disorder than a primary affection. Owing not only to the situation or source of the discharge, but also to the state of vascular action and vital tone of the vessels which yield it, various appearances are presented by it; and hence, in the difficulty attending the investigation of the exact states of disease producing it, the importance of determining the circumstances of appearance of several appearances in the particular morbid conditions upon which they respectively depend.

The accomplishment of this object is not easy, nor probably can it be attained with great precision; still, if reached with even tolerable accuracy, it furnishes an important aid to the diagnosis, not only of the more primary states of this affection, but also of all the maladies of which this is symptomatic.

Hence the attempts of J. P. Frank, and of Sir C. M. Clarke to ascertain the particular part or parts chiefly or solely furnishing the morbid secretion constituting leucorrhoea, is of equal importance with a knowledge of the state of vascular action and vital tone in that part; and, consequently, that both these objects should be made the principal pathological points or facts to which medical treatment ought to be directed; and, although both are attended with difficulties, still these difficulties should not prevent the examinations requisite to the attainment of satisfactory information. The seat or source of the discharge is therefore

Authors:

1. Defin.—A light-coloured discharge from the female genitals, varying in hue from a whitish or colourless to a yellowish green light, or to a slightly red or brown; in consistence, from a limpid exudation to mucous,ropy substance; and in quantity, from a slight increase of the secretion to several ounces in the twenty-four hours.

2. Various forms of this disease have been pointed out by writers, according to its presumed seat or source, and to the several circumstances connected with it. Most of the older writers treated it as a consequence of local relaxation, or of general debility. Dewees viewed it as generally proceeding from local inflammatory excitement; Pinnel considered that it was sometimes accidental, constitutional, and vicarious. Dr. Ferguson has described it with reference to its seat, as vaginal and uterine. Dr. Ferguson has divided it into acute and chronic; and Dr. Ashwell into the common, the inconstant, and the symptomatic. Sir C. M. Clarke has described the varieties of leucorrhoea chiefly with reference to the character of the discharge, believing that the appearances presented by it are indicative not only of its source, but also of the state of vascular action and vital tone in that source. A somewhat similar mode was adopted by J. P. Frank; but the arrangements of these two eminent physicians were formed more as a means of distinguishing the inflammatory and organic diseases of the female organs, than with reference to the functional disorders of these parts.

3. Leucorrhoea, in every form, and in most of the circumstances in which it occurs, is merely symptomatic, either of functional, inflammatory, or organic diseases of the female organs, or of disorder of the general health. It is unnecessary, therefore, at this place, to attempt to give a full account of the several states in which it appears in practice, as its chief symptoms are the forms necessarily comprised in the article under the principal diseases of the vagina and uterus. Leucorrhoea may occur at any period of life from earliest infancy to advanced old age; but it is most frequent between the ages of 15 and 50. In childhood and early infancy discharges from the vagina and vulva are not infrequent, and are commonly the consequence of irritation or inflammatory action; the mucous membrane of the genitals partaking in the phenomena, and all the membranes to be irritated or inflamed at this period of life, and to furnish a copious mucous or muco-puriform secretion. About 45 years of age the disease becomes less frequent, and after 50 it is seldom observed, unless as a symptom of organic lesions of the uterus.
a matter of the first consideration, and hence becomes the most legitimate basis of an arrangement of its several forms. That the secretion is, in many instances, chiefly vaginal, is shown by the circumstance of pregnant females being often the subjects of it; although, even in them, it may partly proceed from the mucous follicles of the ovum of cervix uteri. That, again, the discharge may proceed from the inner surface of the uterus itself, is shown in some cases of prolapus uteri, and by a variety of circumstances about to be noticed (§ 35); and, as Dr. Ferguson observes, there is no reason for doubting that other causes of irritation than those dependant on uterine disorganization may likewise rouse the inner membrane of this viscus to unhealthy secretion. In severe forms of leucorrhoea, whether chronic or acute, the cervix uteri is rarely unaffected, being generally soiler, larger, and not infrequently more sensitive than natural. The portion, too, of the lining membrane extending through the cervix into the orificeumen internum is especially formed for active secretion; the palme plicate which radiate on it, and which become greatly developed in the progress of utero-gestation, and which pour forth such a quantity of mucus in the progress of labour, prove that it can be the seat of active secretion, and therefore proceed from its intestinal origin. The uterine secrections may proceed not only from the cavity of the uterus, but also even from the interior of the Fallopian tubes, appears to be shown by the histories of some cases, as more particularly mentioned by Frank and others. In the following account of leucorrhoea, I shall describe its forms with reference to their seats or sources, and to the grades of action characterizing them.

6. LEUCORRHOA VULVAE, Leucorrhoea Integumentalis—Intimate Larger. I. Distortion.—A discharge occasionally proceeds from the vulva and orifice of the vagina. In children it proceeds from the general surface of the external genitalia, and more rarely from the vagina, unless in delicate and relaxed children, subject to catarrhal and bronchial affections, attended by a copious defluxion, when it assumes a catarrhal form, or in those affected with worms, or other causes of intestinal irritation. When this form occurs in adults its source is often more partial or limited. In both children and adults it may assume either an acute, or subacute inflammatory character, or a chronic state. In the former state, its commencement is evinced by itching or local uneasiness, and by scalding in passing water; and the surface of the vulva is somewhat swollen and red. This condition is soon followed by a colourless, thin, mucous discharge, which becomes more and more copious, thicker, and of a white or yellow hue. It is sometimes so acrid as to excoriate the surface, and even the skin at the margin of the vulva. There is little or no symptomatic fever. In delicate, sickly, and relaxed children, the symptoms are milder, and are more disposed to the chronic form, which, however, may supervene upon the acute or sub-acute attack. In chronic infantile leucorrhoea the discharge is more profuse, milky, or puriform, and is attended by less pain, smarting, or inconvenience. In cachectic, plethoric, and scrofulous children; in those confined in hospitals, or in crowded, ill-ventilated, and low apartments, or in the ill fed and dirty, the disease may assume a very serious and totally different form, or may give rise to a state of phlegemous ulceration or gangrene, which is noticed in the article Vulva. Occasionally infantile leucorrhoea presents a catarrhal form, and is then sometimes associated with slight bronchial or laryngeal fever, or even with pneumonia. In these cases, the secretion from the mucous surfaces generally consists, at first, of a thin or watery mucus, and is thicker and more glutinous as the affection becomes more chronic. It is usually the result of irritation, and proceeds frequently from the vagina as well as from the vulva.

7. II. Treatment.—If the irritation be considerable, the parts should be fomented with a decoction of marsh-mallow leaves, or with any other emollient decoction, three or four times a day. After each fomentation, the black wash, or a weak solution of the sulphate of zinc, or of the acetate of lead, may be applied. When the affection becomes chronic or obstinate, a lotion of nitrate of silver, of gr. vj. to xj. to the ounce of water, is the most efficacious. If the irritation extend up the vagina, a little of the lotion may be injected by means of a small syringe. The patient must be debarr’d from rubbing, or having recourse to friction of the parts, and be kept cool. Care ought to be taken that the urine be not retained too long from fear of the smarting felt when passing it; and when smarting is much complained of, the vulva may be fomented, or bathed with warm water or poppy decoction after each evacuation. Cooling, diaphoretic, and aperient medicines may be given occasionally. The diet should be light, and chiefly farinaceus, and the bed-clothes light. If there be any tendency to adhesion of the labia vulva, lint and a little ointment may be placed between them. The parts ought to be duly examined, lest such adhesion should form. If they are early detected, they are readily destroyed by forcibly separating the labia.

8. Leucorrhoea Vaginale, Vaginal Leucorrhoea.—I. Symptoms.—This form of the disease is sometimes acute, and very frequently chronic.

A. In the acute form, it is simple vaginitis, or inflammation of the mucous surface of the vagina; and, in the more severe forms, is with difficulty distinguished from specific inflammation of the vulva and vagina (see Vaginitis and Vulva, General inflammation of).—a. The earliest symptoms are a sense of heat or soreness in the vagina, often with itching of the external parts. To these are subsequently added pain or smarting, with a sensation of tightness as if the vagina were swollen. If the attack extend along the vagina, there is sometimes a feeling of weight or bearing down, or pains extending down the thighs. The discharge, consisting of a thin, aerial, and colourless fluid, appears soon after these symptoms, seldom later than a day or two; but it soon becomes thicker, whiter, or yellowish, more purulent, and resembling cream. As the discharge increases, the uneasy symptoms abate; and it frequently continues varying in quantity and appearance in a more chronic or sub-acute form. In the early part of the acute stage, the mucous membrane is swollen, and the canal of the vagina is diminished, and it is hot and tender; but these soon subside as the discharge becomes
copious. There is no breach of surface nor erosions of the membrane. In some cases, the labia and vulva are swollen, and more rarely the glands in the groin are enlarged. When the complaint is slighter, the local symptoms are less severe, and little or no constitutional disturbance may attend it; but the more severe attacks are often accompanied with slight rigor and a temperature, followed by pain in the back and loins, by languor, thirst, or a quick pulse, and costiveness, with high-coloured urine, and smarting on passing it. The terminations of this state of the complaint are: 1. In the gradual subsidence of the symptoms and diminution of the discharge; 2. More frequently in chronic disorder, characterized chiefly by the continuance of the discharge, and of the languor.

9. B. The diagnosis of this state of leucorrhoea from gonorrhoea is frequently difficult, particularly when the requisite examinations are not permitted. Sir C. M. Clarke seems to think it impossible in most cases. M. Ricord, however, states, that it is easily determined by the aid of the speculum uteri. Whenever the peculiar erosions or minute superficial ulcers of the mucous membrane covering the cervix uteri, which have been noticed by M. Ricord, are discovered, there can be no doubt of the gonorrhoeal origin of the disease. These erosions or minute superficial ulcers are met with, he states, in nineteen out of twenty cases of the gonorrhoeal discharge. An urethral discharge is much more frequent in gonorrhoea than in simple acute leucorrhoea. M. Ricord states that, of two hundred cases of the former, eight in every twelve had the urethra affected. The glands of the groin are also much less frequently enlarged in leucorrhoea than in gonorrhoea. In general, the symptoms are much more severe, the calls to pass water more frequent, and the pains attending it greater; the extension of the disease to the uterus much more common, with the symptoms indicative of such extension more acute, than in simple acute leucorrhoea.—(See art. Vagina, &c.)

10. C. Chronic leucorrhoea vaginae—chronic vaginitis of Dr. Churchill—is a most common complaint. From the constitution and state of health of some females, and frequently owing to the continuance of the affection itself, it has been very generally viewed as a consequence of debility, local or general—of local relaxation. But a closer attention will often show that the local affection is often the result either of simple or of inflammatory irritation, more especially at its commencement. In many cases, also, it commences in the acute form already noticed, and passes into the chronic, the acute state being sometimes slight or of short duration.

11. a. The symptoms of this form of leucorrhoea are chiefly a more or less colourless or whitish and bland discharge from the vagina. In some cases, however, it is of a deeper hue, being greenish, yellowish, or brownish, and occasionally so acrid as to excoriate the edges of the vulva, and in some cases the insides of the thighs. There is scarcely any increase of heat, and little or no pain or tenderness. The inguinal glands are not enlarged. The patient often complains of weakness and of languor, or weariness after exertion, particularly if the discharge be profuse. The countenance becomes pale, and, if the complaint be prolonged, weakness or aching of the loins, and various dyspeptic symptoms are felt. When vaginal leucorrhoea is neglected, it may, especially in its more acute states, extend to the os and cervix uteri, or even to the interior of the uterus. Ultimately, it may be followed by prolapsus, or descent of the uterus, and increased constitutional disorder.

12. b. Diagnosis.—Chronic vaginal leucorrhoea is distinguished, 1st. From gonorrhoea, by the local irritation being much less in the former than in the latter; by the absence of sympathetic enlargement of the inguinal glands; by the whitish or colourless appearance of the discharge; by the absence of irritation or discharge from the urethra, and of scalding on passing urine; and by the less frequent calls to pass it; 2d. From uterine leucorrhoea, by the absence of the more prominent and constant phenomena attending that form of the complaint, by its not being increased before or after the menstrual period; and by the much less severe constitutional disturbance, and much less marked sympathetic phenomena.

13. D. Causes of the Acute and Chronic Vaginal Leucorrhoea—a. The causes of the acute or inflammatory state of this complaint are, chiefly, cold, violence, excessive indigestion; the circumstances connected with the transition from the virginal to the married state, rapid or frequent soon after delivery, inflammation extending from the vulva or labia; high or rich living, in connexion with habitually sitting on hot cushions; sitting on very cold seats, on stones, or on the ground, especially if accustomed to warm seats; irritation from foreign bodies or stimulating injections, or from inflammatory haemorrhoids, or other inflammatory diseases of the rectum. This form of the complaint is not frequent in unmarried and elderly females, and it is much favoured by the habits, modes of living, and disposition of the patient.

14. b. The causes of the chronic form of the complaint are both local and constitutional or general. The local causes are the acute state of the disease: irritations of various kinds, as of a pessary, or of excessive sexual excitement; displacement of the womb; frequent child-bearing, or abortions; the irritation of worms in the rectum, haemorrhoidal or other affections of the rectum; the local application of cold when unaccustomed to it, or warm, or relaxing ablations or fomentations; sitting and riding on warm cushions, and excessive indulgence in warm bathing. The general and constitutional causes are chiefly full and rich living and a neglect of exercise, favouring the determination of the circulating fluids to the genitals, as duly insisted upon by Sir C. M. Clarke; the influence of cold and vicissitudes of season and weather on the frame, but more especially of warm and tropical climates, as evinced among Europeans residing in the East Indies, and in other warm and intertropical countries; the abuse of spiritual and fermented liquors, previous debility and debilitating diseases; the excitement connected with hot and crowded rooms, with music, dancing, and mental impressions. The period of female life during which this form of the complaint is most common is from the appearance to the termination
of the menstrual epoch of life—the term of uterine activity. It may, however, occur either before or subsequently to this term.

15. E. Treatment.—A. In the acute state of vaginal leucorrhea, local or general vascular depléion, according to the age, habit of body, and strength of the patient, may be prescribed. If the symptoms be acutely inflammatory, this will be the more requisite, and should be aided by fomentations, by vaginal injections of warm water, and by hip baths. Subsequently, injections of a solution of acetate of lead or of sulphate of zinc may be resorted to. The patient should preserve the horizontal position, and sleep on a cool mattress, with light bed-clothes; and the practice of the above would be aided by the means of the cooling saline aperients. Refrigerant diaphoretics may also be prescribed. The diet should be light and spare, and the beverages cooling.

16. b. The chronic state of vaginal leucorrhoea very rarely requires even local depléion. Much more frequently tonics and astringents, either vegetable or mineral, are found necessary, and when the patient is debilitated or cachectic, they should not be neglected. The baths, and the preparatory copaiva balsams, have been recommended by many. I have often given, with much advantage, the copaiva and other balsams in the form of pills with magnesia; and if this combination acted upon the bowels, I have added either small doses of opium or of the compound ipecacuana powder, or of the compound storalx pill, with increased benefit. Dr. Dewers has employed the tincture of cantharides; I have had no experience of it in this complaint. It may probably be advantageously combined with the tincture of the sesqui-chloride of iron, which I have often prescribed with benefit in this disorder. Dr. Blandwell and others advise the eubha in tincture or powder, and the compound tincture of benzoin. These, and other tonics usually prescribed, are of great service when the complaint is limited to the vagina, and when there is irritation about the urethra; for the cupels, benzoin, and even the balsams, operate chiefly upon the urinary passages. In many cases, however, they are inferior to the preparation of coagulations of albumen combined with mineral acids, or the sulphate of quinine. When there are marked debility, relaxation, and pallor, the combination of the sulphate of iron, quinine, camporph, &c., as in the following pills, is very beneficial:

No. 256, R Camphora racem, Ferri Sulphatis, Quinino Sulphatis, άς 3.]: Ext. Anthelmintis, 1.9. : Balsami Pervari- ani, q. s. &c. Def. Podis, xxv. : quarkum cataput dosis vel tres, ha die terve uestcit.

17. Various local means have been resorted to with advantage; and, when the uterus is altogether unaffected, and the system is not predisposed to suffer from the sudden suppression of the discharge, they may be prescribed, but with more caution than I have known them to have been prescribed by several practitioners. Of these the most generally efficacious are the absorption of oak bark, or of eucalypta, or other astrigent barks, with especial advantage; and solutions of the sulphate of zinc, or of alum, or the nattate of silver, thrown up by means of a suitable female syringe. The strength of these astrigent solutions, usually advised, is frequently too great at the commencement of the treatment. I believe it to be more beneficial, as it is safer, to prescribe at first only one dram of the first, half a drachm of the second, and a scruple of the third of these salts to eight ounces of water, and gradually to increase the strength of the solution according to circumstances. These injections should be employed at first tepid, and the temperature may be gradually reduced. They should be administered slowly, while the patient is in the recumbent position, and twice daily. During the treatment, the cold shower bath, or the cold douche on the loins and hips, will be of service. The patient ought to take gentle and regular exercise in the open air, and attend to diet and to the state of the bowels, to be taken by means of the cooling saline aperients. Refrigerant diaphoretics may also be prescribed. The diet should be light and spare, and the beverages cooling.

19. Swelling and painful affections of the joints have been mentioned by Dr. Jewell as having sometimes appeared after the sudden suppression of leucorrhoea by injections. I have met with still more serious, and even fatal consequences, resulting from the use of strong injections, particularly when the uterus has been affected. Some years ago, especially, such occurrences were not infrequent, for the excellence of a practitioner was too often considered a proof of great partiality to these injections, in proportion to his boldness of temper. And even now, when the individual organs and members of the body are taken under the especial protection of their respective physicians—now, when there is a physician for the brain, another for the lungs, a third for the heart, a fourth for the liver, a fifth for the stomach, a sixth for the bowels, a seventh for the urinary organs, an eighth for the female organs, a ninth for the spine, and so on for every prominent viscous, feature, sense, and limb of the human microcosm—now that the division of labour and the numerical calculations, which are applicable to mechanics, to political economy, and statistics, have been transferred to medical practice by the small minds who are incapable of grasping anything beyond a few palpable entities or obvious truths, or of extending their views to the numerous connexions, combinations, and successive states of morbid action—now, when the scientific physician, who pursues his vocation with elevated views of his own profession and of all other branches of knowledge, and of its tendencies and objects, finds the very circumstances which improve his intellects, enlarge his views, and extend his mental vision to the more comprehensive, remote, and influential agents, relations, and results of disease, the strongest barriers he has to surmount in pursuing a successful career of practice—now, when ignorance, presumption, impertinence, absurdity, plausibility, and hasty plagues their several parts in forming the medical character, and in taking advantage of popular errors in the modes of exercising it—and now, when cant, rant, and quackery in religion, politics, government, and morals have infected the public mind, given currency to worthless pretensions, and extended its influence to medical science—the reflecting will not be surprised, nor will the judges be disappointed, when they find physicians, who winds are duly imbued with literature and science, and who believe that the human economy, both in health and in disease, can be successfully studied only as a whole, and in all its parts, relations, and connexions.
altogether overwhelmed by the crowd of noisy pretenders who obstruct the paths of science, knowledge, and honesty.

19. III. Leucorrhcea from Inflammatory Irritation of the Mucous Glands of the Os and Cervix Uteri.—This variety of leucorrhcea was first distinguished and connected with its source by Sir C. M. Clarke. It is characterized by the white appearance of the discharge, by pain in the lowest part of the sacrum, and by the state of the os and cervix uteri.

20. A. The symptoms are aching or pain at the lower part of the sacrum, or at the os cox-gys, and behind the pubis, increased by coughing or straining, or other actions of the abdominal muscles, and by sexual intercourse. The bladder and rectum are often irritable; and menstruation is occasionally difficult. The discharge, particularly in the more acute cases or early stage, is opaque, white, and resembling in consistence a mixture of starch and water without heat, or thin cream. It is readily washed from the finger after an examination, and is capable of being diffused in water. It is often much thicker than cream, and very tenacious. In this case it does not flow off, but remains in the vagina until excorisions to empty the rectum succeed, at the same time as the contents of the vagina. When it becomes more chronic, it is often connected with some degree of vaginal discharge, by which it is rendered more fluid; and it may be associated with uterine leucorrhcea, when it will be attended by the characteristic signs (§ 27) of that variety. An internal examination detects nothing unusual in the vagina, but the os and cervix uteri feel swollen, and are very painful when pressed.

21. Although irritation or inflammatory action of the glandular apparatus of these parts may generally be attended by a white discharge, still it must be admitted that a similar discharge sometimes attends other sexual diseases without the os and cervix uteri being materially affected. During the earlier stages of this affection, constitutional symptoms are either slight or absent; but if the complaint continue long, or if it be associated with discharge from the vagina or uterus, debility, pallor, and somnolence at the same time as the continuance of striction, costiveness, and various dyspeptic symptoms commonly result. Sir C. M. Clarke suspects that this state of disease, particularly when neglected, sometimes precedes the more serious organic or malignant lesions to which this part is liable. This is not improbable, especially when the disease occurs, and proceeds unchecked, in faulty constitutions, and where there is a tendency to malignant or structural changes. The character of the discharge in connexion with the state of the parts just mentioned forms the diagnosis of the complaint.

22. B. The causes of this variety are those already mentioned (§ 13), and more especially cold, irregular habits, excessive indulgences, especially after marriage, great muscular exertions, the suppression of the catamenia, mental excitement, high-seasoned food, late hours, balls, the other forms of leucorrhcea, &c.

23. C. Treatment.—During an early stage of the complaint, cupping on the loin or sacrum, abstracting blood according to the severity of the symptoms, and constitution, and habit of body of the patient, is generally requisite; and a repetition of it may be necessary. If the catamenia be difficult or scanty, a number of leeches should be applied below each groin a day or two before the expected return of this evacuation. The lip bath, or fomentations to the lower part of the abdomen and back, once or twice daily, will often afford additional relief. Injections of tepid water into the vagina three or four times a day, or of a tepid decoction of poppy heads, if pain continue, or if the bladder be irritable, and the horizontal position, are generally beneficial. The bowels should be kept open by gentle and cooling aperients, such as the tartrate of potash, the super-tartrate of potash with confection of senna, or castor oil. Active purging, especially by resins purgatives, ought to be avoided.

24. When this complaint becomes chronic, its removal is difficult, particularly if it be associated, as it often is, with uterine or vaginal leucorrhcea. In these cases, the horizontal position; frequent vaginal injections of tepid, anodyne, and gently astringent fluids; attention to the secretions and excretions, and particularly to the state of the bladder; regular, light, and spare diet, and alternatives suited to the particularities of the case, are usually required. I have been accustomed to administer two doses of potash, with precipitated sulphur, and either with confection of senna or with any aromatic syrup, taken every night, so as to procure one copious pulsatulous evacuation in the morning. If the bladder be irritable, demulcents, with the compound tincture of camphor and liquor potasse, will be serviceable, particularly if aided by tepid anodyne injections. If tenesmus occur, a small cupping on the sacrum, and a starchy or a little syrup of poppies, will be of service. In other respects, the treatment may be much the same as that advised for uterine leucorrhcea (§ 41).

25. IV. Uterine Leucorrhcea.—It is sometimes difficult to determine whether the discharge from the female organs proceeds from the vagina, or from the uterus, or from both; still, a tolerably accurate inference may be drawn, and it is often of consequence, as respects the treatment, that a correct opinion should be formed. It is not improbable that the uterus often is the affected organ, has been proved by the quantity of whitish or colourless fluid found in it after death, the female having been subject to leucorrhcea during life. Blattix states that, in nine cases out of twenty-four that he examined, the discharge proceeded from the uterus. The older writers believed that the uterus was the source of it in common with the vagina, without, however, stating the symptoms which are proper to the affection of this organ. Many modern authors entertain a similar opinion. Bagliii, Friend, Astruc, Manning, and Leake consider that the discharge proceeds chiefly from the uterus. Denman, Burns, and Hamilton distinguish, although briefly and imperfectly, the uterine and vaginal leucorrhcea. Dr. Lecock thinks it difficult to establish a distinction, and does not attempt it.—Dr. Blendell treats of vaginal and uterine leucorrhcea; whilst Gardiner, Carter, Dobbs, Lisfranc, and Nauche consider the complaint as one chiefly of the uterus. Sherold, Jorje, and Churchill have described the uterine variety at due length, and have
insisted upon the importance of recognising the existence of the uterine affection. M. Maxse has given the results of his examinations with the speculum in 193 cases, and they have been referred to by some very recent writers, but without remarking that these examinations were entirely of patients in a venereal hospital: a circumstance that entirely vitiates his data, if made the basis of inferences as to the female community in general. Bearing, however, in mind the description of persons thus examined, the results may be worth recording. In 23 of 193 cases, the uterine officioe was found dry; in 50 there was only a drop of discharge in the orifice; and in 130 the discharge was abundant. The orifice itself was in some quite healthy and pale; in others, red, or deep red; and in some deep red, granulated, and bloody. The following table exhibits the character of the discharge, and the state of the uterine orifice in 111 cases:

[Dr. W. C. Roberts, in the N. Y. Journ. of Med. and the Collat. Sciences, vol. iv., v., has, in a very able and comprehensive essay on the pathology of leucorrhoea, given a summary of the works of preceding writers in relation to its pathology, together with his own views, derived from a very extensive experience with the speculum. Dr. R. thus concludes his observations: "We have now presented to the reader fifty-nine authentic cases in which leucorrhoeal discharge depended upon organic lesion of the womb, or vagina; it would have been easy to have increased the number, but this would be unnecessary, for unless it can be shown that, which is contradicted by the united testimony of all who have published the result of their observations, leucorrhoea is also frequently seen to exist in the absence of any appreciable morbid state, these are surely sufficient to establish the real and symptomatic nature of the flux in question. In forty-six out of these fifty-nine cases, it is distinctly stated that the neck of the uterus was either swollen, red, livid, or granular; in two or three only it presented a natural appearance as to size and colour, the redness being confined to the internal lining membrane. In thirty-three out of the fifty-nine, ulcerations existed; in forty, the discharge was distinctly to be seen escaping from the os uteri; in others, this is not noticed; in five, the vagina was red; and in two only was the discharge chiefly follicular. The last statement sets at rest the idea that leucorrhoea is, for the most part, a vaginal disease; whereas its almost constant connexion with an inflamed state of the neck and internal mucous lining of the uterus and vagina is clearly demonstrated by evidence which we firmly believe cannot be successfully contested. With far other observation will serve only to confirm. The progress and effects of the inflammation are not the same in all cases; in some we find only the mucous membrane of the womb vascular and secreting an increase of its natural, or a somewhat modified discharge. In others, ulcerations of a more or less depth, extent, vividity, and variety of appearance are met with; in many cases associated with general or partial swelling and redness of the neck, with granular tubercles or papules, and with more or less redness of the vagina, in which case the follicular discharge of that part is usually much increased. Which of these lesions is the starting-point it is difficult, though of practical importance, to decide; but it is perhaps sufficient to know that such is their mutual dependence on each other, that each, when met with, requires special attention before coexisting ones can be removed. Thus, a muco-hysteritis may cease upon, or its cure result in the disappearance of a congestion of the neck; while the latter has equally been seen to subside upon the cure of an ulceration, or an ulceration to require the removal of one or both of the other morbid states, before it could be made to subside. So much as we believe to be, even in cases which present the appearance of great constitutional debility, the true pathology of leucorrhoea; and we flatter ourselves that we have, in the foregoing pages, drawn the attention of the profession to the fact, scattered about, we acknowledge, in many volumes, but not before insisted upon and illustrated with equal force and distinctness, of the dependance of leucorrhoea upon certain phlegmasial states of the vagina and uterus, of its being not a disease per se, but a mere symptom of disease in the parts by which it is secreted, and seldom, if ever, the result of simple atony of those parts, as has so long been surmised. Nor is the discharge alone, we apprehend, often, if ever, the sole cause of the debility which confessedly so often attends it, but which depends rather upon the constitutional irritation and derangement of the general health, consequent upon the existence of a chronic local phlegmasia. The error which Broussais so ably exposed relatively to certain cases of dyspepsia has been extended to the leucorrhoea question; the frequent effects of chronic gastro-enteritis and muco-hysteritis, and, to a certain extent, their pathology, are analogous, and their cure depends alike upon a judicious employment of a suitable antiphlogistic treatment, and the avoidance of the natural and artificial stimuli of the organs diseased. But, while we have questioned its frequency, and adduced abundant evidence to justify our incredulity, we have not wholly denied the rare but possible occasional indubitable occurrence of cases of either, dependent, if the result, upon a simple atony of the part, or an increase not appreciably morbid of the secretory irritation, upon which the phenomena of either depend. The term 'weakness' has long been a cloak for ignorance, and the more enlightened pathology of modern times has established that of all chronic fluxes upon a more rational and scientific basis. Few are not now known to depend upon a state of inflammation more or less acute: if there be other causes for the uterine, we have not encountered a case in which they were not counteracted by the discharges of the parts. The lesions of the vagina and uterus, with which we have shown that leucorrhoea is so invariably connected, are not sufficiently appreciable and seldom curable]
without the aid of the speculum, an instrument as indispensable in the treatment of the disease as the stethoscope in those of the heart and lungs, and to the proper use of which the errors of our predecessors on the subject of the uterine catarrh are referable. It is not even now—for two very obvious reasons, the disagreeable nature of the investigation, and the natural repugnance of both physician and patient to its use—the custom to employ it in the treatment of leucorrhœa. But if the physician can but become assured of its value and necessity in these cases, he will, in justice to his patient, particularly recommend and employ it. Its use will then become habitual, surprise at its proposal will soon cease to be felt; may, surprise may even be expressed if the usual means of full investigation be not resorted to, and the sufferer with leucorrhœa will look to be examined with the speculum as with much certainty as the phthisical one does to be Percussed and auscultated. The objections to its use must yield to the sense of its necessity and utility; and when conscientiously and properly urged, the speculum will be found, after all, few sensible and right-minded females who will object to its employment; when properly used, few will refuse to consent to a repetition. We trust that no other than a conscientious belief in both, founded upon our ideas of the nature and cure of the affection, and the opinion of others, impels our advocacy of it in the disease in question; and whenever it shall come to be generally employed, much suffering will be speedily obviated, many errors in diagnosis corrected, many a barren woman become the mother of children, and many a case of ultimate degeneration into incurable malignity will be prevented."

26. That it is important to explain the differences in the local and constitutional symptoms characterizing uterine and vaginal leucorrhœa cannot be questioned, and these have been well shown by Dr. Churchill. That the discharge may proceed from both the uteri and vagina in the same case, must be admitted; and that the vagina is seldom exempt when the uterus is affected, the discharges being generally kept up some degree of affection in the former, may also be conceded; still, a knowledge of the symptoms attending the affection of the uterus aids us remarkably in determining whether or not this organ is the chief source of the complaint.

27. A. Symptoms.—Uterine leucorrhœa is a more or less profuse discharge of fluid from the internal surface of the uterus, varying in colour; and is neither accompanied nor followed, necessarily by organic change. It may affect females of all ages, from the time of approaching puberty; and it may assume acute, sub-acute, and chronic forms; the first and second of these states occurring chiefly in the young, robust, or middle-aged. It may occur in every temperament and habit of body, but with varying local and constitutional phenomena.

28. a. Acute uterine leucorrhœa is not so rare an affection as Dr. Churchill supposes. I have seen several cases of it; and, in some, the symptoms have been so severe as to amount to inflammatory action, the disease being rather hysteritis, with copious discharge from the internal surface of the uterus, than simple uterine leucorrhœa. When gonorrhœa occurs in the female, it is very apt to extend to the uterus, and to simulate an extremely acute form of leucorrhœa, or to cause inflammation of the uterus. Acute uterine leucorrhœa is attended by considerable local suffering and constitutional disturbance; more or less pain or unceasiness is felt between the sacrum and pubis, or in the hypogastrum, and is increased upon firm pressure in the latter situation. The unceasiness extends to the perineum and vulva; and the patient complains of dragging or unceasiness in the loins, sacrum, hips, and thighs, sometimes with frequent desire to pass water, or with a desire of urination, standing, walking, or exertion, and are often accompanied with hysterical symptoms, quickened pulse, and thirst. On examination per vaginam, the cervix uteri is sometimes tender to the touch, or slightly swollen. The discharge varies in quantity and appearance; it sometimes is copious, and evacuated in considerable quantity, affording marked relief, when it becomes scanty or ceases for a time; and it afterward reaccumulates, and is discharged more abundantly. In these cases, the local and constitutional symptoms, varying much with the severity of the disease, and the state of the patient, indicate inflammatory irritation of, or vascular determination to, the internal surface of the uterus, with increased secretion in this situation. In some instances, the secretion seems to accumulate in the uterine cavity, and occasions an increase of the symptoms, especially of the unceasiness or pain in the vicinity of thesoft parts of the body, increase of the pain of the joints before its discharge. In some instances it has presented a puriform appearance, but it varies in different cases, and even in the same case.

29. b. The sub-acute state is merely a milder form of the preceding, and differs from it only in the greater mildness of the symptoms. If either this or the more acute state be not cured, it gradually subsides into the chronic, presenting, however, several exacerbations in its progress, particularly before or after the menstrual period, which it may in some cases even replace, with so marked an aggravation of all the symptoms as to amount to a form of inflammation of the uterus described in the article on that organ.

30. c. Chronic uterine leucorrhœa is a very common complaint; and, although it occasionally follows the preceding states, it much more frequently commences in slight disorder, or with a mild state of the symptoms above enumerated. As the complaint proceeds, languor, weakness in the loins, headache, aching in the joints after exertion, pallor of the countenance, with a darker shade of colour under the eyes, and increased discharge from the genitals, especially at intervals, or shortly before or for some time after menstruation, are commonly present. When it has become persistent, or so chronic as to affect the general health, and especially if it have superseded the catamenial evacuation, the local and general symptoms are much more severe. A constant aching or pain is felt between the pubis and sacrum, with a sense of dragging in the loins, or of weight and occasionally of bearing down in the pelvis.
The patient now often complains of headache, of languor, and indisposition to exertion, of exhaustion after slight exertion, and sometimes of vertigo and faintness, which, with the headache, are owing to debility and insufficient circulation in the brain. Pain is occasionally felt in the spine, or in the back of the head, and is accompanied by intolerance of light and noise. Sympathetic pains are often felt in different parts. The tongue is loaded, sometimes dry, yellowish, pale, sodden, or flabby, and often indented by the teeth. The appetite is impaired or capricious; the bowels and liver become torpid or insufficiently active, the face pallid, the eyes sunken and surrounded by dark circles, and eruptions of *acne pustata* appear on the forehead and face. At last the pulse is small, quick, and weak; the surface is flabby and pale, the ankles swell, and the countenance is waxy, yellowish, or chlorotic.

On examination per vaginam, the body of the uterus feels somewhat enlarged. The os uteri is a little more open than in the healthy state; but its sensibility is not materially increased. The French practitioners, and a few British, who delight in the parade of this mode of research, inform us that the *speculum uteri* should show the cervix uteri pale, slightly rose-colour, deep-red, or spotted; yet I suspect that few reflecting physicians will consider themselves much enlightened by the discovery, or will be induced to prescribe according to the shade of colour thus detected. Yet, the great fuss, parade, and seeming pains evinced, with the apparent object of getting at the truth, especially when it lies deep, are not without their influence upon the mind of the patient; and the knowledge supposed to be obtained thereby is considered great in proportion to the trouble and difficulty of procuring it.

The discharge varies much in quantity. It is sometimes profuse. In most instances it is colourless and semi-transparent; in others it is opaque, and presents either a yellowish, greenish, or brownish tinge. It varies in consistency, from a very thin or watery mucus, to a gelatinous mucus resembling the white of a raw egg, or to a carded-like matter in a few instances (Hamilton, Nauke, &c.). It is usually island; but Dr. Churchill has observed it so acid as to excoriate the labia and adjoining skin. I have observed this acridity in two instances of the complaint occurring in connection with the accession of the catamenia.

Chronic uterine leucorrhoea may continue for a very long period, and prove intractable, however judicious the treatment may be. Its duration will depend upon the constitution of the patient, and the causes which occasioned it. If those causes continue in operation during the treatment, as is very frequently the case, the complete removal of the complaint is not only difficult, but nearly impossible, until a change takes place in the patient’s habits and feelings.

B. Diagnosis. — The circumstances more especially diagnostic of uterine leucorrhoea are, as Dr. Churchill has justly shown, 1. The occurrence of the discharge in young, delicate females at one, two, or three of the monthly periods preceding the evolution of the catamenia; these causes indicate impotent action of the uterus, with deficient vascular determination. 2. The discharge of whites during subsequent monthly periods, where menstruation has been suppressed. 3. An increased discharge during two or three days previous to menstruation, and immediately after it, in those cases where leucorrhoea is more persistent; in these, the leucorrhoea may gradually diminish the catamenia, until it entirely supersedes, or becomes vicarious of it. 4. The occurrence of menorrhagia in connexion with leucorrhoea, the latter preceding or following, or both preceding and following the former, sometimes in great abundance, and occasionally continuing during the intervals between the menorrhagia. 5. The discharge of whites about the cessation of the menses, and the substitution of it for the menstrual discharge. 6. The appearance of leucorrhoea in place of the menses, in chlorotic females, as not infrequently observed. 7. The termination of abortions, or of the coloured discharge attending them, in leucorrhoea. 8. A similar transition of the lochia, after delivery, into the colourless secretion. 9. To these I may add, the copious discharge of the morbid secretions at intervals, and sometimes after an exacerbation of the local symptoms; and, 10. The local and constitutional symptoms characterizing the condition of the patient, as described. It should, however, be kept in recollection that uterine and vaginal leucorrhoea both often coexist in the same case; that the glandular irritation of the os and cervix uteri (§ 19) may be associated with either or both; and that, although vaginal leucorrhoea may often exist alone, uterine leucorrhoea, especially in a chronic form, and when the fluid is at all acid, will be accompanied with a discharge from the vagina, and occasionally even from the vulva also.

b. This variety is with difficulty distinguished from *uterine gonorrhoea*, unless the superficial erosions, described by M. Ricomp, be present. Still, attention to the history of the case, and the greater severity of the symptoms than even in the acute state of the complaint, will indicate its nature. In two cases of uterine gonorrhoea, which were treated by me in 1839 and 1841, and which occurred in recently married ladies, the symptoms were still more acute than those above described, and were consequently upon the affection of the vulva, urethra, and vagina. There were much heat, swelling, and pain in the parts, and in the region of the uterus, the uterine symptoms being exacerbated at intervals, and followed by a copious discharge of yellowish, opaque, puriform matter, occasionally coloured with blood, and generally increased immediately after the exacerbations. The discharge assumed a greenish hue after a time, and the disease subsequently appeared in the usual form of chronic uterine leucorrhoea, presenting many of the features of gleet in the male. The severity, character, and history of the case, and what has already been advanced on the subject, will generally disclose the nature of the complaint.

c. Inflammatory irritation of the glandular apparatus of the os and cervix uteri is distinguished from uterine leucorrhoea by the regular white puriform discharge, and the tenderness of the part on pressure, these characteristics being only occasional or accidental in the
latter. The slightest attention to the history of the case will prevent the discharge of the contents of an abscess of the uterus, ovary, cellular tissue, or adjoining parts, by the vagina, from being mistaken for this complaint.

38. C. The causes of uterine leucorrhoea are diversified, and are often inferred from various circumstances than from direct testimony or satisfactory proofs. They are constitutional, local, and mental; and individual causes belonging to these classes of influences may be variously combined in their operations in different cases. Delicate, susceptible, and scrofulous persons seem most predisposed to this complaint; and the inordinate indulgence of the emotions, especially of the desires, often concurs with other causes in producing it. Local excitement, venereal excesses, masturbation, and sedentary habits, or indolence, are certainly influential agents in developing it. Fatigue, over-exertion, cold, humid, and insanations localities, sedentary occupations, frequent abortions or child-bearing, undue or prolonged sucking, the use of enmenagogues, or of stimulating injections, or of pessaries; a too rich, stimulating, full, or heating diet and regimen; the suppression of other discharges; the too frequent use of restorative purgatives, and the irritation of intestinal worms, may severally, or in various combinations, be concerned in producing this form of leucorrhoea.

39. D. The nature of uterine leucorrhoea can hardly be mistaken. The concomitant signs of debility lead many to infer that it is a disease of debility, and proceeds entirely from relaxation of the internal surface and parietae of the uterus. This may be the case, in some degree, especially after the complaint has continued for a considerable time. Other, again, believe that the discharge is altogether owing to acute, sub-acute, or chronic inflammation of the internal surface of the womb, according to the forms it assumes, and that the local and constitutional symptoms are owing to these states of vascular action in the organ. Probably there are many cases in which inflammatory action truly exists; and others, in which debility, as respects the states of both the internal surface, and of the parietae of the organ, performs its part in itself. Others, again, may be in a case of inflammation exclusively to the one or the other; and that a third state, not necessarily connected with either, although sometimes associated with one or the other, is most frequently concerned in producing the discharge. If the circumstances connected with the occurrence of the complaint be duly considered, there is much reason to infer that it is often owing to the vascular determination to the uterus and female organs, generally consequent upon inattention or irritation of the nerves supplying these organs or parts; and that such excitement, and the vascular determination consequent upon it, are in some cases carried almost to the pitch of inflammatory action, as in the acute states; while in others, as in the more chronic, it is attended by impaired tone of the extreme vessels in the internal surface of the organ, and probably also, in some instances, with deficient tone of the parietae of the organ itself. The importance of correct views as to the nature of the individual cases occurring in practice is manifest; for upon these views must the treatment be altogether based.

40. E. Terminations.—When uterine leucorrhoea is neglected, it may give rise to very serious diseases, both local and constitutional. Amenorrhoea, amenia, chlorosis, sterility, phthisis, and even dyspsisy, are occasionally consequent upon neglected or prostrated states of this affection. These contingencies should influence our prognosis in many instances; but generally a favourable result may be expected in the less prostrated cases, and when the exciting causes are avoided.

41. F. Treatment.—On this subject, the observations of Dr. Churchill are extremely just, especially as regards the use of astringent injections, and agree with those which I have promulgated for many years.—a. In the acute and sub-acute states of the complaint, the local abstraction of blood by cupping on the sacrum or loins, or by applying a number of leeches below both groins, or to the vulva, [or as uteri,] when the catamenia are scanty or suppressed, is generally requisite; and, in some cases, a repetition of the depletion is necessary. The hip bath, and injections of warm water per vaginam, are subsequently of service. The bowels should be kept open by means of cooling aperients and laxatives, such as those mentioned above (§ 23); and small doses of camphor, of the liquor ammonie acetas and spiritus aethers nitrici, to which small quantities either of the vinum ipecacuanhae or of the liquor antimonii tartarisi may be added, according to circumstances, should be given every four or five hours. After the more acute symptoms have been removed by these remedies, the application of a blister on the sacrum, as advised by Dr. Leake and Dr. Churchill, and the repetition of it oftener than once, if the case be obstinate, will be found of great service; or either of the liniments (Nos. 296, 298, 311) in the Appendix may be kept applied, on two or three folds of flannel, as an embrocation.

42. b. In the chronic state of uterine leucorrhoea, blisters on the sacrum, or the terebinthinated embrocation on the sacrum, or loins, or on both; the occasional recourse to an enema with about an ounce of the spirit of rhubarb, with camphor and capsicum, in doses of about two or three grains of each, taken twice or thrice daily, are the means which I have found most beneficial. Dr. Churchill states that the medicines which he has found most useful are: 1st. The balsam of copalina, in pills, or otherwise, increasing the dose from fifteen minims; 2d. The sulphate of iron, with blue pill, or the composed rhubarb pill; 3d. Decoction of logwood; and, 4th. The ergot of rye, in doses of five grains, three or four times a day.

43. The tincture of the sarsaparilla of iron, with tincture of cantharides; the sulphate of iron, with camphor and rhubarb; and the sulphate of zinc, with aromatics, &c., have severally been prescribed by me with advantage. Iodine has been advised by Berra, Gimonial, and Sabailloles, especially in very chronic and obstinate cases. My experience of this medicine leads me to recommend a trial of it when the dyspepsia is associated with scanty or difficult menstruation, and when the system presents a pallid, anemic, or chlorotic appear-
the states of the digestive functions, and particularly of the bowels; and derangements of the menstrual discharge should be ascertained and removed.

47. The diet and regimen always require regulation. I have met with cases, particularly in connexion with a too copious or too frequent menstrual discharge, which appeared to have been prolonged by a too full and stimulating diet, in concert with a too liberal indulgence in drink. In these cases, the quantity and constancy of the food and drink of the patient should be strictly prescribed; and a separate sleeping apartment, and cool but sufficient clothing of the loins, hips, and limbs, early hours, and removal from the dissipations of the metropolis, ought to be directed, and continued according to circumstances. *

* [There is no disease in which treatment is more apt to be empirical than leucorrhoea. This arises from incorrect notions as to its pathology and treatment. The symptoms of the malady vary very widely from each other in degree, and require corresponding variations in treatment. If the discharge is of a mucous, transparent character, it will yield to very simple management, as astrigent injections, rest, abstaining from sexual intercourse, &c.; but if the disease is inflammatory, marked by a purulent discharge, hard pulse, increased heat about the genital organs, with swelling, or pain in the loins and hypogastric region, the antiphlogistic treatment must be promptly resorted to, as general and local bleeding, with applications to the vulva, or os uteri (Dr. Asaull recommends scarifying the cervix with a lancet]
mounted on a piece of whalebone), together with emollient and soothing injections, and the other means usually recommended in such cases.

In the treatment of leucorrhoea, especially when chronic, we have found an injection of the nitrate of silver very successful in arresting the discharge; also of tannin. Creosote may also be used with great advantage by mixing 20 drops of it with 5 of a solution of potash, 75 of the latter, rubbed together with 8 viij. of water, for an injection, to be thrown up three times a day. We have also found an injection of iodine succeed, after other remedies had failed. It should be employed by way of injection, prepared by mixing 5 viij. of iodine with 3j. of alcohol, and 3 viij. of water; one fourth part to be employed night and morning, using the compound tincture of the same article internally. A bit of sponge soaked in this solution, and passed high up the vagina, to remain in contact with the infected part, will often be followed by the best effects. A decoction or infusion of pyroda umbellata, dioxoma ocreata, or the pareira braea, or we have found almost specific in correcting the unhealthy state of the vaginal secretions, and restoring healthy action.

Dr. Kopf, in a recent number of Hecker's Annales, recommends the following mode of treating leucorrhoea, which he says he has frequently employed with advantage: A piece of sponge, of proper size to fill completely the vagina, is to be dipped into the following solution, and is to be applied to it at night, before going to bed: R Decoct. Ratanhus, 288.; Estr. Rutanthis, 88.; Tinct. Catechu, 88.; Tinct. Kino, 888. M. Dr. Cless states that he cures almost all the cases of leucorrhoea that occur in his hospital, at Stuttgard, with culeb.)

lichen simplex. In some cases, one crop of papule has no sooner disappeared than another is thrown out, and so on in succession for many weeks or months, and sometimes even for years. The varices of lichen simplex are:

9a. **L. Gyrate.** In this the papule are developed at the roots of the small hairs which beset the surface of the skin. The eruption is almost always of a chronic character, and is accompanied with great irritability of the skin.

Batem says that it is not infrequently connected with derangement of the digestive organs, induced by ardent spirits.

9b. **L. Linedus.**—This form is not common, and is nearly confined to constitutions broken down by want and misery, or to a cachectic habit of body. The eruption appears chiefly on the legs, and consists of dusky red papule, interspersed with petechiae differing little, if at all, from those of purpur simplex. The disease is often protracted through many weeks by the occurrence of successive eruptions. The papule, when declining, become of a dark brown colour, and finally disappear with slight exfoliation.

8c. **L. Circumscriptus.**—Sometimes the papule of lichen, instead of being irregularly scattered over the surface, are collected in groups of a somewhat circular shape, having a well-defined margin, and the disease then obtains the above name. The patches extend from their circumference by the development of new papule, while those at the centre disappear with slight desquamation. The patches in this manner often coalesce, new ones are formed while the old are desquamating, and the disease may thus be prolonged for an indefinite period. This form of lichen occurs inefficiently on the face, trunk, or extremities; it is most frequent in early youth.

9c. **L. Urticatus.**—This name has been given by M. Biérr to a rare form of the disease, in which the papule are arranged in a kind of tortuous stripe or band. MM. Cazeneve and Schédel describe a case in which this band, commencing at the anterior part of the chest, passed along the inner side of the arm, following exactly the course of the ulnar nerve, and twisting on itself till it reached the extremity of the little finger. Raver says he has seen it forming a kind of collar in front of the neck extending from one ear to the other.

10. **L. Strophulus.**—In this the papule are much larger than in the preceding forms, and coalesce into wheals somewhat resembling the sting of a nettle. **L. utricatus** is most frequent in children, but is occasionally met with in young persons of both sexes, and in females of more advanced age. It is usually confined to the neck and arms, but may also extend over the trunk and extremities. It sometimes disappears and recurs several times in succession, and is sometimes succeeded by a slight desquamation. It is occasionally attended with slight febrile symptoms, especially towards night, when the eruption causes more irritation. This form of lichen occurs principally in spring and autumn.

11. **L. Strophulus.**—This includes several varieties of papular disease, which are all most frequent in infants at the breast. The papule are sometimes red, irregularly scattered, and intermixed with small erythematous patches:

This is the *strophulus intortus* of Willan and Bateman, commonly called the *red gum*. Sometimes the papule are smaller, but more numerous, and collected in large red patches, constituting the *strophulus confusus* of the above named author, and commonly called the rank *red gum*. Less frequently, the eruption consists of small patches of papule, which appear and desquamate successively on different parts of the body: this is the *strophulus rotundus* of Willan and Bateman. In other cases the papule are of a whitish colour, small, hard, rather elevated, and sometimes, though rarely, surrounded with a slight redness: this is the *strophulus albidus*. At other times, again, the papule are of a whitish colour, but touch larger, smooth, and glossy: this is called *strophulus candidus*. The last two varieties are known by the popular name of *white gum*. All the forms of *L. strophulus* are frequently connected with dention, and derangement of the digestive organs; but they often occur, also, independently of these sources of irritation, and without any derangement of the general health.

12. **L. Lichen Agris—aypoe, Papula agrina, Celcus:** *Lichen ferrus*, Gomn.—This species is characterized by acuminate papule of a vivid red colour, very numerous, and accompanied with an exudation resembling blood serum, and sometimes coalescing to some distance around the margin of the patches. The eruption is attended with a sensation of itching and burning, which is so severe that the patient cannot refrain from scratching: this, however, greatly increases the irritation, and by tearing off the summits of the papule, occasions small ulcers, from which a sero-purulent fluid is discharged, forming yellowish crusts, which are detached and replaced by others somewhat thinner. The inflammation often subsides, and the scabs are cast off in about a fortnight; but sometimes the disease assumes a chronic form; the scabs become successively thinner, and terminate in furfuraceous desquamation. This chronic form is often attended with thickening of the skin, which in inveterate cases becomes indurated, rugous, and deeply figured. In this state the disease continues for many months, and may even last for years. *L. agris* is often attended with digestive derangement, and in its acute form, with febrile symptoms. It may appear as an original affection, or succeed to some of the forms of *L. simplex*. It is most frequent in spring and summer.

13. There is a form of *L. agris* called *Lichen tropicus,* or prickly heat, or summer rash—the *Sudamina* of various authors; the *Essera* of Pouquet—which is very frequent, and a source of intolerable annoyance in warm climates. It usually appears in the shape of numerous pimples of a vivid red colour, not larger than a pin's head, situated on the chest, neck, arms, and thighs, and sometimes on the forehead. It is accompanied with intolerable proicking, itching, and tingling. The eruption often disappears almost entirely when the patient is cool, but the moment he becomes heated by exercise, or by taking any warm or stimulating liquid, it recurs with as much violence as ever. New-comers to a warm climate are more liable to it than long residents or natives. A form of lichen, closely allied to the prickly heat, if not identical with it, is sometimes met
with in temperate climates during hot seasons.

14. II. CAUSES.—Lichen very often occurs without any assignable cause, but it is also frequently attributable to exposure to heat, errors in diet, fatigue, and depressing passions of the mind. L. agris, in particular, is often occasioned by heat and the abuse of alcoholic liquors. M. Rayé observes, that the arms and forearms of cooks, founders, smiths, and others habitually exposed to high temperatures, to whom may be added millers, grocers, and others who handle putrefactive substances, are frequently attacked with lichen simplex, or a papular eruption having the same characters. In the course of the eruption discs to be often dependent on intestinal irritation.

15. III. DIAGNOSIS.—Lichen may be confounded with various diseases. L. simplex has been mistaken for prurigo, seborrhœa, and eczema. Prurigo is distinguished by its papule being larger, flatter, and more of the natural colour of the skin than those of lichen; the itching in prurigo is also much more severe than in lichen simplex, and of a different character, being of a burning nature, and not accompanied with the tingling sensations of lichen. Scabies will be easily distinguished from lichen by its vesicular character, though a few vesicles are sometimes interspersed among the papulae of lichen. Scabies appears chiefly on the inner surface of the arms and wrists, between the fingers, and on the abdomen, while lichen affects rather the outer and back part of the extremities; lichen also frequently attacks the face, scabies hardly ever. Eczema may be mistaken for lichen simplex, but only through carelessness, it being easily distinguished by its transparent vesicles.

Syphilitic eruptions will not be confounded with lichen, as they are indolent, free from itching, and have the characteristic copper colour of veneral affections of the skin.

This form of lichen sometimes simulates impetigo and psoriasis, but it may be distinguished from the former by its small, thin, soft, slightly adherent scales, which are generally surrounded with inflamed papule; and from psoriasis by the squamous crusts of the latter being thicker than the furious without desquamating character of the last.

16. Lichen agris, in its chronic form, is very liable to be mistaken for the corresponding form of eczema, and where the skin is thickened, as frequently happens in the latter disease, the diagnosis is extremely difficult. On careful inspection, however, a few of the original vesicles of eczema, or papule of lichen, may generally be detected, which, with the history of the case, will determine the nature of the disease.

17. IV. TREATMENT.—Lichen simplex, in its acute form, usually requires but little treatment; a moderately antiphlogistic diet, a saline laxative, avoidance of exposure to heat, and a few tepid baths being all that is necessary. For allaying the itching, lotions with hydrocyanic acid are highly recommended; slightly stimulating lotions are also serviceable. In those few cases where the disease is attended with fever, gastric derangement, &c., a moderate venesection should be practiced, and a decidually antiphlogistic treatment pursued. The infantile forms of lichen, or strophulus, require no treatment apart from that of the morbid states which they may accompany, as intestinal irritation, the disturbances caused by dentition, &c. (See Antiphlogistics.)

18. Lichen agris, in its acute form, even when not attended with fever, is benefited by decided antiphlogistic treatment; and a venesection tends greatly to relieve the irritation of the skin. Leeches applied around the most inflamed patches are very serviceable, but care must be taken to place them quite beyond the limits of the erythematous surface. Other local means are seldom of much use; among the best are emollient poultices, applied scarcely lukewarm. Tepid baths are beneficial, as in the other forms of the disease.

19. The chronic forms of lichen generally require a tonic treatment. Decoction of bark with sulphuric acid is often very beneficial, and in obstinate cases the arsenical solution may sometimes be used with great advantage. In the advanced stages, when all acute inflammation has subsided, alkaline and sulphureous baths are among the best remedies that can be employed. An ointment containing calomel and camphor, or the proto-iodure of mercury, has been recommended by M. Cazes, and by Scherbel, to be applied to the diseased surfaces.

20. The lichen lividus may be considered as an entirely adynamic affection resulting from distress and starvation, or from a state of general cachexia, and therefore only to be remedied by improved circumstances, change of air, particularly when occurring in the inhabitants of large towns, by nutritious diet, tonics, and restoratives, conjoined with alteratives and debilities, according to the peculiarities of the case.
LIVER—Causes of its Diseases.

1. The importance of the liver in the animal economy has been variously estimated in different times and by different writers. The ancients considered this organ to be the origin of the venous system, and the laboratory in which the red blood is prepared. Some recent physiologists believe that the liver performs the function of oxidizing or combining as well as secreting, while others contend that it is restricted to the discharge of this latter function. It is, however, impossible to determine by experiments, in a satisfactory manner, how far an assimilating function is performed by this organ; but there is much reason to infer that it aids in changing the chyle in the portal and the general circulation into red blood—the extent of aid being, however, doubtful. Admitting, therefore, its chief function to be that of secretion, an additional question arises, viz., how far this function produces, at the same time, an excreting or depurating effect upon the blood, and on the economy in general. A number of years ago (in 1815) I entertained this question, and endeavored to show that the combination of those elements of bile existing in the blood in order to form this fluid necessarily tends to depurate the blood; and that the superabundance of these elements in the blood, and the circumstances conducive to such superabundance, as well as the marked effect of the discharge of bile, provided that the vital endowment and organization of the liver admit of the discharge of its functions; but to this topic more attention will be directed in the sequel. Thus, viewing the functions of the liver to be 1st, and chiefly, that of secretion, 2d, and contingently that of excretion, 3d, and concurrently that of assimilation; and havingraised the nature of the functions performed by this organ, although the exact amount of each, especially of the second and third of these, cannot be ascertained, I proceed to consider, 1st. The chief causes which disturb these functions. 2d. The principal disorders to which these functions are liable; and 3d. The diseases affecting the circulation and structure of the organ.

The three great depurating organs of the system, says Bemm, are the lungs, the liver, and the kidneys. Nitrogen predominates in the compounds which escape through the last-named organ, while the two former separate principally hydrogen and carbon. But it is to be noted, that in the lungs, the hydrogen and carbon pass off burned; that is, in combination with oxygen, as water and carbonic acid; while in the liver they escape uncombined with oxygen, and still uncontrollable. Of course, the larger the amount of these elements discharged by the lungs as water and carbonic acid, the less, ceteris paribus, must remain unburned to form constituents of bile. It is important for the practitioner ever to bear in mind this fundamental relation between the secretion of bile and the great function of respiration.

Lienau supposes, on the authority of Haller and Berden, that a man in health secretes daily from 17 to 24 oz. of bile; and he assumes that this amount is comprised in 90 parts of the oxygen of the air which gives from 816 to 1152 grains of dried bile. Now Bzerelius found that there were only 9 parts of a substance similar to bile in 1000 parts of fresh human faces. Reckoning from this proportion, the daily faces of a man, which do not, on an average, weigh more than 515, contain only 24 grains of dried bile at most, so that, according to this computation, the whole quantity of bile secreted exceeds the quantity that can be detected in the matters discharged from the alimentary canal in at least the proportion of 816 to 24, or 34 to 1. The chief part of the bile is, therefore, reabsorbed, and, as Lienau argues, no traces of it are found in the other excretions; the hydrogen and carbon it contains must evidently be discharged through the lungs in union with oxygen ("burned") as carbonic acid and water, whatever intermediate purposes it may serve. Of course, it might easily be shown that the carbon furnished by the bile can be but a small proportion of that given out in respiration, as 1359 oz. of carbon escape daily through the skin and lungs of a healthy adult, as carbonic acid (for 816 grains of dried bile contain 24 grains of oxygen, or sixty-nine per cent of carbon, give but 563 grains of carbon, or about 1 1/4th ounce). Although it cannot, therefore, he maintained that it is one of the chief purposes of the bile to support respiration and animal heat, as Lienau maintains, yet it is evident that the bile is chiefly reabsorbed and applied to this purpose after having served other at present unknown uses; for which, indeed, it is well fitted by its great solubility, and the large amount of carbon and hydrogen it contains.

It is, however, a popular doctrine in physiology, that the bile is mainly excrecentious, and is voided by the intestines, carrying off all matters rich in hydrogen and carbon that result from the waste of the tissues, and are not discharged from the lungs in union with oxygen. Of course, in this view, these organs, the lungs and liver, are strictly viearious in their office; and in support of this doctrine, it is stated that throughout the animal kingdom, whenever the lungs are large and active, the liver is small, and vice versa. Thus, in all cold-blooded animals—in which respiration is very feeble—the
LIVER—CAUSES of its Diseases.

LIVER is very large and excessively developed when compared with the lungs. But it is a very strong objection to this vicarious theory, that in serpents, whose respiration is extremely feeble, the excrements do not contain a particle of bile. Still, the relation of bile to respiration is direct and fundamental, as already shown; and as the activity and effects of the respiratory function are largely under our control, and as we have the power of modifying these by appropriate regulations having reference to the condition of air, exercise, temper of food, and food, we have means much more effectual than any other in dealing with biliary disorders. (See Bedd on Liver, Phil., 1846.)

2. I. CAUSES of Diseases of the Liver.—In order to prevent unnecessary repetition, while considering the several diseases of the liver, I shall take a general view of the causes which usually occasion them. These causes may produce various effects, or associated effects, according to the temperament, constitution, habits, and as respects the liver and biliary apparatus in general, the specific effects of these causes will vary with those and with other predisposing circumstances.

3. A. Age, Temperament, Diathesis. Habit of Body, &c.—Disease of the liver very seldom occurs until after puberty, unless in the children of Europeans residing in the East Indies or other intertropical countries, and when a change to a more temperate climate has not been adopted for them. It is more frequently observed in the temperate, semitropical, and irritable temperaments; in the scrofulous diathesis, and in a plethoric habit of body, than in others. In young or middle-aged persons the diseases which affect the liver are chiefly acute and inflammatory; at advanced periods of life they are most frequently congestive and structural. The infrequency of the affections of the liver until full puberty has been reached, is evidently owing to the much less frequent operation of their exciting causes before this period. In warm climates, diseases of the liver are more common in males than in females who are natives of Europe, owing to the greater exposure of the former to the exciting causes; but in temperate climates, and in this country, as far as the returns to the Registrar-general of Births, Deaths, &c., show the fact, these diseases are as frequent, or nearly so, in females as in males, especially in large towns.

4. B. High ranges of atmospheric temperature and the circumstances connected with them exert a very considerable influence on the diseases of the liver, although various other causes concur with these in producing the effect. It was long since proved by the experiments of Crawford, Lavoisier, Serbin, Prout, Fyfe, and the author, that the quantity of carbonic acid gas formed during respiration in a given time is much diminished in a high temperature, and under circumstances which lower the vital powers. Drs. Prout and Fyfe observed, in their experiments, that the changes induced in the blood by respiration were diminished during sleep, by the depressing influence, by fatigue, by spirituous liquors, low diet, and by all depressing agents. I found, in 1817, that the changes effected by the air in respiration in a warm, humid, and miasmatic state were even to a less extent, and furnished much less carbonic acid gas in a given time, than in those experiments which I performed in an artificially increased temperature in a cold climate; and this farther diminution of the changes produced upon the air during respiration in a very warm climate I imputed to the presence of malaria, and to the greater humidity of the atmosphere in this latter than in an artificial high temperature. If, therefore, less carbon and its combinations are evolved from the blood by respiration in a given time in a warm climate than in a cold one, while the quantity of carbonaceous materials conveyed into the circulation is equally great, it must follow that this substance will soon be greatly in excess, provided that the elimination of it from the blood is not effected by some other organ. Thus, one of two states may be expected to supervene during high ranges of atmospheric heat, or upon the migration of Europeans to intertropical countries; namely, that, owing to diminution of the changes effected by respiration in the blood, this fluid will possess highly venous characters, and abound in the elements usually eliminated from it during an active state of the respiratory actions; or it will experience changes equivalent to those produced by active respiration, owing to the increased actions of other organs; the diminution of the one function being compensated by the vicarious increase of others. Now, when the office of the lungs is insufficiently performed for the state and wants of the economy, those very elements which pass out of the blood by the veins channel accumulate in it, and furnish the materials for increased biliary secretion; the liver, aided by the skin, the kidneys, and the intestines, performing vicariously an increased function, and supplying the deficiency in the function of the lungs, until the economy becomes accustomed to the change.

5. In a high temperature also, when the air is saturated by moisture, a much less quantity of aqueous vapour is discharged from the lungs than in a cold and dry state of the air; and thus the excreta of the liver are more easily eliminated, which becomes excessive, if it be not excreted more freely by some other part of the economy. Hence the fluid excretions of the skin, of the mucous surface of the intestines, and of the liver, become so frequently augmented in warm and humid seasons, and in Europeans residing in hot climates.

6. C. Climate, and the various physical circumstances constituting climate and endemic influence, have great influence in producing the severe functional and constitutional diseases of the liver. Some part of the influence arising from climates is referrible to a high range of temperature, to malaria, and other states of the air; and yet it is difficult to account for the greater prevalence of hepatic disorders in one country than in another, when the physical circumstances constituting climate appear to be nearly equal in both. Thus, in Jamaica, these disorders are neither prevalent nor fatal; and yet in parts of the East Indies, where the same range of atmospheric heat and humidity is observed, as in this island, and where other physical circumstances, as sources of malaria, &c., seem nearly equal, they are ten times more prevalent than in it.

7. It is difficult to determine the exact in
fluence of great dryness or of great humidity of the air in the production of hepatic diseases. Probably more may be imputed to a very high range of temperature than to either. The influence of malaria in this respect, and of its combinations with humidity of the air, is probably rather indirect than direct and immediate, periodic fevers being the first morbid effect of this combination or consequence of these. In many places of India, where the range of temperature is very high, and at seasons when the air is very dry, primary acute hepatitis is often frequent among Europeans, while in warm, moist, and miasmatic localities, the hepatic disease is generally consecutive of other maladies. It would appear from the statistical report of the troops in the West Indies, that diseases of the liver are about three times as prevalent among them as among the troops in the United Kingdom, and occasion nearly five times as high a rate of mortality, while Mr. Annesley, and other writers on the diseases of the East Indies, estimate the average annual per centage of these diseases in the East to be treble what it is in the West Indies.

8. There are various localities, particularly in the East Indies, where hepatitis appears to be endemic, and where the peculiarities of climate, especially in respect of humidity, temperature, and the usually recognised sources of malaria, seem insufficient to account for the circumstance. How far the nature of the water and other physical agents may concur with the states of the air in producing this effect, cannot be determined in the present state of our knowledge.

9. The exposure to the sun’s rays, to vicissitudes of temperature, and to various allied causes, certainly aid in producing biliary disorders. The action of the sun’s rays on the head, and on the nervous system generally; exposure to the night air and dews, or sleeping in the open air, particularly after having been subjected to the rays of a very hot sun; sleeping on the ground, as in bivouacs and encampments; sudden alterations or transitions of temperature, and sleeping in the sun, occasion not unfrequently the more acute forms of biliary disease, especially in very hot seasons and climates.

10. Diet and regimen, next to temperature and climate, are most productive of hepatic disorders. Eating largely or frequently, especially of animal, rich, and highly seasoned food; stimulating the appetite and palate by a variety of incongruous dishes, and sauces, and spices, and wines, particularly in warm countries and seasons, are most influential causes of these disorders. It is probably owing to such full and stimulating diet that hepatic diseases are more common in the officers than in the troops serving in the West Indies.

11. The use of spirituous or other intoxicating liquors, especially in excess, is productive of the cause, and biliary disease a complication, of the more acute; in temperate countries, of the more chronic and structural maladies—although not, perhaps, to the extent generally supposed, especially when active, continued, or exhausting duties and occupations are performed. It is probable that some liquors are more injurious than others; that brandy and whiskey disorder the liver more than gin and rum; that the strong and brandied wines are more hurtful in this respect than the French and Rhine wines, and that spirits are injurious in proportion to the degree of concentration or strength in which they are used.

12. It is difficult to ascertain what influence, if any, should be imputed to unwholesome food, and to improper or incorrect aliment. The biliary channels, or gall-ducts, which may result, probably, have some relation to the nature of these causes, to the kind of ingesta, and to the impurities existing in the water. It is to be presumed, that, when the ingesta, whether consistent or fluid, is of a septic kind, the functions of the liver will be thereby impaired or otherwise disordered; or that congestion of its vessels, or accumulations of bile in its ducts, will be thereby promoted.

13. F. If irritating matters, whether dietetic or medicinal, taken into the stomach, pass into the portal circulation, they may occasion disease of the liver, particularly if they act conjointly with other causes. It is probable that unwholesome or too rich and heating food, and impure water, act in this way; the influx of an unusual quantity of insufficiently elaborated, or stimulating, or otherwise injurious chyle, and of hurtful fluids, into the general and portal circulation, irritating and inflaming the secreting structure of the organ and the portal vessels, or occasioning congestion of these vessels and alterations of the biliary secretion.

14. Mercurial preparations exert an undoubted influence in producing disease of the liver, either of an inflammatory or of an obstructive character. Dr. Snrkwen and Dr. Duck first noticed the occurrence of chronic disease of this organ after mercurial courses prescribed for venereal complaints. The most convincing proofs, however, of this effect of mercurials are adduced by Dr. Nicholl. Dr. W. Thomson states, that Dr. Chapman, of Philadelphia, ascribed the prevalence of hepatic complaints in his neighbourhood to the use of mercury for the cure of autumnal fevers; some old practitioners remarking that, previously to the introduction of the mercurial practice, hepatitis was scarcely known in it. Dr. Nicholl remarks that disease of the liver followed syphilis and chronic ophthalmia in a great proportion of the cases treated by mercury.

[Dr. Chapman remarks on this subject, that mercury, more than any other article of the Materia Media, has the power of exciting the actions of the liver, and it is a law of our nature, that all high excitement is followed by a correspondent degree of debility. From the circumstance of the prodigious employment of calomel in the treatment of our autumnal fevers and other diseases, it seems to be no unreasonable supposition that the hepatic apparatus, thus over-stimulated, should fall into collapse, and in this condition of exhaustion, torpor to take place in the portal circulation, productive of congestion, and phlegmonous phisic, induration, and other derangements. Doubtless in this mode do miasmata and high temperature, separately or unitedly, and the habitual consumption of ardent spirits, operate to the same effect.

As confirmatory of this view, it is stated by Dr. Somervail, a most respectable physician of the south of Virginia, who has practised medicine for nearly half a century in that section.
of the country, that till the introduction of mercury, a comparatively modern event there, into the treatment of autumnal diseases, hepatitis was hardly known, and subsequently it has most widely prevailed. — "(Lectures on the more important Diseases of the Thoracic and Abdominal Viscera, Svo. Phil. 1844.)"

15. The absorption of morbid or irritable matters from the digestive canal, especially during constipation, may act like other irritating and injurious matters already alluded to (§ 13). MM. Cruveilhier, Andræ, and Percy believe that these and all other irritating matters, when introduced into the abdominal venous circulation, exert an especial effect upon the secreting structure of the liver, and that they act in this way in other than by the extension of irritation from the duodenum along the common biliary duct to the other ducts and parts of the biliary organs, as supposed by many writers. Dr. Saunders states that the diseased structure may be traced in drunkards along the ducts to the gall-bladder and liver, the ducts being so thickened and contracted as not to admit of the passage of bile.

16. G. Indolence and sedentary occupations exert a manifest influence in causing the more insidious, slow, chronic, and obstructive diseases of the liver. It would seem that bodily exercises, especially such exercises and occupations as bring the abdominal and other muscles of the trunk into play, promote the portal circulation and the biliary secretion, and still more remarkably the free discharge of the bile into the duodenum. Inactivity, particularly in conjunction with full living, favours not only congestion of the liver, but also accumulations of bile in the ducts and gall-bladder, morbid states of this organ, jaundice, the formation of gall-stones, and structural changes of the organ.

17. H. The influence of mental emotions on the functions of the liver is generally admitted, and is evidenced by the occurrence of jaundice or of inflammations of the organ after violent fits of passion, and of functional and structural diseases of it after the continuance of anxiety and other depressing emotions. The mental depression, which often causes biliary disorder, is, in its turn, increased by the disorder it occasions, until at last the circulation and structure of the liver are more or less altered, the bile becomes less astringent, anxiety, and other lowering feelings have an evident effect in weakening the abdominal and portal circulation, and in impairing the functions of the liver to the full extent of function 1 have imputed to this organ (§ 1).

18. I. The occurrence of abscess in the liver after injury of the brain has been often observed, and generally imputed to an intimate sympathy existing between both these organs. But there is every reason to believe that the abscesses formed in the liver in such circumstances have often been consecutive upon inflammation of the veins or sinuses within the cranium. Abscess of the liver is sometimes also consecutive of purulent collections in other situations, or caused by the absorption of morbid secretions or puriform matters from other quarters, and by injuries of the joints, fractures, surgical operations and other occasions of phlebitis, as shown in the article Abscess (§ 24, 37, et seq.). However, it is not improbable that severe injuries, as concussions of the brain, sympathetically affect the substance of the liver, and develop acute disease of it. There can be no doubt that the exposure of the body, and more especially of the head, to the rays of a hot sun, is often concerned in producing those insidious forms of hepatitis rapidly passing into abscess, so often observed in India, particularly when aided by intemperance, and by exposure to cold and the night air, or by sleeping without, or with insufficient covering. Injuries of the liver itself, blows on the region of the organ and concussions of it, in falls, &c., are also not infrequently followed by the worst forms of inflammation to which it is liable, particularly in the East.

19. K. Other diseases are, perhaps, the most frequent causes of affection of the liver, more especially in warm, humid, and malarious climates. — a. In these the hepatic malady is generally consecutive of periodic fevers and other ailments; while in very hot and dry regions, diseases of the liver are more generally primary and acute among Europeans exposed to the sun. Various dyspeptic symptoms precede the more chronic and insidious affections of the liver, and comparatively few cases of intermittent or remittent fever occur in hot seasons, and more especially in hot climates and in India, without the liver becoming prominently affected if the fever continue but for a short time. In many cases, also, of continued fever, in these seasons and climates, the liver is prominently affected, and the local disease may continue in a chronic or latent form after the fever has been subdued; or it may be produced or developed into an acute state, by exposure either to the sun, or to vicissitudes of temperature, or by intemperance, during convalescence or soon afterward. b. Affections of the liver, particularly obstructions to the discharge of bile, are often consequent upon, or otherwise connected with duodenitis, or with congestion of the villous coat of the duodenum. In some of these cases the common duct may be obstructed by the swelling of the villous coat at the opening of the duct, and thus give rise to jaundice. Some writers suppose that the affection of the duodenum, or of the stomach and duodenum, acts sympathetically on the liver, and interrupts or otherwise affects the function of this organ, so as to manifest this and other related phenomena. According to M. Ribe, Andræ, and others, disease may be propagated, not only from the villous surface of the duodenum along the interior of the ducts to the liver, as indeed supposed by Dr. Saunders and others, but also from any portion of the intestinal canal along the veins to the portal ramifications in the liver. In this way some recent writers have attempted to account for the occurrence of hepatitis, or, rather, of puer-hepatis in connexion with dysentery: the puriform collections found in the liver in these cases are supposed to have been consequent either upon the passage of puriform or other morbid matters from the bowels into the portal circulation, whereby irritation or inflammation of the ramifications of the portal vessels had been occasioned, or upon a true phlebitis of the mesenteric veins propagated from the origin of these veins in the ulcerated intestines to the portal vein and its ramifications.
This subject, however, requires farther investigation.

21. c. The connexion of impaired function, or torpor of the liver, with severe or prolonged dyspepsia, is very manifest. They are both adynamic affections generally so intimately connected, that the one is soon followed by the other, that of the stomach being most frequently the primary affection. A similar remark also applies to costiveness and constipation. It was supposed by some writers that accumulations of fecal materials in the large bowels may so press upon the duodenum and ducts as to prevent the discharge of bile into the intestines, and that morbid secretions or other matters may so obstruct the opening of the common duct as to produce the same effect. There can be no doubt that, if the causes assigned as productive of the obstruction, were ascertained to be sufficient to occasion it, and if the existence of these causes in such a grade of sufficiency was satisfactorily proved, they should be viewed as efficient agents in the development of hepatic disorders; but, of themselves, it is probable that they are insufficient or frequent causes, and that they only concur with other circumstances, and are most influential when the bile itself is inspissated or does not flow readily along the ducts.

22. d. Of all diseases, the most intimately connected with hepatic abscess are dysenteric and chronic diarrhoea, particularly in the East Indies. From the accounts given of this association of disease, as well as from intimate observation of the cases themselves, it is most difficult to determine which is the primary affection. I believe that either may follow the other; that both may be coetaneous; and that more frequently the bowel complaint is the consequence of puriform collections silently and insidiously formed in the liver, without giving rise to symptoms so severe as to alarm the patient, and to cause him to relinquish his avocations, or so marked as to enable the physician to determine the nature and seat of the malady. As soon, however, as matter is formed, or collected in the liver, it is calculated to affect the organic sensibility of the bowels, particularly in its surfaces, and to awaken the sympathetic sensations of adjoining or related parts; or when the local irritation, or the passage, by absorption of a portion of the contents of the abscess into the circulation, then indications of its existence are manifested: in the first case, by pain, uneasiness, &c.; in the latter, by hectic, chronic, diarrhoea, or dysenteric symptoms. The history of many of these cases will show various dyspeptic and slight bilious disorders to have been complained of for weeks, months, or even years before the bowel complaint had occurred; and in some of the cases, where the hepatic affection seemed to follow the removal of the dysenteric attack, it had evidently existed previously to the disorder of the bowels, the removal or suppression of the one rendering the other, which had pre-existed, merely more prominent.

23. e. The occurrence of disorders of the liver consecutively upon diseases of the heart and lungs has been acknowledged since the connexion was insisted upon by Quin, Visart, and Powell. In these circumstances, particularly when the heart is diseased, congestion of the hepatic veins, often extending to the portal veins, is the first and chief disorder produced. The frequent connexion of fatty degeneration of the liver with pulmonary consumption is remarkable, and will be considered hereafter. Many writers have noticed the coexistence of diseases of the liver and of the brain, and have been at a loss to account for the circumstance. The coexistence is frequent, but not uniform, nor even general. It is sufficiently common, however, to deserve explanation, and is observable both when the mind is deranged and when it is unaffected. When we consider that both the liver and the brain are supplied, as respects their organic actions and functions, only with ganglial nerves; that these organs are hence intimately connected through the medium of this system of nerves; and that the circulation of both is peculiar, and in some degree removed from the circle of the general circulation, and is to a great extent influenced by the ganglial formations supplied to each, we cannot be surprised at observing a disorder and organic change often coexisting in both, so that the functions of both and functions are actuated by the same system, and by the powers exerted by that system; disorder of one part being soon followed by disturbance of other parts intimately related to it.

24. f. Suppression of accustomed discharges—of the haemorrhoids, or of the catamenia, or leukorrhoea, &c.—is sometimes followed by hepatis. The disappearance or drying up of eruptions, ulcers, &c., and the closing of sinuses, or fistulas, as fistula in ano, and operations for haemorrhoids or fistula, have been also sometimes followed by diseases of the liver.

25. Many of the causes above adduced may be insufficient singly to produce well-marked disease of the liver, although each may predispose to it, or even excite it, when acting in an intense form, or without intermission. More frequently two or several of them are combined, or act conjointly or in close succession, in developing the morbid effect; and so various are such combinations and succecessions of these causes in the most personal circumstances, and localities, that it is impossible to instance even a part of them.

26. l. Of the several races or varieties of the human species, the white or fair races are the most prone to diseases of the liver, and more especially to that state of disease which passes insidiously and silently on to abscess. Of these races, the sanguine temperament, the fair complexioned, and the scorfulous diathesis, the last especially, are most liable to this extremely unfavorable form of hepatitis, particularly during very hot seasons, or after emigration to a hot climate. On the other hand, the melancholic and the irritable temperaments, and the sallow and meager habits of body, are the most liable to experience the slighter or functional disorders, and the more chronic structural lesions of the liver. Numerous exceptions, however, occur to these general rules. Owing to the predisposition arising out of temperaments and constitutions, hepatic complaints are often hereditary, or prevalent in the branches of the same family.

27. The immunity of the dark races, particularly of the negro, from diseases of the liver,
is very remarkable, even in climates where these diseases may be considered endemic. I have, in other works, ascribed the immunity of these races, from these and other maladies, to the several points of difference existing between their organization and that of the white races. The former are constituted to live in a climate injurious to the latter—in warm, humid, and inlaminous regions; while the fair races are organized so as to endure, without material injury, the severities of winter, the changes of the seasons, and the vicissitudes of weather under which the greater mass of the darker races would sink. In the negro—the extreme grade of the dark varieties—the liver is small, and performs a more limited range of function, compared with the fair races. The same remark applies to the lungs; for I ascertained, by experiments made in a hot climate many years ago, that the lungs of a negro furnish much less carbonic acid gas in a given time than those of an European of the same size and similarly circumstanced. The skin of the dark races, however, performs a compensating function—one, in some respects, subsidiary to both respiration and biliary secretion, particularly as regards the depuration of the blood. The brain, also, in them, is better protected by nature from the injurious influence of a vertical sun than that of the fair races, and is less liable to experience the effects of such influence, either in the more sudden and severe forms of sun-stroke, or in those less appreciable states and affections of invagination, which disorder the hepatic functions more severely than even the cerebro-spinal influence and locomotive powers.

28. M. The causes which produce hepatic disease in Europeans in warm climates have been already noticed; but there are certain combinations of them that may be briefly enumerated. It is generally overlooked by medical writers, and is certainly neglected by those chiefly concerned, that nature intends the food and clothing of the inhabitants to be suited to the circumstances of the climate in which they live. The suggestions arising out of our sensations, reflections, and observation are unheeded in the quick succession and crowding of contending desires, and habits, and fashions; and health is sacrificed, and life endangered, to pamper the palate, and to follow the mode rather than adopt what reason approves of and our feelings suggest. The full, rich, and stimulating animal diet, which might be required, and readily disposed of in cold countries, by persons engaged in active occupations, is no longer suited to the European consummator when removed to a hot climate, and the more injurious does it become the more frequently it is indulged in, and the more it is accompanied with the use of the heating wines and other fermented liquors suited only to northern or temperate regions. The clothing, also, of those who leave the latter to reside in warm climates is rarely adapted to the novel physical circumstances in which they are placed. The head of the European, which nature has protected sufficiently in his native climate, is dangerously exposed with in the tropics, and requires a greater protection than is generally given it. In this particular, as well as in several others, fool-hardiness is characteristic of many. The common error is a total disregard of those accumulations of clothing to the differences and changes of temperature which often occur with remarkable rapidity in intertropical countries, and are more hurtful in these than in temperate climates.

29. Intemperance of all kinds, but particularly in eating and drinking; exposure to the sun, and subsequently to the night air, or to cold or wet, especially when the body is perspiring; copious draughts of cold fluids during fatigue; or in a state of perspiration; repeditions of the stomach after long fasting; addiction to warming and cooling draughts after fatigue and exposure to the sun, particularly either upon or near the ground; disappointments, grief, and the depressing passions generally, and the diseases above mentioned (§ 19, et seq.), are the most influential causes of the diseases of the liver in hot countries, and those to which soldiers and sailors in those climates are most exposed.

30. II. Of the Functional Disorders of the Liver. Under the head of functional disorder may be comprised all those changes of the biliary secretion which differ from the healthy state and lead to farther disease. These conditions generally are manifested in the quantity and quality of this secretion, and, although connected with changes in the state of the blood circulating in the liver, are not necessarily allied to inflammatory action or structural change; these latter states, however, being also and necessarily attended by alterations from the healthy function of the organ. This latter circumstance—this frequent dependence of disordered function upon alterations of vascular action, or of structure, or of both—requires from the physician the utmost care in determining the state and amount of disease. Even when the disorder of function is ascertained to be independent of these more serious changes, it should be recollected that it often passes into inflammatory states, or even into structural lesions. Indeed, these latter generally proceed from this source, either immediately upon the first functional disorder, or after repeated or prolonged attacks of it. The chief disorders which fall under this head are: 1st. Diminished secretion of bile; 2d. Increased secretion of bile; and, 3d. Secretion of morbid or altered bile. To these might be added, accumulations of bile in the gall-bladder and ducts; but as these arise from various circumstances, both functional and organic, and are followed by several changes both in the bile itself and in the parts containing it, this subject is more appropriately considered in the articles GALL-BLADDER AND DUCTS, AND CONCRETIONS, BILARY.

31. The three functional disorders of the liver about to be considered have been usually denominated bilious, without, however, any precise idea being annexed to the term, which has, even by professional persons, been applied to a deficient secretion of bile equally with an increased secretion. These disorders may be referred to two principal pathological conditions: 1st. The state of the blood, as furnishing the elements of bile; and, 2d. The state of organic nervous or vital influence, as acting both the hepatic circulation and the biliary secretion.

32. I have contended above (§ 4–8), and in other works, that the blood abounds, more or
less, according to modes of living and ranges of temperature, with the materials for biliary secretion. According to such abundance or deficiency, and to changes experienced by the blood during its circulation in the organ, so may it be supposed that the bile will be either abundant, or deficient, or altered.

33. That the vital or nervous influence will act not merely dynamically in promoting or imped ing the circulation and the secreting function of the liver, but also qualitatively, may be admitted, although this latter change may depend more upon the state of the blood than upon the condition of the nervous or vital power. Much will depend, however, upon the states of the stomach and bowels, in modifying the vital power and functions of the liver. The states of the stomach are often influential in promoting or impeding biliary secretion. When the vital actions of the stomach are energetic, those of the liver are usually co-ordinate with them; and when these actions are impaired, the functions of the liver equally suffer. Hence the general association of torpor or inactivity of the liver with indigestion; and the frequent supervention of biliary disorders. Of the other factors, the history of these, upon dyspeptic complaints, especially when the latter are neglected and prolonged. Disorders of the duodenum have a similar, and sometimes even a more remarkable influence on the functions of the liver; and, besides occasioning sympathetic effects, such as those which are produced by the stomach, they sometimes completely interrupt the passage of bile into the intestines, thereby disordering the secreting function and the secretion itself; and, if this obstruction continue, ultimately affecting the circulation and structure of the organ.

34. Diminished Secretion of Bile.—Torpor of the Liver.—Torpor of the Biliary Organs.

Classification.—I. Class: I. Order (Author).

Definition.—An irregular or costive state of the bowels, the stools being insufficiently coloured with bile; flatulency and various dyspeptic symptoms; a sallow or muddy appearance of the countenance; and lowness of spirits.

36. The circumstances more especially occasioning impaired action of the liver are, the neglect of exercise; sedentary occupations of indulgent indulgences; exposure to cold, humidity, or malaria after fatigue or excessive perspiration; copious draughts of cold fluids; habitual over-excitement of the stomach and liver, from eating and drinking rich and heating articles, particularly when these are suddenly withdrawn; and a neglected state of the bowels, or accumulations of secretions and fecal matters in the intestinal canal. When the duode num and intestinal canal are weakened, and when mucous or other secretions accumulate on their villous surface, the ingesta and bile poured into them fail of exciting their healthy action. Hence the emollient effect usually produced on the ducts from continuity of surface and consent of action is inefficiently performed, if at all; and thus a similar state of function to that existing in the digestive canal is extended to the liver. Habitual inattention to the due evacuation of the bowels thus becomes one of the chief causes of inertia of the biliary organs.

37. B. The symptoms of impaired action of the liver are not always very manifest; and it is often very difficult, or even impossible, to determine, even when these symptoms are well marked, whether they arise merely upon diminished energy, or upon change of the structure of the organ and of its appendages, unless we are acquainted with the patient's habits, and with the nature of his former ailments. When the patient complains—after having enjoyed good health, or without having experienced, on former occasions, either acute or chronic affections of the liver or stomach, or other severe diseases likely to have implicated the former organ—of dyspeptic symptoms, with a costive or irregular state of the bowels, the stools being pale or clayey, and the urina dark or high-coloured, or thick, after having cooled—of want of appetite, drowsiness or pain over the eyebrows, lowness of spirits and hypochondriacal feelings—of flatulency of the stomach and bowels, a foul and loaded tongue, and a bitter or disagreeable taste of the mouth, particularly in the morning—and of a dark, sallow, or muddy appearance of the countenance and skin, but without any pain, febrile movement towards night, or thirst, or chills followed by heat or hardness of the pulse, or fullness or tenderness in the region of the liver, it may be reasonably inferred that the functions of the liver are simply impaired.

38. When, however, the above symptoms occur in a person who has lived intemperately as respects either eating or drinking, or who has resided long in a warm climate, or who has suffered former attacks of hepatic disorder or protracted periodic fever, it may be inferred that the impaired function is associated with congestion, inflammatory action, or with some organic lesion of the biliary apparatus, more especially if any or all of the symptoms last mentioned be present.

39. When the vital energy of the biliary apparatus is impaired by any of the above causes, or exhausted by drunkenness, dissipation, &c., bile is formed either in diminished quantity or of deprived quality, and sometimes it is both the one and the other. When this state exists, and particularly if it have been of considerable duration, congestion of the portal vessels should always be dreaded, and its existence, as far as may be ascertained, ought to be carefully inquired after. Portal congestion having supervened upon torpor of the secreting function of the liver, the two morbid states tend to perpetuate and increase each other by mutual reaction, until enlargement of the organ, or chronic, or even acute attacks of inflammation of its substance take place, according to the concurrence of exciting causes and the predisposition arising out of the diathesis or constitution of the patient.

40. Torpor of the liver, then, may arise simply from a depressed or exhausted state of the vital energy of the organ; or from this state associated with accumulations of bile in the gall-bladder and hepatic ducts, or with congestion of the blood-vessels of the organ, or with both; the former disorder gradually inducing, and becoming complicated with, the latter de arrangements. Impaired secretion of bile is generally associated, also, with dyspepsia; and it often originates in that disorder, particularly in protracted cases. In many of these instan-
LIVER—FUNCTIONAL DISORDERS OF.

ces, the bile is not merely diminished in quantity, but it is also changed in its appearance and properties: it becomes viscid or otherwise vitiated, so as to flow with difficulty along the ducts, thereby causing a loaded state of them, obstruction, and, ultimately, vascular congestion, biliary concretions, and organic lesions.

41. It is comparatively rare that inaction of the liver is so complete as to amount to an entire suppression or arrest of its functions, unless in parietal cholera, and in organic lesions of the organ and biliary passages. When the vital action of the liver is so far suppressed as to render it incapable of combining the elements of bile into this fluid, however scanty or morbid, the circulation of these elements or materials in the blood, as shown in the articles Blood (§ 115-121) and Disease (§ 97), becomes most injurious and vitally depressing to the economy. This is fully shown in the pustulent malady just mentioned, and even in other cases and diseases where the actions of the liver are not entirely suppressed. In many of these latter (particularly when the inaction approaches and proceeds more gradually than in that malady), other organs, as the kidneys and skin, seem to compensate, in some degree, for the torpor of the liver, and to eliminate from the blood a portion of the injurious materials accumulated in it, owing to this cause. The connexion of this subject with the functional disorders of the gall-bladder, more particularly with inaction of, or accumulation of bile in the gall-bladder and ducts, with biliary concretions and with jaundice, will suggest a reference to these articles.

42. C. Treatment. — The means usually resorted to in this and in warm climates, in order to increase the biliary secretion, are mercurials in some form or other, and particularly calomel and blue pill, given at bedtime, and followed in the morning by a saline or other aperient draught. Various modifications of this treatment have been advised; in some cases large doses of calomel, in others moderate doses of Plummer's or of bluish small-pox pills, frequently saline purgatives, often a combination of tonic infusions, with the infusion of senna, and with salts. Each of these may answer the purpose, if judiciously employed. It is generally advantageous to combine Plummer's pill with soap, and to give, at the same time, full doses of taraxacum. Different modes of accounting for the action of mercury in these cases have been adduced. Some suppose that the mercury has the effect of stimulating the biliary apparatus; others believe that it acts only in the digestive mucous surface, by removing mucous collyriums from it, and exciting it so as more fully to emulsify the biliary ducts. It would seem, from experiments tried on some of the inferior animals, as well as from the well-known effects of the preparations of mercury, that they diminish inflammatory irritation of the villous surface of the stomach and duodenum, and carry off mucous matters from the intestinal surface. In this way they may diminish congestion around the orifice of the common duct, remove spasm or irritation of the ducts, and thereby favour a free discharge of bile into the intestines.

43. The next most efficient means of procuring a free secretion of bile, especially after mercurials have been prescribed, are the bitartrate of potash with confection of senna and extract of taraxacum; but the potash should be given in large doses, or in smaller doses with the biorberate of soda. Instead of exhibiting mercurials in so large or frequent doses as have been usually prescribed, these medicines, or those about to be mentioned, should be resorted to, and a full or decided dose of a mercurial ought only occasionally to be given; but generally it should be fairly but cautiously tried in the first instance. In some cases, Plummer's pill may be given every night, for some days, with the purified extract of aloes and soap, and a saline, or a bitter stomachic aperient in the morning.

44. If these means fail, and if no symptom appears to contra-indicate the practice, an emetic may be exhibited, and its operation promoted by diuretics or the warm infusion of chamomile flowers, with bitartrate of potash and biorberate of soda dissolved in it. Subsequently, blisters may be applied over the hepatic region; or the retro-nuxtic acid may be given internally, and also employed in the form of a lotion over the hypochondriac and epigastic regions. After blistering, I have seen advantage derived from wearing a large plaster over these regions, consisting of the emplastrum picis compositum and emplast. ammoniaci cum hydrogrydo. In cases of torpor of the liver unconnected with congestion of the blood-vessels, gentle tonics, with alkales, taraxacum, iodide of potass, or aperients, may prove beneficial; but when the torpor results from a passive engorgement of the biliary ducts, or from congestion of the portal or hepatic veins, recourse to these might be injurious, by developing chronic or acute inflammation of the organ. Much advantage, however, will be often derived, when the torpor is thus associated, from the continued use of deobstruant aperients, and an occasional recourse to a full dose of calomel, followed by a cathartic draught, with the view of carrying off the bile accumulated in the ducts, and the viscid secretions often adhering, in these cases, to the villous surface of the intestines. In these latter circumstances, the bitartrate of potash and biorberate of soda, conjoined with other medicines, according to the peculiarities of the cases, are often beneficial.

45. It is sometimes requisite to conjoin with the medicines employed to excite the liver a substance which may prove a substitute for the bile which is deficient. I have for many years prescribed inspissated ox-gall in this way, usually with the aloes and myrrh pill, or the purified extract of aloes, soap, taraxacum, blue pill, &c.

46. Several of the deobstruant and aperient mineral waters, as the Cheltenham, Beulah, St. sidehutz, Pulma, [Aron, Saratoga, and the Virginia Sulphur,] or other waters, may be taken in order to excite the action of the liver, and remove obstructions in the ducts. The causes of the disorder should be avoided; and change of air, travelling, and horse exercise recommended.

47. ii. Excessive Secretion of Bile.—Increased Biliary Secretion.

Class. — II. Class; I. Order (Author in Preface).

48. Defin.—Copious, fluid, alvine evacuations,
Highly coloured with bile, often preceded by griping, by nausea, and sometimes by vomiting, or attended by this latter, and acceleration of pulse.

49. Excessive biliary secretion is more frequently inferred from circumstances than proved by unequivocal evidence. Accumulations of bile may have formed in the gall-bladder and ducts, and when their discharge into the bowels has become imperceptible, the liver may possibly have expelled an excess of bile by exhalation from the intestinal villous surface, and so deeply tinge the stools, as to give rise to all the phenomena of increased secretion when only an increased discharge of previously obstructed or accumulated bile has taken place.

In this climate, particularly in summer and autumn, these occurrences are common, and are merely minor grades of the same pathological states which, in a higher degree, constitute bilious diarrhoea or bilious cholera (chillock se). Still in warm climates, and in warm seasons in cold or temperate countries, a more than usually abundant secretion of bile sometimes takes place, without amounting to severe diarrhoea or to cholera; the stools being fluid, bilious, and copious, and continuing in this state for a considerable time. This occurs more frequently in persons who have recently removed to a hot climate, owing to the cause above assigned (§ 4–8). It is evident from this, that excessive biliary secretion belongs to the same class of phenomena as is just mentioned, and that its pathology and treatment involve the same principles as they.

*We have stated that Burdach and Haller have estimated the amount of bile secreted, under ordinary circumstances in a healthy adult, to be from 17 to 24 4; but it was observed, on account of the activity of the liver, the quantity and quality of the food, if not in the quantity of matter thrown off by the skin. A very interesting case, showing the great amount of bile that is sometimes secreted for a considerable time together, was recently reported to the Medico-Chirurgical Society of London (Trans. Medico-Chir. Soc. Lond. Nov. vol. xxvii. p. 379), as follows: 'A strong, healthy man, 51 years of age, injured himself by lifting a heavy ladder, on the 28th of August, 1813. When seen by Mr. Barlow, the same day, he complained of so much pain in the region of the liver, and in its vicinity, that a rupture of that organ was apprehended. He was very faint, in a cold sweat, and the pulse could scarcely be felt. Some brandy and water was given him, and he recovered sufficiently to have walked a distance of some three miles. Five grains of calomel and a grain of opium were given him at night, and 51 of castor oil on the following morning, which produced several natural evacuations. On the 29th he was bled, and continued the calomel and opium, with a dose of saline mixture every four hours. On the 30th, it was observed that the evacuations from the bowels were white and without bile, while the urine was dark, as in pancy. Five grains of blue pill were ordered every six hours. As the pain in the region of the liver continued, the bleeding was repeated at different times, and a blister was applied over the right hypochondrium. The same medicine was continued till the 25th of October, when a swelling in the region of the liver, and a discomfort over the region of the liver. This gradually increased, and, on the 9th of October, was so large, and caused so much pain by distension, that it was thought proper to tap it. Seven pints of fluid were drawn off, which, from its colour and taste, appeared to be pure bile. The pain was immediately relieved, and the swallowing entirely reestablished. This case is remarkable, as being the first in which it was necessary to repeat the tapping on the 21st of the same month, when six quarts and a half of fluid were drawn off. This 25th of September, Mr. Taylor, and found to be composed in great part of bile. Dr. Rees guessed the proportion of bile in the fluid to be about eight quarts. Mr. Barlow thought it probable that the 21st of October he was tapped again, and seven quarts were drawn off. On the 9th of November the operation was repeated for the fourth time, and again four quarts were taken. Mr. Barlow suspected, on the 18th of November he was taken to St. Bartholomew's, and was tapped again, when nine quarts of fluid escaped. On the 20th of November he was tapped for the last time, when only three pints escaped. The eye was not employed, as on the former operation, and he suffered extreme pain from the tapping, which he had not previously done. On the 14th of November he was taken to St. Bartholomew's, and was tapped again, when nine quarts of fluid escaped. On the 20th of November he was tapped for the last time, when only three pints escaped. The eye was not employed, as on the former operation, and he suffered extreme pain from the tapping, which he had not previously done.

50. Dr. Abercrombie suspects "that the term bilious stools is often applied in a very vague manner, to evacuations which merely consist of their feculent matter mixed with mucus from the intestinal membrane." There can be no doubt of the vague manner in which pathological phenomena are observed by many, even of those who are the most critical, and in appearance to those who have seen bilious evacuations could confound them with those Dr. Abercrombie has mentioned. Those who are conversant with the diseases of hot climates well know that copious and frequent discharges of bile, the stools sometimes containing a large proportion of this fluid, simply from excitement of the organ, caused by the abundance of the biliary elements in the blood, not infrequently take place, and that similar discharges occur during bilious fevers, and when determination of blood to the liver is favoured by circumstances increasing or accelerating the abdominal venous circulation, or by causes irritating the liver itself, and even by the irritation produced by an abscess in a portion of the organ.

51. There is the best reason to suppose, namely, the evidence furnished by observation, that an augmented secretion of bile sometimes follows the more violent mental emotions, and occasionally precedes and even attends certain states of inflammation of the organ. It sometimes also attends or follows those affections and diseases, in which the requisite changes are not effected by respiration on the blood.

52. Respecting the causes, symptoms, and treatment of increased biliary secretion, it is unnecessary to add what has been already stated, both in the foregoing remarks, and in the articles bilious diarrhoea, bilious cholera, and gall-bladder.

53. III. VITIATED BILARY SECREATION—Morbid Bile.—A. There is every reason to suppose that the bile is not frequently possessed of morbid appearances or properties at the moment of, or just after its secretion; but that it acquires these properties after it has passed into the hepatic ducts and gall-bladder, and that during its remora or accumulation there, such properties are developed, either by the reaction of its elements or components on each other, or by the absorption of its watery or more fluid parts. That, however, the bile is sometimes secreted with remarkably altered appearances and properties, is proved by the pale yellow and albuminous state of that which is found in the gall-bladder and ducts of a few cases after death; but these alterations are only met with in lowing day bile appeared in his stools, and the urine was higher coloured. On the 30th of December the motions were of proper colour, containing plenty of bile. The swelling gradually subsided, and towards the end of the month he became slightly jaundiced and enteral. This subsided. Thus it appears that, from the 9th of October to the 21st, thirteen pints of fluid accumulated in the sac; and if, as Dr. Rees supposes, 60 pints of blood be lost, nearly ten pints and a half of bile must have been discharged—not far short of a put a day.

Another case, reported by Mr. Fryer, in the 4th vol. of the Med. Chir. Transactions, where a boy, 13 years of age, was affected in a similar manner, and the quantity of bile discharged still larger in proportion to the intervals. In this latter case, the outward symptoms were not, so far as they were observed, different from those of other cases; the discharges, as before mentioned, are not warranted, of course, in assuming from these cases that the same amount of bile is secreted under ordinary circumstances; or, at any rate, in drawing from such an estimate any important physiological inference not warranted by other reasons.—(Budd)
in connexion with chronic structural change of the organ. That the bile often presents a very dark greenish or greenish brown hue, or is tar-like in consistence and colour, and thicker and more acrid than natural, is indubitable. These characters are often presented even in the evacuations, but more unequivocally in dissections, the gall-bladder and ducts being loaded with bile of this description. Although it probably acquired these characters during its accumulation in these situations, yet it is not impossible that it possessed them to some degree from the first, especially as bile of this kind is often secreted after a generation of alimentation of the elements or materials of biliary secretion in the blood have been manifested.

54. It is unnecessary to adduce proofs of vitiation of the bile while it still remains in the system, as this has been proved by chemical analysis, and by the irritating effects sometimes produced by it when applied to several tissues, and even to the skin, although protected by the cuticle. These more vitiated or morbid conditions are, however, observed chiefly in malignant or pestilential maladies; the slighter modifications only of the secretion occurring in the more simple functional and inflammatory states of the organ. It is probable, that in cases of congestion of the portal and abdominal venous circulation, the bile is secreted with modified characters, and that it then often assumes a darker appearance, and more acrid properties.

55. A vitiated state of the bile may attend either a deficient or an increased secretion of it. The former association is in a few instances observed in dissections, what has been inferred to exist during life being actually proved by inspection after death. An increased, and, at the same time, a morbid or vitiated secretion and discharge of bile, is observed upon recovery from pestilential cholera, when, owing to the suppression of the vital actions of the liver, and to the abdominal congestion, the materials of biliary secretion have accumulated in the blood, and the restored function of the organ, acting upon a redundancy of these materials, furnishes an increased as well as modified supply of this fluid. A similar state of the bile is sometimes observed after partial asphyxia, and during or after an asthmatic attack, particularly when the functions of the liver are roused by chologeic purgatives. In these cases, the obstructed function of the lungs having caused an accumulation of the elements of bile in the blood, the liver, when its energy is restored, combines them into this fluid, which, owing to the redundancy of these elements, is not only increased in quantity, but is also more or less modified in its characters.

56. It is, however, most probable that the bile becomes vitiated in the majority of cases, or chiefly after it has accumulated in the gall-bladder and hepatic ducts; that the acrid properties it there acquires sometimes promote its discharge into the duodenum; that its action upon the intestinal mucous surface greatly increases the secretions and exhalations in this situation; and that its deep tinge is more or less imparted in the fluid stools thus produced, the secretion and discharge of bile thereby appearing greater than it really is.

57. B. The treatment most appropriate to vitiated, morbid states of the bile should depend upon the phenomena attending it. If it give rise to diarrhœa, griping, &c., dilute, demulcent, the warm bath, and other means advised in the article Diarrhoea (§ 57), small doses of ipecacuanha, with alkalies, anodynes, and gentle aperients, are often of service. If the irritation proceed so far as to give rise to symptoms approaching to bilious cholera, the means then advised should be employed.

—Syrup. Hepatigia; Dolor Hepatis; Colica Hepatica, of various Authors.—Severe Pains of the Liver. This affection has been noticed by Ackermann, Rocker, and others, and in the works of Bartholin, Blanch, and several other writers; and recently by Grossman, Andral, and Dr. Stokes.

59. It consists of very severe pain in the region of the liver—which is not accounted for by any organic lesion of this viscus or of its excretory ducts that can be discovered during life or after death—of severe pain without fever, swelling, or other indication of structural disease of the organ.

60. It is most frequently observed in the nervous temperament, and in hysterical persons. Dr. Stokes states that he has met with it only in females, and that in some of those a decidedly hysterical tendency existed, while in others this disposition was not indicated. In one case it seemed connected with what has been called "spinal irritation."

61. A. The principal symptom of this affection is the pain, which is more or less constant, but subject to occasional and violent exacerbations, in some cases, and in others more intermittent, the state of health being tolerably good during the intervals. The exacerbations, or returns of the pain, are often owing to mental emotions, over-excitement, derangement of the bowels, fatigue, irregularity of the catamenia, or the return of this discharge. The pain, during its exacerbations, is apparently more intense than in acute hepatitis, and is generally attended by tenderness of the hypochondrium and epigastrium. There is sometimes, also, slight jaundice; but generally there is no sign of structural lesion of the organ, except pain. Neither fever, nor swelling, nor thirst, nor biliary obstruction is present: the tongue is not loaded; the urine is not dark, turbid, or scanty; the stools are natural, or not materially disordered; and the functions of the stomach not greatly affected. Dr. Stokes remarks, that in several cases the patients were subject to neuralgic affections in other situations, as the face or extremities; in one severe case, dysmenorrhea had long existed. I have seen this affection connected with excessive menstruation, and with other disorders of the uterine functions. I have referred it, in more than one case, to excessive bleeding, and the use of mercury, and other exhausting or depressing causes.

62. The nature of the pains— their severity, the suddenness of their succession and disappearance, their intermissions, the good state of health in the intervals—all tend to the belief that they are the result of morbid sensibility, manifested in the nervous filaments orplexuses of the liver—of the nerves supplied by the great sympathetic or pneumogastric. Whether or no there may be, in some cases, latent caus-
es of irritation of these nerves, as biliary concrections lodged in the ducts, or in the gall-bladder, although not productive either of bilious obstruction or of vascular disturbance, has not been fully ascertained. M. André states that he has not found them in cases which he has inspected; but in one case, where hepaticgia had been complained of for many years, the gall-bladder contained a number of concrections; and in another, the patient had once experienced an attack which had been recognised as having arisen from the passage of gall-stones into the duodenum. The following is abridged from Dr. Stokes's treatise, as similar instances have since then occurred. Various habits and nervous temperament had been attacked, when in India, with pain in the region of the liver, which was imputed to acute hepatitis. She was largely bled and affected with mercury, without relief. On her passage to England, she was bled several times, and twice mercurialized. After her arrival, she experienced returns of the violent pain, for which she was also bled, leeched, blistered, and mercurialized. These means had afforded temporary relief; but the complaint returned with increased severity, her constitution became shattered, hysterical paroxysms were frequent and violent, and the stomach irritable. Finding that fever was absent, the right hypochondriac supple, the lower part of the chest sounding clear, the tongue clean, the complexion clear, the above treatment was inhibited, and generous diet, change of air, and full doses of the carbonate of iron were prescribed in the course of a few weeks the lady had recovered. Another lady had been treated from hepatitis, and was subsequently treated for another disease. A physician was consulted, who could not detect any evidence of hepatic disease besides the pain. She was treated by the carbonate of iron with complete success.  

63. A lady who had resided in India, and experienced hepatic disease, for which she had been bled, mercurialized, &c, on her return to this country consulted an eminent acconcheur, on account of leucorræa and uterine disorder. She was hysterical and much weakened; and, in this state, she suffered a severe attack of hepaticgia, which was mistaken for hepatitis, and treated accordingly, with marked aggravation of the pain. The disease was viewed as neuralgia, upon my visiting her, and a treatment conformable to this view soon restored her to health. Instances, however, are continually occurring of disease—not merely of this kind, but also of various seats and forms—being aggravated, and the constitutional powers injured, by the empirical and routine practice of bleeding, mercurializing, over-dosing, and over-drugging; and although these practises are less remarkable now than twenty or thirty years ago, they are still notorious, and furnish arguments for the knaves of homeopathy, of hydropathy, and of other kinds of humbug, to assail the public mind.  

B. Of the Treatment of hepaticgia, it is unnecessary to add anything to what is stated respecting the removal of 

65. Connected with functional disorders of the liver, the reader is referred to Bilious Disease and Choleræ; Gall-Concretions, Biliary; and Gall-bladder and Ducts.  

66. II. CONGESTIONS OF THE LIVER, Sanguineous and Biliary.  

Classif.—L. Class.; I. Order (Author).  

Definit. Dyspeptic symptoms; costiveness or irregularity of the bowels, the stools being more or less unwholesome; loudened tongue; oppression at the scrobiculus cordis; a pale, sallow, or muddy state of the complexion, and often an increased bulk of the liver, as shown by percussion.  

68. Congestion of the liver is of frequent occurrence, but in various grades and associations. Congestion, as shown by Mr. Kerrnan, may be confined chiefly to the hepatic veins, or it may exist in the portal vessels, or in both. These states of sanguineous congestion may be associated, especially when considerable or prolonged, with biliary congestion.  

69. The slighter states of congestion, more particularly partial congestion, are often met with in dissections, particularly when the patient has died from disease attended by difficult respiration. Mr. Maclean has observed, that in partial congestion, the liver and spleen are often pink in colour, and though it has been supposed that these states often can hardly be considered as amounting to actual disease, but are rather consequences of the changes immediately preceding and attending dissolution; but they frequently assume more decided and serious forms; and, although the attendants, or merely the precursors of several serious maladies, they often present themselves as primary and simple affections. They may be arranged as follows: 1st. Partial Sanguineous Congestion of the Liver; 2d. General Sanguineous Congestion of the Liver; 3d. Biliary Congestion.  

70. A. The first, or partial congestion, may exist in either of the series of vessels concerned in the double circulation of the liver. But before I proceed to notice the two varieties of partial congestion, I may premise that the researches of Mr. Kerrnan have shown that the differences which have arisen between Malphigii, Reussch, Ferrein, Autenrieth, Meckel, Mappe's, M. C. T., and P. Herber's, are instances of anatomists having examined livers in different states of congestion in respect of the hepatic and portal veins; that the structure of the lobules* is similar, and the

---

* The lobules are small granular bodies, about the size of millet seeds. Each lobule is composed of a plexus of biliary ducts, of a venousplexus, formed by branches of the portal vein, of a branch (intralobular) of an hepatic vein, and of minute arteries; nerves and absorbents, it is presumed, also belonging to their formation. If we cut into them. Examined with the microscope, a lobule is apparently composed of numerous minute bodies, of a yellowish colour, and containing blood-vessels connected with other vessels. These minute bodies are the actis of Malphigii. If an unincised lobule be examined and contrasted with an incised lobule, it will be found that the actis of Malphigii in the former are identical with the injected lobular biliary plexus in the latter, and the blood-vessels in both will be easily distinguished from the ducts.—Kerrnan.

Thus each lobule receives a branch of the portal vein, which rams into its margins and a minute artery, the portal vein and artery being distributed to it; and gives origens to an hepatic duct and an hepatic vein, which vein forms a small trunk in its centre, and returns the blood, circulated into the lobule by the portal vein and artery, to the general circulation.  

The following excellent summary of the anatomy of the liver is given by Mr. Erasmus Wilson, in his admirable work on anatomy: *The liver has been shown to be composed of lobules; the lobules (excepting their bases) are im-
same throughout; that one part of a lobule is actually not more vascular than another; and that there is, therefore, no distinction of red and white colour in the liver, the red colour resulting from congestion only, and, according as the congestion is in the hepatic or portal veins, appearing in the central or marginal portions of the lobules.

71. As Mr. Erasmus Wilson has succinctly and clearly stated, each lobule is a perfect gland, of uniform structure, of uniform colour, &c. "It is the seat of a double venous circulation, the vessels of the one (hepatic) being situated in the centre of the lobule, and those of the other (portal) in the circumference. Now the colour of the lobule, as of the entire liver, depends chiefly upon the proportion of blood contained within these two sets of vessels; and so long as the circulation is natural, the colour will be uniform. But the instant that any cause is developed which shall interfere with the free circulation of either, there will be an immediate diversity in the colour of the lobule.

72. "Thus, if there be any impediment to the free circulation of the venous blood through these hepatic vessels, the hepatic veins will be retarded, and the sublobular and the intralobular veins will become congested, giving rise to a more or less extensive redness in the centre of each of the lobules, while the marginal or non-congested portion presents a distinct border of a yellowish white, yellow, or green colour, according to the quantity and quality of the bile it may contain. This is 'passive congestion' of the liver, the usual and natural state of the organ after death; and, as it commences with the hepatic vein, it may be called the first stage of hepatic venous congestion.

73. "But if the causes which produce the state of congestion continue, or be from the beginning of a more active kind, the congestion will extend through the lobular venous plexuses into those branches of the portal vein situated in the interlobular fissures, but not to those in the spaces, which, being larger, and giving origin to those in the fissures, are the last to be congested." In this second stage the liver has a mottled appearance, the non-congested substance is arranged in shaped, circular, and round, yellow patches, in the centres of which the spaces and parts of the fissures are seen. This is an extended degree of hepatic-venous congestion; it is 'active congestion' of the liver, and very commonly attends diseases of the heart and lungs.

74. "There is another form of partial venous congestion which commences in the portal vein; this is, therefore, portal-venous congestion. It is of very rare occurrence, and Mr. Kierman has observed it in children only. In this case, the congested substance never assumes the deep red colour which characterizes hepatic-venous congestion; the interlobular fissures and spaces, and the marginal portions of the lobules are of a deeper colour than usual; the congested substance is continuous and cortical, the non-congested substance being medullary, and occupying the centres of the lobules. The second stage of hepatic-venous congestion, in which the congested substance appears, but is not cortical, may be closely conformed with portal-venous congestion.

75. "These are instances of partial congestion, but there is sometimes general congestion of the organ. 'In general congestion the whole liver is of a deep red colour, but the central portions of the lobules are usually of a deeper hue than the marginal portions.'"

76. The second stage of hepatic-venous congestion, when combined with biliary congestion, gives rise to those varied appearances which are observed in children's or mature liver.

77. When the circulation of the liver is impeded in consequence of depressed organic nervous or vital power, or of any other cause, or when the circulation through the capillaries of the lungs is interrupted, or when the general circulation is embarrassed by disease of the orifices or valves of the heart, congestion takes place in the liver. A slight degree of obstacle in the lungs or heart causes congestion of the hepatic veins only, the venous turgescence being limited to these, and a greater degree of obstruction produces congestion of the lobular venous plexus itself; and if the obstacle continue, or is increased, the congestion extends through the interlobular fissures into the neighbouring lobules, and, in a more advanced degree, it spreads itself throughout the whole of the lobules and becomes general. From the liver the congestion extends to the alimentary canal, occasioning haemorrhoids, intestinal haemorrhages, &c.; for, although the portal vein receives its blood from two sources, viz., from the chylus-visible, and from the capillaries of the hepatic artery, yet the blood of the blood of the latter vessel having passed through its capillaries into the portal vein, or in extremely small quantity into the capillary network of the lobular venous plexus, is sufficient to establish its venous character.
The liver at the same time, particularly in hot climates, is more or less swollen, so as to extend, in some cases, below the margins of the ribs, but more frequently to rise higher than usual in the right thorax.

Congestion is often present, but in various degrees. In the slighter grades it may be the chief lesion, and in these it is merely one of function, depending principally upon deficient vital energy of the organ, or upon temporary impediments in the way of the passage of bile along the common or hepatic duct. In its more chronic, general, or severe states, it may be consequent upon hepatic venous congestion, which causes pressure upon the lobular biliary plexus and interlobular ducts. It may also set in function of the hepatic vessels, and is due to a prolonged turgescence or thickening of the mucous lining of the ducts, or from capillary congestion or inflammatory action, diminishing the caliber of the ducts. This obstruction, as Mr. E. Wilson remarks, may subside after a shorter or longer period; or it may become chronic, and be a permanent impediment to the current of bile. Congestion, however, of the bile ducts, is probably more frequently caused, when slight or temporary, by causes affecting the states of the biliary or nervous, or vital influence of the organ, and, when more chronic and severe, by morbid states of the bile itself, rendering it disposed to become viscid and thick, and thus to flow with greater difficulty along the ducts ("Difficult bile tumultuous."—Hor.) and by mechanical obstacles in the large ducts.

Of these last, the most common are the impaction of biliary concretions in the ductus communis, or hepatic duct, inflammation of these ducts, enlargement of the absorbent glands in their vicinity, and the pressure of these or of other tumours, disease of the pancreas, turgescence of the mucous coat of the duodenum, and other changes fully described in the articles Gall-Bladder and Ducts, andJaundice.

79. In proportion, generally, as the obstacle is complete, so are the ducts loaded with bile, which imparts a deep yellowish, or yellowish green, or deep green, or greenish brown tint to the organ. Much, however, both of the tumefaction and depth of colour depends upon the ducts of the nervous, or of the biliary ducts, or upon the contraction attending the biliary congestion, the hepatic veins being generally loaded in chronic cases of biliary accumulation. When one of the bile ducts is obstructed by a biliary concretion, the branches above the obstruction become dilated and filled with bile, which is thick and viscid when the obstacle has been of some continuance; but this subject is more fully discussed in the articles just named, and in that on Concretions, Biliary.

80. In Nervous. Whatever directly or indirectly depresses the vital energy of the liver, necessarily impairs the tonicity of the veins and favours congestion of them. That the portal veins are more frequently the seat of congestion than is usually supposed, may be inferred from their removal beyond the direct current of the circulation, and from their forming a circulating system of themselves, depending entirely upon their own vitality and that of the liver for the due performance of their circulatory function. The circumstance of the portal vessels being found less loaded than the hepatic veins after death, is no proof of the absence of congestion of them during life; for, being endowed with certain of the properties of arteries, they also possess, in some degree, that of contracting or of emptying themselves partially at the moment of dissolution.

81. The ingestion of much food and fluid farther promotes congestion of the portal system, inasmuch as a part of these materials find their way directly into the veins which pour their contents into the portal vein; and, although such supply of new materials may not materially affect the robust person who promotes the circulating and secreting functions of the liver by regular and sufficient exercise, yet, when we introduce into the portal and the hepatic veins of the weak, the dyspeptic, the predisposed to disorder of the biliary organs, particularly if they be indolent and doomed to sedentary occupations, and favour a morbid secretion of bile, and accumulations of it in the ducts and gall-bladder. Of the causes of the congestive conditions of the liver, the most influential are high ranges of temperature followed by sudden changes, and exposure to cold or to moisture and malaria; too much animal food; intemperance; over-exercise, particularly in the open air; periodic fevers, and the other causes above adduced (§ 19, et seq.).

82. It ought not to be forgotten that an accurate examination will detect congestions of the liver—sanguineous, or biliary, or both—at the commencement of many diseases, especially of periodic and continued fevers, and of inflammations of the organ. They not infrequently originate, when neglected or improperly treated, other maladies, particularly inflammations, bilious fevers, dysentery, cholera, haemorrhoids, &c.; and they often attend or follow periodic fevers, and diseases of the brain, of the lungs, and of the heart, of the aorta, &c.

[We believe, with Dr. Bunn (Dis. of Liver, p. 54), that congestion of the liver may also result from a faulty state of the blood, quite independently of any mechanical impediment to its course through the lungs or heart, as we often see in purpura haemorrhagica, scarlet fever. From the late researches of M. Andral, it would seem that a great diminution in the proportion of fibrin is the change in the blood that most disposes to such congestions.]

83. In warm climates, especially in the East Indies, congestions of the liver frequently assume very active states, and more prominent features than in temperate climates; and, owing to the general association of biliary with sanguineous congestion, and the great amount of both, it is much more difficult to determine the exact share which each portion of the circulation of the organ bears in the production of the morbid appearances. Generally, however, the vescus is much increased in size, particularly the right lobe, and the increase in bulk often takes place chiefly in the direction of the thoracic cavity, the right lobe rising up into the chest. The difference of colour observed in different cases, and even in the same, seems to depend upon the particular set of vessels chiefly affected, and upon the absence or coexistence of biliary congestion, and the colour
of bile in the ducts. The surface of the congested liver is of a dark brown, greenish-black, occasionally passing abruptly into a reddish or light brown tinge. Sometimes it is mottled, or streaked, or clouded with tints of various degressions. The shades of colour are usually most remarkable upon the convex surface, and most frequently observed there. In some cases the surface of the liver is very dark, yet, upon dividing its substance, the internal texture is of the usual colour, but more commonly it is darker, and much black fluid blood escapes. The bile found in cases of biliary congestion varies in its characters, but it is commonly darker and thicker than natural, and as described in the article Gall-Bladder and Ducts.

84. Passive or mechanical congestion of the liver is not infrequently met with in infants, owing to asphyxia upon coming into the air at birth. Those who die in this state present the liver enormously congested.

85. D. The symptoms of sanguineous and biliary congestions of the liver cannot be individually depended upon; they should be viewed in connexion, and duly estimated. We may, however, infer the existence of these disorders when several of the following phenomena present themselves. A pale, sallow, anxious, or muddy hue of the countenance; a white, loaded, or furred tongue; costiveness or irregularity of the bowels, the stools being watery, dark, or otherwise morbid, and preceded by griping, difficult or slow digestion, with flatulence or nausea, and various dyspeptic symptoms; uneasiness, weight, or oppression, particularly after a meal, at the pit of the stomach and region of the liver; oppressed or heaving respiration; the sudden occurrence of pain, fullness or weight at the epigastrium, hypochondrium, or across the shoulder-blades, or below the right scapula, the uneasiness being increased by full inspiration and pressure; a full, slow, oppressed, or irregular pulse; a cool, clammy, dingy state of the skin, a turbid state of the urine; and headache, restlessness, disturbed sleep, and unpleasant dreams. Upon examination of the region of the liver by percussion, the sphere of dulness will be found extended particularly towards the thoracic cavity. Many of these symptoms, indeed most of them, are observed in inflammations of the organ, but they are then attended by increased frequency and hardness of pulse; by heat of skin and feverishness, particularly at night; by thirst, sometimes with retching, and by aggravation of the symptoms enumerated. Hence it is as much by the absence of the symptoms characterizing the more serious diseases of the liver as by the absolute value of those enumerated, that we infer the existence of congestions of the organ.

86. The pulse in congestions is variable, and cannot often be depended upon. Although a dull or aching pain, weight, or oppression about the epigastrium, or under the scapula, characterize in general inflammation of the substance of the liver, yet these are often signs of congestion also, especially when they occur suddenly, and are attended by many of the symptoms above described. Inflammation does not arise or reach its acme in a few hours, but congestion may. Neither can pain be always considered indicative of inflammation, since the membranes of the liver are often stretched by congestion so as to occasion pain. When biliary congestion is at the same time considerable, a withness at the epigastrium, a shallow, lightness, or even jaundiced state of the countenance and skin, slowness of pulse, lowness of spirits, inactivity, &c., become prominent symptoms. If an increased secretion of bile follow this state, the congested state of the vessels is relieved, and the circulation rendered more free and natural. But if the congestion continue, inflammation and other consequences already noticed, very often ensue.

[Professor Chapman has treated ("Lectures on the Pathology of the Biliary and Abdominal Vessels, p. 339") of a chronic disease of the liver allied to hepatitis, which he terms hepticula, which is extremely frequent in the southern parts of our country, and which is doubtless a passive congestion of this organ. "It is characterized," he observes, "by a sallow complexion, more of a lemon than an orange tinge, or sometimes by a dingy white, by much laxity of the integuments, with the aspect of blottedness, particularly of the abdomen, which is exceedingly tumid; occasional hæmorrhage of the lower limbs; dry, husky, unperishable skin; shortness of breath on the slightest exertion; by anorexia, and imperfect digestion; foul tongue; costive bowels; clay, ash, or slate-coloured stools; deficient, dark, or loaded urine; slaggishness of body; hebetude of mind; peevishness of temper, and dejection of spirits. The pulse is mostly little affected, sometimes, however, feeble; while in other instances it is full, slow, and may be intermittent, or otherwise irregular. Acuteness of pain is felt in the region of the liver, or tenderness betrayed on pressure, the complaint being of a disagreeable ache, or a severe sense of distention. This state of things may continue for a long period without much alteration, prone, as it generally is, to farther degenerations. Commonly these are a wasting, slow, irritable fever, heightened by an exacerbation at night, subsiding with copious perspiration, ultimately followed by colliquative diarrhoea, or it may speedily extinguish in haemorrhage of dark blood, or general dropsy, or the whole united, or some other fatal disorder. It is familiarly called throughout our Southern States, where it abounds, inward fever. Examples of this affection are to be met with among persons of all ages, though more so in children habituated to the influence of miasmata. Being partially acclimated, as it were, this cause of fever, and of the more special disturbances of the liver in such situations operates with comparative lightness, and hence the only sensible effect is to swell and derange that organ. But it is also consequent, sometimes, on ill-cured intermittent and other fall fevers." Dr. C. refers these symptoms to venous engorgement of the liver, induced by torpor of the portal circulation, from constant exposure to the operation of miasmatic influence.

In this affection, which may be distinguished from chronic hepatitis by the general physiognomy and absence of acute pain, there is a deficiency of the biliary secretion, although the popular opinion is, that there is an excess of
bile; that the patient is bilious, and that this is the cause of all his sufferings. This mistake is doubtless owing to the fact that both these opposite conditions are attended by the same symptoms, as headache, loss of appetite, nausea, depraved digestion, nervous wretchedness, &c. We believe this condition of the liver to be very common in females of very indolent habits, who indulge especially in much animal food, strong tea and coffee; and it is also one of the most frequent causes of headache, languor, debility, and want of appetite in literary men, who take but little active exercise. The remedies are a change of habits, country air and exercise, a regular state of the bowels, the flesh-brush, blue pill, with compound extract of coloeycyon occasionally; and especially the natural sulphur waters of Virginia, Avon, Sharon, Clarendon, &c., and the Saratoga waters."

87. E. Treatment.—When the symptoms of acute sanguineous congestion of the liver are well marked, and when the patient is strong, young, or plethoric, a recent arrival in a hot climate, general or local blood-letting, according to the peculiarities of the case, is required. The state of the pulse in this affection should not preclude having recourse to this practice if other circumstances show the propriety of it. In some instances, where a repetition of the bleeding may be necessary, in order to prevent the appearance of inflammatory reaction, which is apt to follow the congestion, particularly in warm climates, when bleeding has been neglected or insufficient, subsequently a full dose of a mercurial medicine, followed by deobstruent and saline aperients, and by enemata if requisite, and a blister applied over the epigastrum and right hypochondrium, will generally remove all disorder. When, however, much biliary congestion or accumulation is associated with vascular congestion, a frequent recourse to chologogue purgatives is required. In many of these cases an emetic may be given with advantage, after vascular depletion has been practised where it has been indicated. In more severe cases, however, of vascular congestion, emetics are hazardous unless copious depletion has been resorted to, and the state of the biliary function indicate the propriety of prescribing them. However slight vascular congestion may seem, it should be recollected, particularly by the East Indian practitioner, that it often originates the most dangerous forms of hepatitis, and that abscess may quickly follow inflammation consequent upon the congestion.

[Free cupping, or leeching over the hypochondriac region, is of the highest importance in many of these cases of hepatic congestion; free vomiting immediately after vascular fullness has been thus reduced will often be followed by decided relief. In many cases of relaxed fibre and debilitated constitution, diffusive and energetic stimuli may be employed to advantage at the same time we are practising local depletion. External refulvis of a powerful kind, as mustard, turpentine, &c., should never be omitted; while soda, from its effect in thinning the bile, and thus emulgating the biliary ducts, should be freely administered. The congestion above described is frequently one of the early symptoms of the cold stage of the malignant autumnal and intermittent fevers of our Western and Southern States, and seems to be brought on by extreme heat and moisture, combined with the malignant principle. A high state of the dew-point, as we have shown elsewhere, has much agency in inducing this form of congestive disease.]

88. In the passive states of vascular congestion of the liver consequent upon interrupted capillary circulation in the lungs, or upon impeded circulation through the heart or aorta, or associated with adynamic periodic fevers, febril, &c., the treatment entirely depend upon the nature and state of the primary affection, and upon its pathological relations. In several of these, particularly when the lungs are congested or inflamed, vascular depletions are necessary; but in asthmatic, chronic bronchitis, and similar affections, the hepatic congestion thereby caused requires chologogue purgatives, occasionally emetics, and deobstruents. If the hepatic vascular congestion be followed by affection of the heart, blood-letting may be injurious; it ought to be cautiously employed, if employed at all, the chief attention being paid to the regulation and correction of the secretions and excretions, and to the support of the vital powers.

89. III. Hemorrhage of the Liver.—Hemorrhage into, or from the liver, is very rarely observed. When the blood is effused into some part of the substance of the organ, producing what the French pathologists have termed apo-plexy of the liver, the extravasation has been a consequent either upon passive congestion of the organ, owing to impeded circulation through the heart, aorta, or lungs, or upon deficient tone of the capillaries of the organ, or softening of the part, the seat of hemorrhage. In an interesting case, recorded by Sir G. BLAKE (Trans. of Soc. for Imp. Med. Knowledge, vol. ii.; p. 18), the hemorhage seemed to have been consecutive of the latter changes, as it was associated with purpura. It had formed cavities in the substance of the organ; these had burst, owing to return of the extravasation, and effused their contents into the abdominal cavity. M. ANDRAL supposes that hemorrhage may take place in the structure of the organ in consequence of acute inflammation, but this is not very probable. The extravasation is rarely owing to the rupture of a considerable vessel, but rather to exudation from a number of capillaries, giving rise to several minute collections of fluid or coagulated blood. M. ANDRAL supposes, from specimens furnished him by MM. BOREL and PHILIPPE, that many of these collections, when deprived of the red particles, gives origin to certain new productions, encephaloid and others, that are found in the liver; but this requires farther proof.

90. Several writers have supposed that hemorrhage may take place from the liver along the hepatic ducts, the blood passing into the radicles of these ducts, or into their branches or trunks, owing to laceration of the part where the extravasation occurs; but no satisfactory proof of either occurrence has been adduced. The blood, however, may possibly pass into the commencement of the hepatic ducts in cases of extreme congestion. This subject deserves, but does not readily admit of farther elucidation.
91. Hemorrhage from the liver is most frequently caused by external injury and rupture of the organ. When the liver is congested, and at the same time softened—changes occasionally produced in humid and miasmatic situations, either primarily or in connexion with adynamic remittent or intermittent fevers—comparatively slight external injuries have ruptured the organ and caused fatal hemorrhage into the abdomen.

92. Ulceration of one of the hollow viscera may occur, and the inflammation thereby induced in the peritoneal covering may be followed by adhesion to the liver; the ulcer ultimately penetrating into the substance of this organ, eroding one or more of the vessels, and thus producing fatal hemorrhage into the alimentary canal. I have seen altogether three instances of this kind of hemorrhage: two where the ulceration commenced in the stomach, extending through the peritoneum, which was firmly adherent to the liver, and terminating in the parenchyma of the latter; and one where it originated in the right flexure of the colon, and proceeded in a similar manner. (See Stomach, Ulceration of.)

93. In all these cases the source of hemorrhage can be determined only by examination after death. Granting the possibility of the passage of the blood from the portal veins into the biliary ducts, and thence from the bowels, the symptoms are not such as will indicate it during life, for we have no means of determining whether the blood vomited from the bowels proceeds from the liver or from the small intestines.

94. DEPÆN.—Pain, aching, tenderness, or fulness in the right hypochondrium or epigastrium, the pain often extending to the right shoulder-blade, and other parts; inflammatory fever; surred tongue; frequently cough or bilious vomiting; colic or irregular bowels; scanty, high-coloured urine, with a yellow tinge of the face, and sometimes complete jaundice.

95. Inflammation of the liver frequently originates, silently and insidiously, in some one of the functional disorders already noticed. In warm climates particularly, it is sometimes preceded by increased secretion of bile, marking existence of the organ, with febrile symptoms, diarrhoea, or slight dysentery, which often attract the chief notice and mislead the physician. In some cases, the biliary congestion becomes a cause of irritation to the circulation of the organ, and kindles the inflammatory action it is already prone to undergo; and this is the more to be dreaded, if vascular congestion is also present; such congestion being commonly the antecedent of inflammation in some one or other of its forms. It is comparatively rare that hepatitis occurs in a previously sound state of the functions of the organ, unless the exciting causes are energetic, and in warm climates, especially among the new residents. When inflammation thus originates in any of the functional disorders of the liver, it is most difficult to date its commencement; for a slight or early grade of inflammatory action, affecting a part only, as it usually does, of the substance of the organ, may give rise to the symptoms of any one of these disorders, those indicating inflammation being so slight as to escape attention.

96. Inflammation may be limited to the following parts of the organ, namely, the superior or convex surface, the inferior or concave surface, the internal or parenchymatous structure, and the right or left lobe. The right lobe is most frequently the seat of inflammation; next the right and left together; and the left lobe only, the last in frequency. The inflammatory appearances in the superior surface of the liver are often limited by the broad ligament. When the surface of the liver is the seat of the anterior varicose action, the adjoining internal structure of the organ generally participates in it to a greater or less extent; and likewise when it commences in the parenchymatous structure, it sometimes extends to the external surface; but this more rarely occurs, especially in warm climates, than the former mode of extension; the internal structure being the seat of inflammation more frequently than the surfaces, which seldom participate in it until an advanced stage of the disease. Sometimes, however, inflammation of the surface of the liver may arise from inflammation and the exudation of lymph from an adjoining viscous, as from the stomach or duodenum; and, in these cases, the surface is the chief seat of disease, which may be either limited to it or extended partially to the substance of the organ. When inflammation originates in the surfaces, or extends to them consecutively, coagulable lymph is generally thrown out on them, and the peritoneal covering is then or has been inflamed; but the parts immediately subjacent may present every mark of inflammatory action, and yet the investing membrane may not participate in it, to the extent at least of throwing out coagulable lymph. In warm climates, particularly in the East Indies, the substance of the liver is often the seat of acute inflammation, or of large abscesses, without any decided mark of inflammation of the envelope of the organ, besides alterations in the liver. These are, therefore, inflammatory alterations are often independent of the inflammation, or connected with the state of the biliary congestion. Abscesses may even proceed to their utmost extent, and ultimately break into the abdominal cavity, without having induced inflammation of the serous membrane where they point, without having produced coagulable lymph on its surface, and, consequently, without having formed adhesions to adjoining parts.

97. The relations, connexions, and integral structure of the organ being so various, the seat of inflammation being often limited to a particular part or tissue, and the character and intensity of the disease also varying greatly, it
may be expected that the symptoms will also differ accordingly in different cases; that they will be often obscure, or equivocal; and that they will be still more so when hepaticis is complexed, as it often is, with gastritis, or with duodenitis, or with dysentery or chronic diarrhoea.

98. Owing to the varying seat and intensity of hepatitis, the different forms of it have been arranged, accordingly, into inflammation of the surface and of the substance; into acute and chronic. These and other arrangements are merely, however, conventional; and although the terms acute and chronic indicate chiefly extreme grades of the disease, in the diagnoses not the only one assumed, or if assumed at first, it is not generally preserved. In warm, and even in temperate climates, the most acute inflammation of the liver, as respects many of its symptoms as well as its duration, affects both the substance of the organ and some part of its surface, or the former only. It has likewise been supposed that, as suppuration takes place in the substance of the organ, it is most commonly a consequence of chronic inflammatory disease. But this is not the case, especially in India and tropical warm climates, for decay often follows with great rapidity the most acute form of the disease, as regards the quickness of its progress.

99. Investigation of the diseases of the liver, more especially of those which are inflammatory, should be made patiently and attentively; and an oculur as well as a manual examination of the region of the liver ought always to be made. Even in cases where the nature of the disease is obvious, this ought not to be neglected. Although such investigations may give us but little information in the functional disorders, or in the early stages of inflammatory diseases of the organ, yet it should be resorted to. Information, even of a negative kind, is always requisite in hepatic affections, and particularly in those which are acute. The trunk of the body should be exposed to view, so as to ascertain the existence of bulging or fulness in any part of the hypochondrium or its vicinity. When making manual examination, one hand should be pressed gently on the hypochondrium near the base of the right shoulder-blade and the spine, while with the other the physician endeavours to detect tenderness, fulness, or distention, either beneath the false ribs, or at the epigastrical region, or to the left of this region, or between the right hypochondrium and umbilicus. The state of the intercostal spaces should also be examined on the right side; and if pain be complained of in any of these situations, its nature ought to be ascertained by careful and varied pressure, while the division they make on the back, in the place just named, and during full inspiration and forced expiration. When the examination is going on, the patient should be directed to bend or move his body in various directions, and to stand, stooping forward, leaning with the hands on the flap of his back of a chair. If fulness, swelling, or distinct tumour be felt, the physician should endeavour to ascertain its nature and connexions, by gentle and varied pressure with the points of the fingers; and the existence of tenderness, and the degree of tenderness, the depth at which it seems to be seated, and the presence of fluctuation, whether obscure or palpable, ought to be inquired into with as much dexterity as possible. A rough, rude, or forcible examination ought to be avoided, as causing contraction of the muscles, and as being productive of pain, and even of serious injury, in abscess of the organ, or in states of inflammatory congestion of the parenchyma, when more or less softening also often exists.

100. Acute and subacute inflammation may affect either the parenchymatous structure or the surface of the organ; but it may also implicate both, although either one or the other in a greater degree or extent.—1. When the substance of the organ is solely or chiefly inflamed, the disease may commence with or without fever, or with diarrhoea, or without either, particularly after exposure to cold, wet, currents of air, the night dew, or to malaria. When chills usher in the attack, then many of the symptoms indicating vascular congestion of the vasa (§ 85) are usually present, and generally attend the inflammation during its course. The patient complains of oppression, weight, or uneasiness in the right hypochondrium and at the pit of the stomach, extending sometimes to the ensiform cartilage, and sometimes to the back and shoulder-blades. These are usually increased on a full inspiration, when pressure is made beneath the ribs, or upon the stomach and back at the same time. The pulse is hardly affected at this early period of the disease; but it soon becomes quicker at night. It is sometimes slow and oppressed, and occasionally irregular, or even intermittent. The countenance is now pale, sallow, or somewhat anxious; the spirits much depressed; the tongue pale or yellowish; or, when it is white, with an unpleasant taste of the mouth, sickness, and loss of appetite. The bowels are at first often custive or irregular, or diarrhoea may exist, and the urine is scanty and high coloured. Oppression at the chest and epigastrium; slight dyspepsia and sighing; headache and disturbed sleep, with night fever and restlessness, are also generally present.

101. a. As the disease advances, the pulse becomes quicker, fuller, and more irritable, during the evening and night, and is often oppressed or embarrassed during the morning and day. The uneasiness in the region of the liver and epigastrium is augmented; and if vascular fulness of the organ be great, and if the disease has followed congestion, the patient complains of a heavy dragging pain, increased by sudden motion, or by turning quickly in bed. There is sometimes a short, suppressed cough, dyspepsia, shortness of breathing, a catch in full inspiration, particularly after sudden motion. On examination, turgidity of the vasa is evinced by the protrusion of faintness or fulness beneath the ribs and subcostal cords, and by the diuresis of sound extending higher than
usual in the right thorax. A dull pain or aching
is often felt in the region of the liver, in the
lower part of the thorax, and in the epigastric
region, occasionally extending from the right side
under the shoulder-blade to the spine. It is
times referred to the top of the right shoulder,
frequently to the right shoulder-blade, occasionally
to both scapulae, or only to the
loins. In a few instances, it is felt in the right
clavicle and side of the neck; and, in others,
it extends downward to the right thigh. It
more rarely affects the left shoulder and should-
er-blade only. When pain is present in the top of the right shoulder, in
the disease of the right lobe of the liver; but this symp-
tom is often absent. In some cases it is in-
creased, or excited when not previously felt,
upon any sudden concession of the trunk, or
upon quick motion, or making a false step, or
turning suddenly from one side to the other.
But, in many cases, there is little or no pain;
or it is complained of on these latter occasions;
or there is merely a sense of aching or drag-
ging, with oppression at the precordia, anxiety,
and frequent sighing. Pain is seldom acute,
tensive, or pungent, unless the surfaces or lig-
ments become affected. It occasionally ex-
tends from under the ensiform cartilage, in the
direction of the mediastinum, to the back or
shoulder-blades, and it is then attended by dys-
pepsia, oppression or a sudden catch in breath-
ing, and a dry cough.
102. The position of the patient varies with
the severity and seat of pain. Frequently he is
easiest in a semi-recumbent posture. Difficulty
of lying on the right side is not often felt, un-
less the pain in it is acute. In many cases,
any position may be preserved for a time
without pain, although uneasiness and a change of
posture may follow. Occasionally the patient
prefers to sit gently bent forward.
103. In proportion to the attendant conges-
tion or tumefaction of the organ, the right cav-
ity of the chest is encroached upon by it, as
shown by the extended sphere of dulness on
percussion. In this case, there is also greater
fullness observed in the right hypochondrium
and epigastrium, the margins of the ribs being
pushed slightly outward. Oppressed breathing,
frequent dry cough, occasionally acute pain,
owing to stretching of the envelopes of the or-
gan, and increased discharge of bronchial mu-
cus, are complained of; and these symptoms,
with exacerbation of pain in the chest on full
inspiration, or on coughing, the flushed or full
appearance of the countenance, occasioned by
the impeded circulation through the lungs, may
lead to a suspicion of pulmonary disease, or
pneumonia; but, in these cases there are pain or
uneasiness about the scapula, or top of the
right shoulder; occasionally numbness of the
right arm, with pain about the insertion of the
deltoid muscle, or at the wrist; and more
rarely, numbness or pain extending to the right
hip or thigh; symptoms indicative of the seat
of the malady.
104. Nausea and vomiting are often concom-
ants of the most acute attacks; but, when ur-
gent or continued, there is reason to believe
that the concave part of the liver is affected, or
that the inflammation extends thence to the
stomach, or that it proceeds in the course of the
hepatic ducts to the gall-bladder and duo-
denum. In these cases, the patient complains
of a sense of fluttering, weight, or fulness in
the right hypochondrium and epigastric regions;
sometimes of pain in the abdomen, and reclines
chiefly on the left side or back. The stools are
generally watery, frequent, scanty, and dark
coloured, with tenesmus, occasional discharges
of blood, and other symptoms of dysentery, for
which it is often mistaken. Even when little
sickness at stomach is present, there are loss
of appetite, and heartburn, or gripes, about an
hour or two after a meal, with thirst and low-
ness of spirits.
105. As inflammation of the substance of the
liver advances, the febrile symptoms, partic-
ularly the evening exacerbations, become
more marked, and the pulse more irritable.
The tongue is covered by a white or yellowish
brown fur—moist in the early, but dry in the
advanced stages. Where the disease has fol-
lowed disorder of the alimentary canal, or re-
peated attacks of hepatic disorder, the tongue
is often smooth and glossy, marked by fissures,
and lobulated, particularly in the most severe
cases, and in those about to terminate in,
which have already terminated in abscesses. In
other cases, especially when congestion, san-
guinous or biliary, has passed into inflamma-
tion, the papilae of the tongue are large and
distinct, and the surface of it foul and coated.
106. The countenance and skin at the inva-
sion of the disease, or when chills or rigours are
present, are pale or sallow. But as the in-
flammation is developed, the countenance fills
out more fully, particularly when there are ful-
ness and oppression in the region of the liver
and chest, and a dusky redness appears in the
cheeks. The face and eyes, however, still
possess a muddy or sallow hue, and a dark
circle surrounds the eye, particularly beneath
it. The patient often complains of pain in the
forehead or over the eyes. The skin on the
trunk is warmer than natural, especially towards
evening, sometimes with a greasy feel, and a
scanty or partial perspiration. When the per-
spiration is more copious, it is often offensive.
Jaundice is a frequent symptom, particularly in
the habitus of Europeans, particularly when passing on to
abscess, but it seldom takes place in warm cli-
mates, unless the gall-bladder or ducts are in-
volved, or when hepatitis follows biliary calculi or
obstruction of the ducts. The eyes and
countenance are always deficient in clearness,
and present a slight yellowish or sickly hue.
107. Deficiency of bile in the stools is often
observed in connexion with hepatitis, but in
warm climates it does not often occur, although it is
incident to the more severe cases, and to abscess;
and to abundant secretion. When hepatitis is con-
nectcd with congestion, or with accumulations
of acrid or morbid bile in the hepatic ducts and
gall-bladder, the stools are disordered from the
commencement; they are foul, dark-coloured,
foul, watery, and frequent: or dark green, and
offensive; or at first feculent and brown, and
afterward morbid and dysenteric. There is
generally tenesmus, owing to the irritation of
the morbid secretions on the mucous surface
of the rectum, and this, with other dysenteric
symptoms, often masks the hepatic disease.
108. The urine is scanty, high-coloured, de-
posits a lateritious or pinky sediment, and
seals the patient in passing it. If the bile be
obstructed, a brown, or dark, flaky sediment is often deposited.

109. c. The progress of inflammation of the substance of the liver is commonly such as now described, both in temperate and in warm climates, until it is resolved by treatment, or has passed into suppuration. But it may present certain modifications. It may commence as bilious inflammatory fever, with a full, strong, and frequent pulse, great heat of skin, vomiting, thirst, and various symptoms referrible to the liver and bowels, and indicating predominant affection of them. This form is plethoric in persons and particularly those who have recently arrived in a warm climate.

110. In some cases, inflammation affects the substance of the liver, and proceeds to suppuration in a more obscure and insidious manner than that above described. The patient may have complained merely of dyspeptic symptoms, and irregularity or looseness of the bowels, when shivering, followed by heat of skin, and profuse clammy perspirations, ushering in true hepatic fever, quickly giving way to suppuration. In most of these cases, the case is neglected, or its nature overlooked, until the inflammation either extends to the coverings of the liver, or has given rise to abscess; the symptoms, produced by the one or the other, being those which first attract attention, and disclose the true state of the disease.

111. d. The duration of acute and sub-acute inflammation of the substance of the liver varies from three or four days to as many months, with the severity of the attack, the intensity of the exciting causes, the habit and temperament of the patient, and the treatment employed; and, as these circumstances may combine, so will the disease be disposed to terminate in resolution, in abscess, or in some other organic change.

112. B. Inflammation of the Surface of the Liver assumes a more acute and definite character than that of the parenchyma.—a. Inflammation of this part, acute extra-hepatitis, may occur primarily or consecutively; in the latter case, the reddish action extends to the surface common to an adjoining part of the substance of the organ, or from the peritoneal covering of an adjoining viscus. In this state of the disease, the febrile reaction is prominent, and generally consequent upon chills or rigours. The pulse is much accelerated and hard; pain in the right hypochondrium is more or less acute; and when the upper surface of the right lobe is affected, or when the lobe is much tumefied, so that it rises into the chest, considerable tension and pain are felt also in the right thorax, and under the ensiform cartilage and sternum, resembling an attack of pleuritis. Cough, increased pain, or a catch on full inspiration, and tenderness on pressure, especially at the time of a full inspiration, are also present. When the whole of the upper surface of the organ is inflamed, the disease may be mistaken for pneumonia, if the chest be not accurately examined by the stethoscope and percussion; oppression, difficulty of breathing, pain in the course of the diaphragm, and under the sternum, being generally considerable. Heat and dryness of the skin, thirst, and other constitutional symptoms, are more fully developed than in the former variety of hepatitis, and are such as usually accompany acute inflamations of serious membrane.

113. The stools are generally disordered and variable. They are at first scanty, infrequent, and constive; more rarely loose. They are often deficient in bile; but in warm climates this is comparatively rare, unless sero-hepatitis has followed torpor or congestion of the organ; more frequently the bile seems unhealthy, and occasionally redundant. At an advanced stage, the bowels are often more relaxed, and the bile is increa.ed, that continues diarrhoceous, tenesmus, or even dysentery, supervenes in warm climates, during the advanced periods of the disease, apparently owing to an increased discharge of morbid bile. The urine is generally high-coloured.

114. b. When the superior surface of the liver is affected, and there are much tumefaction and congestion of the organ, the symptoms are partly referred to the chest. Coagulable lymph is often thrown out upon this surface, and inflammation is thereby induced in the peritoneal covering. In men, the diaphragm is affected; and the symptoms of diaphragmitis often supervene, associated with those of the liver, and with considerable congestion of the lungs. In these cases, the distress and febrile symptoms are very prominent. The patient breathes chiefly by the intercostal muscles, and expresses anxiety at the epigastrum and precordia, with a sense of tension or stricture across the chest, and an inability to sit or lie otherwise than bent forward. Cough is frequent, hard, and suppressed, with great increase of the pain, inability to take a full inspiration, and occasionally slight serous and mucous expectoration. There are also often fullness at the false ribs and epigastrum, shortness of breath, inability of motion or exertion, headache; a full, dusky, and anxious state of countenance.

115. When the outer surface and part of the right lobe is chiefly affected, the pain is most severe in the right hypochondrium, and at the margins of the ribs, sometimes extending to the right scapula and top of the shoulder. A fullness is often perceptible under the margins of the ribs, with tenderness on pressure. The temperature in the region of the liver is sometimes higher than in any other part. The patient most frequently lies on his back, or in a semi-recumbent posture.

116. c. When the concave surface of the liver is the seat of the disease, and the posterior part or margin is affected, or when the inflammation extends to these situations, the functions of the stomach are then prominently disturbed. Nausea and vomiting are often present soon after substances are taken into the stomach. Thirst, anxiety, and pain in the epigastrium, or in the back, are urgent; and sometimes the pain extends to the right shoulder and right side of the neck. The pulse is variable, but generally irritating, quick, small, contracted, or hard. There are often a sense of fluttering at the sericulus cordis, a heavy dragging pain in the same situation, anxiety, frequent sighing, and occasionally, at an advanced stage, hicough, particularly after cold fluids are taken into the stomach. The patient generally lies on the right side, or on his back.

117. d. When the inflammation extends to
the gall-bladder or ducts, or to the stomach or duodenum, all the symptoms become more severe. The vomiting is frequent and distressing when the disease impinges the stomach or duodenum; and burning heat and fulness are felt at the epigastrium, with frequent and painful eructations of flatus, and great tenderness at the epigastrium and right hypochondrium; sunk, anxious countenance, increased heat of the trunk, cold, clammy hands, and quick pulse. If the ducts and gall-bladder be affected, the pain darts to the right side and back, from the epigastrium; it is also often felt in or near the angle formed by the spine and base of the right scapula. Sometimes it extends from under the ensiform cartilage to the umbilicus, and back to the right hypochondrium. Singultus and acrid eructations are not infrequent in the advanced course of the disease. The patient can seldom bear pressure on the right side and epigastrium, the uneasiness being increased on a full inspiration. In most of the cases of acrohepatities, ascasis, or pain in the left side, mentioned not only on a full inspiration, but also on a forced expiration; for this latter mode of ascertaining the seat of pain ought never to be neglected in our investigations of diseases of the liver. Restlessness, want of sleep, a foul, loaded tongue, irregular or disordered bowels, scanty urine, and sometimes jaundice, attend inflammation of the concave surface of the liver; and, if the ducts are implicated, the jaundice is generally complete.

118. a. If the left lobe is alone involved—a very rare occurrence—the more acute symptoms are referred to the left side. If this lobe is affected, the right is generally still more affected, and the local symptoms are correspondent, or are most severe towards the epigastrium. Flatulent distention of the stomach is sometimes urgent, and so great as to push the liver more than is usual to the right side, or to embarrass respiration. In these cases, the stomach often becomes implicated, if the lobar affection is acute.

119. ii. Chronic inflammation of the liver may be seated either in the substance or in any part of the surface of the organ. It may occur primarily, or the acute or sub-acute forms of the disease may have been so far subdued as to subside into a slow, inactive state. —A. When chronic hepatitis is primary, it is usually seated in the substance of the organ, often gives rise to few local symptoms, and occasions very slight constitutional disturbance. But chronic illness is generally conveying no precise idea, and merely signifies a slow state of disease, presenting every grade from that state which may be viewed as only slightly deviating from health. When chronic hepatitis follows the acute, it is usually seated in the substance of the organ; but it may affect the surface, or both. Inflammation may also commence in a chronic form, and, after an indefinite time, be aggravated into the acute state, either by the continued operation of the exciting causes, or by injudicious treatment. —B. Ducts and gall-bladder affected, the pain may be severe forms, the nature of the disease is seldom evinced by distinct phenomena. Various dyspeptic symptoms, flatulence, acid or acrid eructations; sometimes nausea, and less frequently vomiting; loss of flesh; muddy or sallow complexion; dry cough, or embarrassed respiration; torpid state of the bowels; aching or pain in the back, or in the right hypochondrium, or a sense of weight or tenderness in the region of the liver; an irregular state of the bowels, or dark-colored, offensive, slimy, greenish, or watery or muddy evacuations; dark saffron colour of the urine; slight acceleration or irritation of the pulse in the evening; increased heat and restlessness in the night; heat of the palms of the hands and soles of the feet in the evening, and chilliness in the morning; white, foul, or rough tongue; bitter taste of the mouth; sickly or yellowish hue of the countenance; depression of spirits, and, in some cases, elevation of the shoulders, are the chief symptoms of this variety of hepatitis; but some of these may be absent, and other symptoms may be very slight or evanescent, or slightly manifest.

121. b. In the severer states of the chronic disease, the symptoms are often nearly the same as those attending the subacute form, only differ in degree, and more distinctly mark the organ and part affected; but in the slighter cases they are less precise, more equivocal, and less to be depended upon in forming a diagnosis. They may even preserve this character until the inflammation passes into suppuration, or a large abscess forms, when similar phenomena to those which indicate it in the more acute disease begin to appear. Chronic hepatitis, in any of its grades and states, is often associated with slight or chronic inflammatory irritation of the gastro-intestinal villous surface, and hence several of the symptoms of both affections are associated in many cases.

122. B. If the surfaces of the liver become involved in this disease, the symptoms are then more acute and acute. —Chronic acrohepatitis. Pain or aching is more defined and marked; and as the superior or the inferior surface is chiefly affected, so is it referred to the chest in the one case, or to the stomach and bowels in the other. When the superior and exterior part of the right lobe is affected, the patient then lies with most ease on the right side, and often feels, at an advanced stage of the disease, more or less acute pain, or a dragging sensation, upon turning to the left. If this latter occur, the entire absence of indentations between the liver and right side may be inferred. He therefore prefers the semicircular position, or lies on his back or right side.

123. C. In many cases of chronic hepatitis, the disease affects both the substance and the surface of the organ, although either may be more especially implicated. In these, the symptoms are variously manifested. There is generally much loss of flesh, and frequently enlargement of the viscera may be detected. Tumefaction or enlargement may arise from three conditions: 1st. From congestion, sanguineous or bilary, or both; 2d. From the more chronic deposition of lymph between the lobules, or from other lesions of structure; and, 3d. From suppuration and the formation of an abscess or abscesses in the substance of the organ. The
first of these generally soon subsides after deploration and an active recourse to chologogue purgation; the second is more obstinate, is persistent, and attended by symptoms about to be noticed; and the third gives rise to a regular hectic remittance, and other phenomena, local and constitutional, which will be considered in the sequel.

124. iii. Terminations or Consequences of Hepatitis.—A. The acute and sub-acute states of the disease: 1st. Terminate in resolution with a more or less gradual subsidence of the morbid phenomena; 2d. They pass into the chronic state, and the various terminal changes connect ed with it; 3d. They give rise to suppuration and its several states and consequences; 4th. They may occasion exudations of lymph on some portion of the surface of the organ, and extension of the disease to adjoining viscera or parts; and, 5th, and most rarely, the most acute state may produce gangrenous softening. The other changes observed, in consequence of acute hepatitis, are rather parts of the morbid process, especially in its progress to suppuration, as red and grayish softening of the structure, infiltration of the organ with lymph, &c., as will more fully appear hereafter.

125. In the course of the disease, and particularly of the more unfavourable cases, various complications arise, and favour a fatal issue. When suppuration occurs, such complications more readily and generally take place, and sometimes destroy the patient, or aid the hepatic malady in producing this result, even before the abscess has opened into any other viscus. Some of these complications may arise indirectly, in consequence of the general morbid vascular action still continuing, although somewhat modified in character or activity. Chronic hepatitis: 1st. May terminate in resolution, and a return of the healthy functions; 2d. It may pass into the acute or sub-acute states, and the several resulting structural changes; 3d. It may give rise to suppuration and abscesses; 4th. It may occasion enlargement and other organic lesions; 5th. It may implicate the duets and gall-bladder, and occasion various changes of them, of the bile, &c., with jaundice; and, 6th. It may give rise to various complications or serious maladies of adjoining or related organs, owing either to exudations of lymph on the surface of the organ, to the extension of inflammatory irritation along continuous parts, to the irritation of morbid secrétions on the intestinal villous surface, and to the absorption of such secretions into the blood. The most important of the above terminations and consequences of acute and chronic hepatitis require a separate treatise.

127. A. Resolution is indicated by subsidence of pain, uneasiness, and fever; by the tongue becoming cleaner, the urine paler and more copious, and the stools more natural; and by the subsidence of the temperature or the gastric symptoms, according as either may have been present. Tumefaction of the organ also rapidly subsides, as shown by the extended clearness of sound on percussion in the lower part of the chest; and by the diminished fulness and tension of the right hypochondrium and epigastrium. The existence of swelling is one of the chief indications of the persistence of the disease, in a less acute form, if the other symptoms are ameliorated, or of the supervision of suppuration.

128. B. Abscess is one of the most frequent and dangerous consequences of hepatitis, particularly in warm climates; and occurs chiefly in those insidious states of the disease which are not attended by acute symptoms, although often rapid in their progress. It may follow any grade of inflammatory action—the acute, sub-acute, and chronic; and it may occur with any rate of rapidity; but it is most frequent, and the most to be dreaded, in the sub-acute inflammation of the substance of the organ, attended with no distinct affection of the hepatitis region contained, especially if it increase after the more acute symptoms are partially subdued; and when the patient is exposed to hurtful influences during the treatment, or at an early period of convalescence, or indulges in stimulants or too much food during this period, or before the healthy functions of the stomach and bowels are restored. In these circumstances, and in debilitated persons of a scrofulous diathesis and sanguine temperament; in the fair-haired and fair-complexioned, the blue-eyed, the relaxed and enervated, those subject to bowel complaints and the sedentary, abscess often forms suddenly and unexpectedly, no very prominent symptom preceding or marking its occurrence. In these persons there is often little or no sign of existing inflammation, or the symptoms are ill-defined, by no means acute and equivocal, presenting more of a passive than of an active character, although the course of the disease is frequently rapid. In those, even when suppuration takes place, there and with no definite indication of its occurrence, although the physician may be aware of the existence of hepatitis. In these circumstances patients often neglect themselves, until abscess has actually formed, and some consecutive disease, as dysentery and chronic diarrhea, may have made its appearance, which may mark the primary malady, and engage the chief attention of both patient and physician.

129. On the other hand, the inflammation preceding abscess is often active, acute, and attended by evident local symptoms and inflammatory symptomatic fever in strong, plect
LIVER—Inflammation—Consequences.

...or, and unimpaired constitutions. When the attack is very acute in these, particularly if the serofulous diathesis is present, and if the organ be congested and tumefied, abscess rapidly forms if the disease be not actively and promptly treated; and it is generally preceded and attended by symptoms enabling the physician to prevent and to ascertain its occurrence. It is often owing to the diathesis, to previous disorder, or to some fault in the state of the organ, that abscess appears in these more acute and well-defined cases, when early and judiciously treated.

130. The pre-existence of congestion, sanguineous or biliary, or both, favours greatly the occurrence of suppuration as a consequence of inflammation of the liver. The previous congestion also increases the swelling generally consequent upon inflammation of the substance of the organ. When the swelling, or the signs indicative of it, attend the commencement of hepatitis, coincident congestion may be inferred; and when they follow the disease, or appear at an advanced stage, they indicate the effusion or infiltration of lymph in the interstices between the small lobules, and denote a similar state of parts to that accompanying inflammation of more superficial and tangible glands, often, however, in connexion with vascular and biliary congestion. When suppuration commences, and as it proceeds, tumefaction of the liver, fulness of the hepatic region, the sphere of dulness on percussion in the infra-mammary region of the right thorax, oppression, weight, and aching at the epigastrium and hypochondrium, are generally increased. When the increase of bulk, owing to incipient suppuration, is chiefly in the lower or concave part of the organ, it is less evident upon examination than when it is seated in the superior and outer portion.

131. a. When suppuration occurs the pulse becomes quicker and softer, or more irritable, and shiverings are often observed, either with or without perspirations. The countenance becomes pale, or sallow, or more sunk; the oppression, uneasiness, or weight in the hepatic region increases; and the perspiration sour or otherwise offensive. As suppuration proceeds the hectic fever attending it is more distinctly marked, and is never wanting. The other symptoms vary with the constitution and previous health of the patient, with the part of the organ diseased, and with various other circumstances. But when a large abscess is formed in the liver, or when it is seated towards the upper part of the right lobe, the following phenomena are usually observed: 1st. Tumefaction of the organ, without any sign of fluctuation, but with a doughy, edematous, or boggy feel of the hepatic region, or in some part of it; 2d. Distinct swelling or tumours below the margins of the ribs, or at or near the epigastrium; 3d. Bulging of the false ribs with increased fulness of the intercostal spaces; and, 4th. Fluctuation becoming more or less manifest in such tumours.

132. In some cases, the pain in the right side has been confined to a particular spot, which has corresponded with the situation of the abscess; and frequently increased heat has been felt in the part more especially tumefied. In a few instances the enlargement has been found low in the right hypochondrium, or even extending to the left hypochondrium, across the epigastrium. However, these local symptoms, if no fluctuation or doughiness be felt, and if the constitutional signs of suppuration be not present, may indicate only that state of parts about to pass into abscess, and may exist for some time before the local and general signs of this change present themselves.

133. b. The constitutional symptoms of abscesses of the liver are often as equivocal as the local signs. In persons whose constitutions are broken and in whom the disease is not protracted, the nature of the disease may altogether escape detection, until disclosed by post-mortem inspection, more particularly when suppuration has followed chronic inflammation, and has been attended by dysentery or chronic diarrhoea. Rigours are not always complained of, but slight shudderings and formications are often substituted. When, however, they occur, and are followed by copious night perspirations, after states of disorder above described, there is no reason to infer that the existence of abscess is indicated, for they indicate the formation of matter in the organ. In some instances, an internal sense of throbbing and fluttering in the region of the liver, followed by a soft pulse and night perspirations, with clamminess of the extremities, indicate this change, particularly when viewed in connexion with the previous disorder and concomitant phenomena. In the advanced progress of abscesses, cold sweats and faintness, or leipothymia, often occur, with anxiety and oppression at the precordia. If these symptoms appear in a person whose system has not been affected with mercury, given with this object, we may the more certainly infer the existence of abscesses. The impossibility of affecting the mouth by mercury when suppuration has commenced is acknowledged by all experienced writers on the disease.

134. In connexion with the hectic produced by abscesses, the state of the tongue varies; but it becomes at last brown, red, smooth, lobulated, &c., or dry and parched. The stools are always disordered, and present in different cases, and at different periods in the same case, every possible appearance, with straining, tenesmus, discharges of blood from the bowels, and frequent calls to evacuation, particularly at night. When disease of the bowels becomes complicated with abscess, both the small and large intestines are affected; at first functionally, and afterward organically; and the patient is often carried off by the bowel disease, before the abscess has been discovered in the abdomen or any other viscus. In some cases of hepatitis, in warm climates, associated with dysentery, especially of chronic hepatitis, the termination in abscess is either accelerated or caused by the sudden arrest of the dysenteric affection; or the hepatic malady becomes more severe and apparent as the affection of the bowels subsides.

135. In an advanced stage of abscesses, especially when seated in the posterior or parts of the liver, and pressing upon the diaphragm, anxiety and oppression at the precordia become urgent, with attacks of dyspnoea and hiccup. The position preferred by the patient depends upon the seat and direction of the abscess. He most frequently reclines on the back, or on the left
side, or in a semi-recumbent posture: and he sometimes has most ease when sitting and leaning forward. Pain is a very uncertain symptom. During the tunecfaecia of the organ preceding the formation of matter, pain is often considerable; and is afterward converted into a heat or throbbing sensation, sometimes attended by shooting or darting pains in various directions, or merely by prickings chiefly in the situation of the abscess. In the more chronic cases, these latter sensations may be the only painful feelings complained of, unless occasionally on sudden motion, on sneezing, coughing, &c. The countenance generally becomes sunk, sallow, or jaundiced; and when jaundice does not appear, the eyes are generally either yellowish or of a pearly hue. Emanation increases, and is most apparent in the extremities, the upper regions of the abdomen appearing fuller than usual. The urine sometimes becomes turbid, and in rarer instances puriform or muco-puriform.

136. Suppuration of the liver, however, has occurred where the symptoms of hepatitis have not been observed, and where the abscesses which has formed has not been suspected during life—pain, tumour of the hepatic region, jaundice, &c., not having been present. Instances of this kind have been recorded by many writers in this country, and by most of those who have treated of intertropical maladies. In many cases, the disease has not been recognised in consequence of the imperfect examination of the case; in others, from the complications or forms in which it has occurred. Its association with gastro-enteritis, with pneumonia, or with dysentery, or its appearing consequently upon continued or remittent bilious fever, or after ague, will sometimes entirely mask it from the superficial or careless observer. There is much truth in the remark of Mr. Twining, that he has never seen a case terminate in abscess without being able to detect the disease that is in progress by a careful examination before suppuration commences; but then, as Mr. Martin justly adds, the examination must be most rigorous, and repeated daily until we are quite satisfied as to the nature of the case.

137. Abscess may have formed in the liver, and death ensue before it makes its way beyond its seat. This result is owing, 1st. To the constitutional irritation produced by it; 2d. To the absorption into the circulation of a portion of the puriform matter as it is formed; 3d. To the consecutive disease thereby occasioned in other organs. The hectic fever attending abscess is probably caused by the passage of the morbid matter into the blood, and the bowel disorder, which so frequently attends it, may be the result of this circumstance. There can be no doubt, however, that the disease of the bowels is sometimes so severe, and the organic lesions found in them so extensive, as to fully account for the death of the patient before the abscess had opened into any part. Consecutive disease in the lungs and in the brain may likewise be occasioned before abscess has made its way from the liver, and prove the more immediate cause of death. Pneumonia and coma are not rare in such cases.

138. When abscess makes its way beyond its seat, or through the coverings of the liver, the direction it takes much depends upon the part of the organ in which it is seated. If, in consequence of the absence of inflammation from that part of the surface or coverings of the liver, the seat of abscess, or of the inflamed deposit of coagulable lymph, no adhesions are formed between the external surface of the abscess and the part opposite to it, the matter will be necessarily effused into the peritoneal cavity, where it will produce peritonitis. But if adhesions form through the medium of coagulable lymph with the parts opposite, the abscess will proceed accordingly, and open into an adjoining viscus. Hence, abscesses of the liver terminates as follows: 1st. As most frequently in death; (a) from the effects on the constitution and to the complications induced without having opened or passed from the organs; (b) in consequence of having opened into adjoining parts, and of the additional disease thereby induced, as well as of the persistence or increase of the lesion of the liver; 2d. And more rarely in recovery, (a) in very rare instances, without opening of the abscess into adjoining parts, the matter having been absorbed and eliminated by the kidney; (b) after it has opened in certain circumstances.

139. The situations in which the abscess opens are, 1st. Without having formed adhesions into the peritoneal cavity; 2d. Having formed adhesions externally through the abdominal parietes; 3d. Through the diaphragm into (a) the pleural cavity; (b) the lungs and bronchi; (c) the pericardium; 4th. Into the stomach; 5th. Into the gall-bladder or ducts, passing thence into the duodenum; 6th. Into the colon, duodenum, or some portion of the small intestines, particularly the latter; 7th. Most rarely into the right kidney, or into the vena cava. Certain of these terminations may be recognised during life, and recovery may take place in a few instances.

140. a. The external opening of an abscess of the liver is preceded by much swelling in the hypochondrium and epigastrium, and often by increased heat. As the matter makes its way to the surface, the swelling becomes less diffused, assumes more the form of a distinct tumour, and appears as a firm, fixed, hard swelling, particularly the latter, with a very deep-seated base, the integuments over its apex becoming discoloured and inflamed; and it becomes softer and more fluctuating in this situation, while it continues hard towards the base. The softness and the discoloration which take place in the integuments over the apex or centre of the tumour, are the only indications which can be relied upon of the abscess having formed an adhesion to the external parietes of the abdomen, and are the only circumstances in which an operation should be resorted to; if they are absent it ought not to be attempted. Owing to the neglect of these indications, I have seen great mischief result from having recourse to an external opening; and I have farther seen the tumour caused by a distended gall-bladder mistaken for an abscess, and an operation on the point of being performed. Owing to pressure on the common duct, or to permanent closure of it, the accumulation of bile in the gall-bladder may produce so great distention of it as to simulate a productive abscess of the liver so closely as to be distinguished from it with great difficulty. The dis-
tention of the gall-bladder may even be associated with or caused by abscess, in which case the diagnosis becomes still more difficult, as all the antecedent and concomitant symptoms of the latter are observed. But attention to the insinuations just named will guide the physician aright. The diagnosis is very fully stated in the article Gall-bladder (§ 22). The abscess may make its way externally, not only at the margins of or below the ribs, but also by a fistulous opening between the ribs, or beneath the axilla, or diaphragm.

141. β. The passage of matter from an abscess in the liver through the diaphragm into either the plural cavity or into the lungs is not infrequent. In these cases the peritoneal surface of the diaphragm adheres to the part of the covering of the liver external to the abscess, and generally a similar adhesion of the opposite surfaces of the pleura also takes place, and the matter passes into the bronchi. In this case the patient sometimes recovers; but, in the generality of cases, the rare instance of the effusion of the matter into the pleura, fatal pleuritis results. When the matter is about to make its way into the lungs, many of the symptoms of diaphragmitis and of pleuritis of the diaphragm are present, with severe dry cough, pain, constriction, and oppression at the base of the thorax, hectic fever, hicouss, anxiety, dyspnea, rarely jaundice, the semi-recumbent or sitting posture, and absence of the auscultatory signs of pneumonia; and, as soon as the abscess bursts into the bronchi, the patient experiences a sudden feeling of suffocation, followed by a copious expectoration of puriform matter, attended by diminution of the swelling, fulness, or tumour in the hepatic region; the lung (commonly the right) into which the abscess had burst having lost its respiratory murmur, and become dull on percussion. Generally, as the matter is evacuated, the lung recovers, or partly recovers its permeability, turgidity, and tension, and, by filling itself with air, diverges, and is sometimes palpable above the ribs.

142. γ. When abscess points upon the stomach or duodenum, there are generally much diffused swelling and hardness at the right hypochondrium and epigastrium, frequently jaundice, huskless, and distressing vomiting, especially soon after substances are taken into the stomach, occasionally attacks of dyspnea, difficulty of swallowing, flatulent eructations, and singultus. After an exacerbation of these symptoms, with clammy perspirations, coldness of the extremities, &c., the patient throws up a quantity of purulent matter, sometimes mixed with a little blood, and the hepatic swelling subsides. When the abscess opens into an intestine, diarrhea suddenly appears, the stools consisting chiefly of purulent matter. When there is only a single abscess of the liver, and the organ is not otherwise diseased, and the malady no farther complicated, the opening into the alimentary canal may close, and the patient ultimately recover; but more frequently a fistulous opening remains, and matter continues to be discharged from time to time until the patient sinks.

143. δ. Of the opening of the abscess into the peritoneal sac, or into the plural cavity, or in any other situation, it is unnecessary to offer any remark. Of these, rupture into the abdomen is the most frequent. When this occurs, the consequent peritonitis is most acute. Cases have occurred of rupture of the abscess, both into the digestive canal and into the peritoneal cavity. A case of this kind is recorded by Dr. Graves, where the abscess opened into the stomach by three perforations, and also into the pericardium. Cases have also been recorded of an abscess making its way both into the lungs and into the bowels; and others have occurred when it has been opened externally and afterward burst into the digestive canal, or some other situation. In these cases there have probably been more than one abscess.

144. C. Chronic enlargement of the liver is a frequent consequence of inflammatory states, particularly of repeated attacks of chronic inflammation, and even of the several states of congestion and of functional disorder, complicated with, or consequent upon, remittent and intermittent fevers. The liver is generally enlarged in a gradual manner, but also so perceptibly as hardly to be mistaken. Its function is much impaired, the bile becoming scanty and depraved. The urine is also much disordered. A frequent, hacking, dry cough, a salivary, paroxysmal dyspnea, dyspepsia in various forms, emaciation, general ill health, and cachexia, with lowness of spirits and despondency, are usually present. A careful examination of the hepatic region, and due consideration of the history of the case, will enable the physician to distinguish this state of disease from chronic pleurisy with effusion, with which some writers believe that it may be confused.

145. The diagnosis insisted upon by Doctor Stokes as marking the differences between these two diseases may be here noticed: in both, the physician will find extensive dulness of the side on percussion, absence of respiration, and the other stethoscopic signs nearly the same, with a full or dilated side, and decubitus upon it. The swelling in the hepatic region may be the same, that arising from displacement nearly equalling that caused by enlargement of the organ. But when the side is dilated by a fluid, the intercostal spaces are raised either to a level with the ribs, or even protruded beyond them, and the side has a smooth and rounded appearance. "On the other hand, when the dilatation is caused by a solid tumour, the reverse of this occurs; the pressure being made upon the ribs, these are pushed outward, but the intercostal spaces preserve their relative positions with them, and the side does not present anything of the smooth and rounded appearance described."
the pressure of the ribs, and thus to protrude the intercostal spaces as much as fluid effusion. Attention to the extent and sphere of dulness on percussion, in different positions, to the history of the case, and to the toto ensemble of phenomena, will be a surer guide to the thinking observer than dependance upon single points, however nicely distinguished.

146. There is often greater difficulty in distinguishing the chronic enlargement of the liver, now under consideration, from that attending or preceding abscess; and the importance of the diagnosis is sometimes great. In both instances there is enlargement; therefore, as to this, no distinctions can be offered. The question is: 1. Is an abscess formed? and if this be answered in the negative; 2d. Is there one about to form? The answer to the first question can be made only from the evidence of abscess above furnished (§ 131, et seq.), or from the want of such evidence. The answer to the second question is furnished by the symptoms of inflammation preceding suppuration, by the symptomatic fever, with the other phenomena attending it; and by the general and local symptoms of chronic enlargement. In the former case there will be no evidence of inflammation in a state of progression; in the latter, the consequence only of inflammation is presented to us, the increased vascular action that occasioned it and the attendant fever having subsided. In chronic enlargement there are more decided proofs of general cachexia furnished, which are either not seen, or seen only in a less degree, in the enlargement preceding suppuration.

147. The changes observed on dissection of fatal cases of hepatitis and its consequences are fully stated in the section on the Structural Lesions presented by the Liver.

148. IV. The Diagnosis of Hepatitis will not detain me, as the descriptions given above comprise the chief distinctions between those states and consequences of the disease and other maladies which most closely resemble them. A very slight attention will distinguish between gastro-enteritis, or duodenitis, and hepatitis. The seat of pain or unceranness; the swelling in the hepatic region; and the inflammatory character of the symptomatic fever, with the attendant phenomena, will point out the disease. In gastro-enteritis these characters are wanting, the fever attending it being more hydramy than in hepatitis. (See art. Gastro-Enteric Disease, § 12, 13.)

149. The details furnished above also serve to distinguish chronic pleurisy with effusion from chronic enlargement and from abscess of the liver, as well as the differences existing between the several functional and inflammatory affections of the organ.

150. V. Complications of hepatitis.—The several states and consequences of hepatitis very frequently occur in connexion with other diseases, the hepatic malady being either primary or consequent of these diseases. Although I cannot, within my limits, describe the several complications which thus arise, yet I will briefly notice the chief of them, as the mere suggestion of them will often lead to their recognition in practice, and to the not unimportant inquiry into the nature of their connexion and succession.

151. A. I have already mentioned the great influence of remittent and intermittent fevers in causing hepatic disease. In many cases, the latter is almost coextensive with the former; and, in some instances, hepatic disorder precedes the periodic fever, and becomes developed into acute inflammatory, or even structural disease, as the fever proceeds. In these the fever presents more or less of what has been called the bilious character; and the specific cause of the fever superadds a constitutional malady to the local affection, and thereby aggravates it. Such complications soon become familiar to physicians in warm, insalubrious climates. Again in many instances, the hepatic affection is developed in the progress of the fever, and in others it does not appear until the decline of, or during convalescence from the latter. In these circumstances, the substance of the organ is principally affected, and the form and course of the local disease are frequently obscured. In all cases of periodic fever, therefore, and especially if the attacks have been frequent or prolonged, the functions and state of the liver, and the region of the organ, should be carefully examined both during and after the disease. (See FEVERS, Remit.)

152. B. The complication of hepatitis with dysentery, diarrhoea, or gastro-enteric disease is one of the most frequent and most important which comes under the observation of the intertropical and Indian physician. The association often escapes observation, owing to the seat and nature of the hepatic malady, and the exact procession of the morbid changes is seldom so manifested as to admit of recognition. In some instances, the superficial view of the liver, either attending or preceding inflammatory disease in it, seems so to irritate the gastro-intestinal mucous surface as to inflame, and ultimately to disorganize it. In others, disease of both the bowels and the liver appears to be contemporaneous; and in many the gastro-intestinal irritation is primary, and seems to be propagated from the duodenum along the ducts to the substance of the liver. This is, however, not so frequent a mode of extension as is supposed by many physicians. In most cases, the most intimate association of hepatitis with dysentery or diarrhoea, this can hardly be considered to obtain; and although the vitiated secretions from a diseased liver may irritate and inflame the internal surface of the large bowels, thus occasion diarrhoea or dysentery, and indicate the priority of affection to be in the former viscous, still other instances will, if accurately observed, show an opposite course of disorder to this, namely, indications of diseased liver appearing either in the course, or upon the decline or disappearance of the dysenteric affection. In these cases it has been supposed that, phlebitis having been produced in the veins arising in the ulcerated bowel, it has been propagated to the portal vein and its ramifications, giving rise to infiltrations of pus in the interstices between the lobules that have ultimately formed themselves into larger collections or abscesses. Others, again, believe that morbid secretions or other matters have been imbibed by the veins, and, mingling with the blood, have been carried to the capillaries of the liver, where they have
excited suppurative inflammation in the substance of the organ.

153. Without denying the probability of either of these views, a change closely allied to them evidently takes place in many cases, and the purulent collections so often found in the liver after chronic dysentery bear the same relation to that disease as other consecutive or symptomatic abscesses bear to maladies in which phlebitis occurs, as erysipelas, &c. In dysentery, therefore, it may be inferred that, in the progress of inflammation, phlebitis of the capillary veins of the bowels sometimes occurs; and that the matter or pus thus formed in these veins passes with the blood into the portal circulation, where it irritates or inflames the minute ramifications of the portal vessels and the structure of the liver, giving rise to purulent infiltrations and collections in the organ similar to those consequent upon phlebitis in other parts, but always occurring in the liver, and there only, because the morbid matter thus formed only enters the bowels into the portal circulation. As in other forms of consecutive or symptomatic abscess of the liver, so in this, the formation of matter is unattended by active or acute symptoms, or by the tumefaction of the organ generally preceding abscess consequent upon primary or active inflammation of it, as described above. (See section on Structural Lesions of the Liver.)

154. C. Of the association of inflammation of the liver with gastritis some notice has already been taken (§ 118). The extension of the disease from the concave surface of the organ to the stomach is not unfrequent, even without an abscess having formed; and in these cases the gall-bladder, ducts, and even the duodenum, are sometimes involved. More rarely, the inflammation seems to have extended from these parts to the concave surface of the liver, as shown by extensive organic lesions in the former, and by adhesions to the latter. In several instances of chronic disease of the digestive organs, with complete jaundice and obstruction of bile, with vomitings, &c., I have found the duodenum, the pylorus, and sometimes a portion of the stomach, firmly adherent to the liver; the pancreas greatly enlarged; the gall-ducks involved in the disease; the pylorus thickened and indurated, and its caliber remarkably reduced; the stomach enormously distended; the liver and gall-bladder variously altered, and the hepatic ducts loaded with dark bile. (See art. Gall-bladder and Ducts, § 18-24, et seq.)

(Dr. Burnett, in his recent elaborate work (On the Diseases of the Liver, Am. ed., Phil., 1846), has made the following divisions of the inflammatory diseases of the liver, viz.:

1st. Suppurative inflammation, or that which leads to suppuration and abscess.
2d. Gangrenous inflammation.
3d. Adhesive inflammation, or inflammation that causes effusion of coagulable lymph.
4th. Inflammation of the veins of the liver.
5th. Inflammation of the gall-bladder and ducts.

Suppurative inflammation, he supposes, either arises from a blow or from suppurative inflammation of some vein, and the consequent contamination of the blood by pus; or from ulceration of the intestines, the stomach, gall-bladder, and ducts—parts which return thin blood to the portal vein, to be then transmitted through the capillaries of the liver.

The association of suppurative inflammation of the liver with phlebitis, as in cases of surgical operations, is too well known to need particular remark; and it doubtless arises from the irritation of the pus globules in the capillary vessels of the liver, as when quicksilver is injected into the veins. Of 29 cases of abscess of the liver recorded by Ansley, in 21 there were either more or less extensive in the large intestine. Dr. Burnett maintains, with much plausibility, that in dysentery complicated with hepatic abscess, the liver does not become involved by spreading of the inflammation, but by contamination of the portal blood by pus, formed by suppurative inflammation of one of the small intestinal veins; or by matter of other kind, resulting from softening of the tissues; or by the fecal, gaseous, and liquid contents of the large intestine, which must be absorbed, and could not immediately cause abscess. He thinks it probable that contamination of the first kind usually gives rise to small, scattered abscesses; of the last, to diffuse inflammation, and a larger, perhaps single, collection of pus.

If the morbid matter be such that it does not mix readily with the blood, as globules of pus or mercury, it will cause small, circumscribed abscesses in the rest of the liver. If, on the contrary, the morbid matter be readily diffusible in the blood, all the blood will be vitiated, and diffuse inflammation result. In this view of the subject, suppurative inflammation of the liver is, in a large majority of cases, a purely secondary affection, consequent on the formation of pus in some other part of the system; but many observations and facts are still wanting to establish this doctrine on a permanent footing. We believe, with Dr. B., that spirit drinking produces adhesive inflammation and duration of the liver, not suppurative inflammation and abscess.

155. vi. Prognosis.—A. In the acute and subacute states of hepatitis, the prognosis will depend upon the part of the organ especially affected, and upon the progress and consequences of the disease. In temperate climates, when hepatitis is treated early and is duly recognised, it terminates favourably in most instances—probably in 39 cases out of 40; but in warm climates, and especially in the East, the proportion of fatal cases in those attacked by the disease varies from 1 in 20 to 1 in 7, as shown in the annexed abstract from the returns made to the Army Medical Board. In warm climates, the natives are less subject to hepatitis than the inhabitants of temperate countries.

("Of hepatic affections," says Dr. Forry (Climate of the United States, p. 301), "including acute and chronic hepatitis, and icterus, there are reported, in the Northern division, 98 cases and 3 deaths; and in the Southern and Middle, 166 cases and 4 deaths. The ratio of cases and of deaths per 1000 is given in the length given in different countries is as follows:

156. The circumstances which more particularly indicate danger are, the occurrence of the disease in cachectic, broken-down, or debilitated constitutions, especially among Europeans resident in warm climates, or in those previously the subjects of hepatitis; its affecting the substance of the organ, and its insidious progress and association with other diseases, especially with those of the bowels; its advanced progress before treatment had been prescribed, and the failure of judicious means employed at an early stage, and symptoms of inept or advanced abscess, and fully-developed hectic phenomena: in short, while the symptoms of resolution (§ 128) show a favourable termination of the disease, those which attend the other terminations and consequences of it (§ 129) evince more or less risk; and, although they may not indicate extreme danger in several circumstances and in many cases, yet in others, particularly where suppuration and hectic have been established, the chances of ultimate recovery are but few.

157. B. The prognosis in the chronic states of hepatitis varies with the changes and consequences of the disease, as manifested in different forms, stages, and cases of it; and depends upon circumstances connected with the patient and with the causes which produced the malady, as well as with those which may still continue to perpetuate or to aggravate it. Hence the physician will be guided in forming his opinion, not only by the form of the disease, but also in the acute and sub-acute states of it, by circumstances so numerous and varying as to preclude the possibility of advertizing to them with sufficient or satisfactory particularity. The soundness of his prognosis must necessarily depend upon the accuracy of his diagnosis, and of his recognition of modifying, exasperating, or countervailing circumstances and influences—upon his natural acumen, knowledge, and powers of observation.

158. VII. Treatment. — A. In the acute and sub-acute states of the disease, the propriety, and, indeed, necessity of having recourse to energetic measures as early as possible are manifest. In warm climates, the delay, even of a few hours, may place the patient in danger. The first and most important means of cure is blood-letting; and, especially when the substance of the organ is affected (§ 101), it should be promptly and energetically practised. Mr. Mawry's just observation, that "however long the disease may have existed, provided there be no symptoms indicative of suppuration, general blood-letting—repeated as the symptoms may demand—and copious in relation to age, health, and length of residence in India, must be instantly had recourse to; and the measure of depletion should be the sense of local and general relief, with softening of the skin." This advice is equally applicable to the acute hepatitis of other warm climates, and of temperate countries. The patient should be seen in from six to eight hours after the first bleeding; and if vascular reaction has returned or has increased, as often observed, venesection must be again prescribed and performed in the manner so often advised in this work.

159. Instantly after the first blood-letting, a full dose of calomel, conjoined with James's powder, or with some other preparation of antimony, ought to be given, generally in the form of a powder, and a saline purgative should be taken a few hours afterward. These may be repeated at intervals, according to their effects.

160. The above comprises the most efficient means of treating the more acute states of hepatitis; yet there are others which are powerful aids; and one of those which have been mentioned requires more particular notice, as respects not only the propriety, but also the mode of prescribing it. I shall, therefore, and particularly on account of the great importance of the matter, consider the latter of these subjects before I discuss the former, and examine the questions: 1st. As to the propriety of employing mercury in hepatitis; and, 2d. As to the mode of prescribing them in cases where their use appears to be required.

161. B. Of the Use of Mercurials in Hepatitis. — The question as to the propriety of employing these medicines in hepatitis has been very generally answered in the affirmative by most physicians, and yet few agree as to the states of the disease in which they either should or
should not be prescribed. There can be no doubt that these medicines have been employed, especially in India, in a most indiscriminating and empirical manner, and to a most injurious extent; and that even those who have used them the most liberally, as well as those who had no precise idea of their modes of operation, and even of the existing pathological conditions for which they were prescribed. Some physicians in the East Indies have contended that hepatitis there is a different disease from that which occurs in this country; and, consequently, that views of the treatment of it in the one climate cannot be extended to the other. This, however, is only partially true: it is essentially the same disease, although occasional symptoms modified in both climates; and the principles of practice are the same in both, for similar states of the disease slight alterations only being required, arising out of the persistent influence of the causes producing it, and the circumstances of individual cases. The mistakes and numerous evils to which they lead, of considering the hepatic diseases of India to be different from those of Europe, and of employing mercurials empirically in their cure, will soon be remedied with any examination of the mode in the former, if, indeed, they are not already manifest to many, and especially to the best educated and the most enlightened. I know, from repeated observation, that inflammations of the liver may be cured without mercury, in this country, quite as well, as safely, and as quickly as with it; but that there are certain states and consequences of these inflammations that require this medicine, and that are benefited by it more rapidly than by any other; and I believe that the same will be found to be the case in India, and in warm countries in general.

162. Some physicians prescribe mercurials in hepatitis with the intention of emulging the bile ducts; others simply as a purgative; and some with the same view as in other inflammations, when it is desired to affect the constitution with them, and thereby to change the state of capillary action in the affected organ. Now these several views have been promulgated and are manifestly the mode of operation of mercurials upon the biliary organs, and upon the assumption that they actually excite the organ, and enable it to discharge its functions. This assumption has arisen from the circumstance of an increased discharge of bile having followed the exhibition of them in many cases where this secretion appeared to be impeded or interrupted. Even these very writers who have argued for this mode of operation of these medicines, have employed them most consistently in the reverse views; even for acute inflammations of the liver, where, according to these views, they must have aggravated or perpetuated the morbid action which they were given to subdue.

163. Mercurials, like most other medicines, when employed in small doses, exert a stimulant influence for a short time upon living tissues; but, in large doses, this effect is either rapidly exhausted, or hardly produced, and a sedative operation results, which is the chief or the only effect usually observed. In doses either small or moderately large, they also exert a qualitative or alternate influence, relatively to the state of vital energy and vascular action, that becomes more and more manifest the more frequently they are prescribed, and the shorter the intervals between the doses. All the milder preparations, and the more acrid ones in a state of dilution, produce upon the capillaries of the skin a greater or less pronounced, somewhat of an astringent effect, resulting most probably from the influences already assigned to them; these preparations diminishing for a time the vascularity of the surface, and modifying its vital actions. This is shown by inflamed or vascular surfaces becoming less inflamed and less vascular soon after calomel and the other milder preparations of mercury are applied to them. Such, then, appear to be the changes produced by the usual medicinal doses of mercurials upon the states of vital energy and vascular action of parts to which they are more immediately applied; such, I infer, are their topical effects upon living structures in health and in disease; provided, however, that the vitality of the part be not remarkably depressed, or capillary action not altogether suppressed. Vital agents cannot influence dead structures, or structures approaching to this state, unless in as far as they may exert a chemical action, or less upon tissues, exclusively to their antiseptic or septic agency, by combining with the tissues or with the fluids they contain.

164. The consecutive or constitutional effects of mercurials are equally important, and ought always to be considered in connexion with the topical effects; for the former, in some cases, rapidly follow the latter, while in others they are produced with difficulty. The circumstances connected with this, and the consecutive operation of mercurials will be attended to hereafter. Having produced, or while producing their topical changes, mercurials are absorbed and carried into the circulation from the external surface of the body, by means of the absorbents, and from the digestive canal, either by the mucous absorbents or by the veins; if by the last, they will necessarily pass almost directly into the portal circulation. When carried into the blood, their effects are manifested by either a change and intensity, according to existing states of vascular action and vital power; but, in ordinary circumstances, and in a time which bears some relation to the frequency and largeness of the dose, they effect these states; increasing the frequency and impairing the tone of the former, and depressing the latter; and, ultimately, they weaken or otherwise change the crisis or culpability of the blood, and even the vital cohesion of the vital tissues.

165. Being partly to their local influence, and the sympathetic extension of that influence, and partly to their absorption, mercurials soon increase the exhalations and secretions from the cutaneous and mucous surfaces, and the secretions of glandular structures, while they diminish exhalation into serous or shut cavities. Those secretions in which are exerted effects or injurious materials from the blood, as the bile, the mucus, and the purgative fluids, the menstrual discharge, &c., are especially augmented by large or repeated doses of mercurials; nutrition, however, being impaired, and absorption increased, especially of interstitial or imperfectly organized deposits. If the ex-
hibation of these medicines, in frequent or large doses, be persisted in, these effects become more manifest; secretion and excretion, more especially salivary secretion, are greatly augmented; the crisis, or coagulability of the blood, that is often increased at first by them, is afterward either weakened or altogether lost; vital cohesion is remarkably impaired; and sometimes, as much as to amount to gangrenous softening and spahelation; the flow of the saliva becomes excessive; absorption and vital exhaustion are rapidly augmented; and low, irritative fever, consequent upon these latter conditions, and the transit of morbid or effete elements into the circulation, during the rapidity of absorption, exhausts and ultimately sinks the patient, either with or without certain local effects of a still more remarkable nature, as sloughing of the gums and cheeks, caries of bones, &c.

166. These being the local, consecutive, and progressive effects of mercurials, their influence upon diseases, particularly those of glandular organs and serous membranes, may be more accurately inferred. From these effects we may explain their beneficial influence in many instances of inflammatory irritation or action in the villous coat of the stomach and small intestine, that has been already referred to. When the substance of the liver is inflamed, a similar recourse to mercurials is not so generally advantageous, unless the inflammation be consequent upon or attended by active congestion of the organ, or accumulations of bile in the biliary ducts, and blood-letting has been largely prescribed. When the pulse is quick, soft, and irritable, and the bowels much relaxed or dysenteric, mercurials are frequently more injurious than beneficial, and mercurialism followed to produce their usual effects upon the mouth and salivary glands are either unavailing, or productive of injury by accelerating the accession or progress of suppuration.

167. The propriety of having recourse to mercurials in the more acute inflammations of the liver depending thus upon the peculiarities of individual cases of the disease, general rules as to the employment of them cannot be stated with sufficient precision. Much should depend upon the pathological deductions formed by the physician as to each case which comes before him. Authorities on the subject are contradictory, and are more calculated to perplex than to guide the inexperienced.

168. Formerly mercury was employed in hepatitis, by Indian practitioners, as a substitute for blood-letting. The injurious effects of this practice were first exposed by Dr. Ballingall. About the same time, or soon after he wrote, I endeavoured to form and publish observations employed only to aid, not to supersede blood-letting, to remove accumulations of bile in the bilary passages and liver, and to restore the secreting functions of the organ. Many of the writers on hepatitis, during the latter part of the last century and the early part of this, relied solely or chiefly upon the use of mercury for the cure of hepatitis, and yet had no precise ideas as to its operation, beyond the production of its specific effects; and the majority of them, moreover, never discovered, notwithstanding the extent of their unfortunate experience, that it was difficult to produce these effects while inflammatory reaction continued, and almost impossible when suppuration had commenced. Still, believing or being told that mercury was the cure for the disease, they continued to dose their victims with it in every instance and in all circumstances, actually producing thereby most of the unfavourable consequences of the malady, and other serious affections of related organs. The rectum-operators of the present day have been under no small obligations to the calomel and mercury hallucination of the last half century, for the extensive field of practice with which it has furnished them. Nor have they alone experienced the bliss of the practice, for both East Indian and British practitioners have in some way or other reaped the advantages accruing from it, and from the habit of using it wisely or unwisely, if not generally, prompted it. The slightest dyspeptic, often denominated hepatic disorder, was a sufficient indication, with the great mass of the profession, for the exhibition of five or six grains of calomel every night, or every other night, in this country, and of twenty grains every night in India; and the tenesmus and other consequences of irritation of the rectum thereby produced were rarely recognised as the necessary results of this practice, set up as a part of the disease, requiring only a repetition of the same means for its removal, until fatal dysentery, abscess of the liver, or other disorganizing lesions were produced, and the fatal issue, which ultimately supervened, was most innocently and complacently viewed as the uncontrollable course and consequence of the malady, instead of the common result of a treatment prescribed with complete ignorance of the nature of the disease and of the operations in the organs made thereby. If there is no over-charged statement. Numerous proofs of it have fallen under my observation in this country. I have seen still more numerous proofs of it in the hospital books kept at an East Indian presidency, and some of these books I can still refer to and even produce. There is, perhaps, no other disease that more fully proves how very little mere experience—the blind experience of exclusive practitioners, incapable of close observation and legitimate deduction—serves the advancement of real knowledge, than the history of the treatment of hepatitis during the last seventy years. The following abstract of the opinions of a few of the many writers on diseases of the liver—of those more especially enlightened by Indian practice and extensive experience—shows the amount of obligation which is still their due.

170. Mr. Annesley recommends twenty grains of calomel to be given at bedtime, and a purgative in the morning. He attended many cases, and especially in those where the membranes are chiefly affected, or where bilious
LIVER—INFLAMMATION OF—TREATMENT.

171. Dr. Saunders remarks, that it is a matter of dispute among those who recommend calomel as a specific in liver complaints, "whether it acts by purging or by exercising any local operation on the biliary ducts, or by acting on the general system, and ultimately by salvation, it being a prevailing opinion that, when the system is impregnated with mercury, suppuration of the liver seldom takes place;" but the question is not as to which of these ways the medicine operates, but as to whether or not it acts in all these ways, producing, moreover, other effects, such as have been already particularized, certain of these effects being more prominently produced in some circumstances and cases than in others.

172. b. This question, then, is so much as to the propriety of exhibiting mercury in acute hepatitis, after blood-letting has been duly premised, and repeated in cases requiring its repetition, for that is very generally conceded, with the exception I have made above (§ 167), but as to the quantity and manner in which it should be given. Although the difficulty of answering this question has been already shown (§ 170), yet some have attempted to answer it with more precision and to dispense with application than is compatible with the rational employment of medicinal agents to control morbid actions. On the one hand, we have Mr. Annesley's twenty-grain doses of calomel, which are sometimes required, but which have been recommended by him as the almost only mode of employing this medicine; on the other, we find Mr. Cekirs, another Indian practitioner, advising only three grains of calomel to be given with four grains of mercury and rubarb, every night and morning, in which combination the calomel is decomposed, and the patient takes only the oxide of mercury. In many cases, this latter plan will be preferable, especially when it is desired, as in states of inaction of the liver consequent upon inflammation, or connected with congestion, infarction, or enlargement, to stimulate the functions of the organ, and promote the absorption of morbidly engorged parts; in other cases, where the objects are to derive from the liver the powers of discharge, and to arrest with the utmost speed inflammatory action and its consequences, scruple doses of calomel every night, or smaller doses taken more frequently, will be more efficacious. Many years ago, I stated, as a reason for exhibiting mercury with decision, in order to arrest the progress of hepatitis, that the salivation thereby produced, and the determination of the fluids to the salivary glands, acted as a powerful check on morbid action in this organ to subside, and the healthy functions to be restored.

173. c. Another question suggests itself, namely, are there other means which may be used in aid of blood-letting, or after vascular depletions have been carried sufficiently far, in order to procure a free discharge of bile, and prevent suppuration? I believe that there are, although farther experience is required to determine which will be best suited to obtain the end sought from them, and the particular circumstances in which they are more especially indicated. Some of these may be employed either as

*From considerable experience in the treatment of acute hepatitis, we have come to the conclusion that mercury in it is not only an unnecessary, but a hazardous remedy, when given to any extent. We say it is unnecessary, for we have never seen a case which has not promptly yielded to free, general, and local blood-letting, with fomentations, blisters, free catharsis, with cream of tartar and potassa, the use of cold and warm saline and antimony in poisoning doses. Dr. Dickson of Charleston, also states (Essays on Pathology, &c., p. 163, vol. 1.), that he has never seen a fatal case of hepatitis when treated in this manner. In chronic disease, however, we believe small doses of mercurials are highly useful and necessary. If suppuration sets in, then the mineral tonics, given freely, are in the highest degree beneficial.*
stitutes for or in aid of mercury; the mecurial being taken at bedtime, and the other remedies in the morning and course of the day. Among these the bitartrate of potass is the most efficacious in promoting a discharge of bile, in removing viscid and tenacious secretions from the alimentary canal, and in lowering inflammatory action. It should, however, be prescribed in full doses—from one to three or four drachms twice or thrice daily, in the form of electuary; and it is often advantageously conjoined with small doses of tartrized antimony, or with biborate of soda, &c., according to circumstances. The sulphate and bisulphate of potash, the phosphate of potash, the nitrate of soda, and other neutral salts, are also of service when given in full or frequent doses, and judiciously conjoined with appropriate medicines.

174. C. Acute hepatitis affecting Europeans residing in the East Indies or in warm climates requires a similar treatment to that already advised; the only difference being the necessity of greater activity and promptitude in the use of the means of cure. Blood-letting, general or local, or both, should be freely practised. A full dose of calomel, from ten to twenty grains, may be given at bedtime, as it will not disturb the rest of the night; but operation will act upon the secretions until morning, when a brisk purgative should be taken to carry off accumulated faces, and those morbid secretions which the calomel had prepared for removal. The purgative that may be given in the morning may be either any of the saline solutions above mentioned, or the compound jalap powder, or the Seidlitz powders.

175. In warm climates, the rest of the patient ought not to be disturbed by the operation of purgatives during the night; and when it is necessary to continue the mecurial without disturbing the patient, it may still be given with one or two grains of opium, and with one grain of ipecacuanha, if the stomach be not irritable. In some cases, particularly when the bowels are irritated, an anodyne draught, or an anodyne enema, may also be administered at bedtime. These precautions against disturbing the patient during the night require especial attention in some localities, and where there is a free ingress of the night air, and where the nights are cold, damp, and chilly.

176. If the calomel at bedtime, and the purgative in the morning, saline diaphoretics and refrigerants being given in the course of the day, be followed by affection of the mouth, as usually happens in the course of three, four, or five days, when vascular depletions have been duly premised, then it is sometimes necessary to induce ptialism as quickly as possible, particularly in the circumstances and with the exceptions above noted (§ 167). This may be done by the use of calomel, which, in the form of a purgative, may be given in a dose of from one to four drachms, or even more, in the fluid form of a solution or electuary. The calomel in this form will act quickly, and in a more thorough manner, than in any other form; and the patient will have a full bowel movement in one, two, or even three hours after its administration. It is not necessary to continue the full dose of calomel at bedtime with James's powder, or ipecacuanha and opium, is most to be relied upon. Combining calomel with any of the preparations of antimony tends to hasten the specific effects of the former, particularly after blood-letting. If irritation of the large bowels supervene, emollient enemata should be administered; and a cooling aperient may be taken occasionally to evacuate the morbid bile which the warm climate allows to accumulate in hepatic diseases, and which, if not removed from the bowels, irritate, inflame, and ulcerate the parts in which they lodge. As soon as ptialism is produced mecurials should be intermitted, and gentle tonics, refrigerants, and alkaline carbonates, saline aperients, and a light abstentious diet should be prescribed. It is not necessary, in hepatic diseases, to continue this effect upon the salivary apparatus above a few days; for its influence upon the complaint is produced in a short time.
LIVER.—Inflammation of—Treatment.

180. In the sub-acute and less active cases, particularly those which have been of somewhat long standing, or which have supervened on previous disorder of the liver, debodobstruent and saline aperients, alternated with mild cherishands and alteratives, and occasionally with a full dose of calomel at bedtime, is generally beneficial, particularly after local depletions have been duly prescribed. If these means fail, then the full effects of mercury should be induced as quickly as possible; after the appearance of which mercurial medicines may be laid aside, at least for a time.

181. When great congestion and enlargement of the liver accompany the inflammatory state, repeated leeching, or cupping under the scapula, and debodobstruent and antiphlogistic aperients are requisite. After the inflammatory action is entirely removed, blisters applied to the region of the liver are generally useful; and in the more chronic or obstinate cases, the blister should be kept open, or an issue made in the side. Laxatives and aperients act more copiously after vascular depletions, and blisters applied on the region of the liver promote the secretion and excretion of bile. In all instances the evacuations should be inspected by the physician, they furnish the chief part of the information required as to the state of the disease and the effects of remedies. The patient's or the nurse's account of them ought never to be trusted.

182. If fulness, swelling, or congestion continue after inflammatory action is removed, and after debodobstruent aperients have been duly employed, and if the disease thus assumes a chronic form, the means hereafter to be recommended become appropriate. In this state of disease, I have prescribed medicinal doses of the iodide of potassium, with liquor potassae and decoction of tararum, and occasionally the spirits of nitric ether, with marked advantage. A liniment rubbed on the region of the liver, or an embrocation, or debodobstruent plaster, in this situation, is also of service.

183. After the acute symptoms have yielded, and the digestive functions appear restored, still much torpor of the liver often continues, and a course of gentle laxatives and debodobstruents, with digital pills and mineral tonics, is often required, in order to assist the vital action of the organ, and to excite the sluggish bowels. If any enlargement still exist in these cases, either the debodobstruents just mentioned, or small doses of Plummer's pill, or of blue pill, should be given at night, and weak solutions of salts in the morning. But care should be taken to detect any remains or return of inflammatory action, and to remove it by local depletions and cooling diaphoretics. In many of these cases the treatment appropriate for chronic hepatitis is appropriate, particularly the nitro-hydrochloric acid bath or lotion, and the nitric and hydrochloric acids, or either of them singly, taken in any of the simple beverages used by the patient. When torpor of the liver remains after acute hepatitis, a course of these acids promotes the re-establishment of the bilary secretion and the return of strength, particularly when combined with mild tonics and a suitable regimen.

184. Treatment of the Complication of acute Hepatitis.—These complications generally result from the neglect of treatment of the primary disease, or of the early stage of the disease, and more especially from the neglect of blood-letting—a. When the concave or posterior part of the liver is inflamed, the extension of disease to the stomach, gall-bladder, or ducts, is often rapid, particularly in warm climates, if an appropriate treatment be not promptly employed. In this complication general and local depletions, and full or large doses of calomel, with or without opium, are especially requisite; and from having recourse to these, the state of the pulse and feelings of the patient should not deter the physician, as the symptoms will all improve after resorting to them. Subsequently, external derivation, the semicuprum, or pedilivum, &c., may be prescribed. Irritating purgatives should not be given by the mouth; but the action of the bowels should be produced by means of purgative enemata. The treatment of this complication is, however, not different in any respect from that of the simple disease; it requires only to be more energetic and more promptly resorted to.

185. Diaphragmitis, pleuritis, pneumonia, or even pericarditis, is not infrequently associated with acute hepatitis, particularly when the convex surface of the liver is affected; and it is sometimes difficult to determine, especially when the patient comes under treatment late in the disease, which of these was the primary affection. In some cases disease commences in the form of pleuritis and extends to the diaphragm, or liver, or both; but more frequently it attacks first the superior surface of the liver, and subsequently the diaphragm, the pleura, and lastly the lungs, or more rarely the pericardium. The respiration, expectoration, and physical signs will indicate the presence of one or more of these complications; and phlegm, or phlegm, is the most frequent, as respects the affection of either of its serous surfaces, although it is not that which is most frequently detected during life. (See art. Diaphragm, § 8. et seq.) In some cases, however, the liver rises, in consequence of the congestion and swelling attendant inflammation of it, so high in the right thoracic cavity, as to simulate either simple pleuritis, or pneumonia, or the complication of hepatitis with these. When hepatitis is neglected, or inadequately treated, it may extend to the diaphragm, thoracic membranes, and lungs is of frequent occurrence, both in warm and in temperate climates. In these complications, active depletions, and the antiphlogistic treatment and regimen in all their details, are required. In order to aid in lowering vascular action, and to prevent or to remove the consequences of inflammation, full doses of calomel with James's powder, with or without opiates or anodynes, according to the circumstances of the case, should be prescribed. Antimonials ought never to be omitted whenever there is reason to suppose that disease exists in the thorax, or is advancing thence from the liver. They may be given so as to occasion some degree of nausea; but it is doubtful whether or not they should be prescribed so as to produce full vomiting when the liver is unequivocally inflamed; for, although vomiting may relieve the affection of the lungs, it may aggravate that of the liver. In some cases good has indirectly resulted from the exhibition of an emetic, in developing and
rendering more manifest an obscure disease, and thereby leading to a more energetic and suitable treatment than would otherwise have been employed. Where anaemia is the primary thing is subdued, these blisters, rubefacients, or the tartarized ointment may be applied; and if the case become chronic, a seeton or issue may be made in the side. In this complicated state of disease mercurial medicines should be given in combination with antimony, camphor, or opium, or with either or all, according to circumstances. If no effusion has taken place into the thoracic cavity, vascular depletions having been duly employed, benefit will be derived from the instillation of potassium hydroxy or opium, applied over the seat of uneasiness; but if effusion have taken place, the repeated application of blisters, persistence in the use of mercurials until the mouth is slightly affected, and the continuance of this affection by means of the milder preparations every night, while small doses of the hydroxy of potash are given in the course of the day with the liquor potassae, will generally remove the disease, if extensive disorganization have not taken place.

176. Treatment of Abscess of the Liver.—When the symptoms noticed above (§ 131, et seq.) indicate commencing, or even impending suppuration, then mercurials ought not to be prescribed; for they will only lower the vital powers, and extend the local disorganization. Moreover, it has been shown by Marshall, Malcolmson, Graves, Stokes, and others, that it is impossible to affect the salivary glands with mercury when an abscess has once formed; and I have long ago insisted that it is also difficult to prejudice of. When an inflammatory action exists, or is unobserved. Although matter may be actually forming, the inflammation producing it does not cease upon this event. Suppuration in parenchymatous structures especially is a consequence, but not a termination, of inflammation. In some cases, inflammatory action continues with much activity until the abscess makes its way either externally or into some viscous or cavity; while in others it subsides considerably, the circulation exhibiting merely the irritable state, and the hectic symptoms usually attending the formation or the existence of matter in vital organs. When, therefore, it is inferred that an abscess is formed, it is necessary to control, as much as possible, the state of vascular action, locally and generally, particularly where we find, from the existence of pain, excited state of the tongue and character of the pulse, that inflammatory action is considerable. In these cases, small or repeated local depletions, cooling diaphoretics, and a refrigerant and febrifuge regimen, are the most appropriate means. By these the morbid action should be diminished, vital power is preserved by attention to air and diet. While depleting locally and prescribing aperients in order to evacuate morbid secretions and feacal accumulations, which always increase disorder when allowed to remain, the physician will often see the necessity, in these cases, of supporting the vital functions by a gently nutritious and cooling diet, allowing the patient no more food than the digestive organs can calmly and healthily perform. The embrocation applications fail, he will endeavour to rally them by gentle tonics conjoined with refrigerants, as the nitrate of potash, the hydrochlorate of ammonia, or the mineral acids, knowing well that if these formulæ are allowed to work in a struggle they have to endure against the organic changes going on in the liver, the purulent formation becomes the more extensive and formidable.

187. a. When there are general tumefaction and throbbing in the region of the liver, with pain, firmness of pulse, and erythematic appearance of the tongue, but without either rigours, cold sweats, faintings, or a sense of sinking, anxiety at the scrobicular cords, or night perspirations, then local depletions should be freely employed; but the amount of such depletions should depend upon the strength of the patient, his age, and on what has previously been done. In this state it is generally too late to have recourse to mercurials, excepting as aperients; they will merely add irritability to an irritable pulse, and lower vital power. In general, the abscess which is forming has not yet materially deteriorated the circulating fluids; and leeches applied over the seat of swelling, and followed by a sweat, or poultices, may tend both to lower the local action and to favour the extension of the matter to the surface.

188. When formications, rigours, cold, or profuse sweats, a sense of sinking, and other signs of change in the circulating fluids, and of vital depression are present, even local depletions will then be injurious, and mercurials not less so. But the nitro-hydrochloric acid, or the nitric acid, taken frequently, or in the patient’s usual drink, is often grateful and restorative, does not produce the same harm as the bowels. If it have this latter effect, the tincture of opium should be used along with it. Either of these acids may also be taken in gentle tonic infusions. When it becomes still more necessary to support the powers of the system, the sulphate of quinine with sulphuric acid, the infusion, decoction, or other preparations of cinchona, with chloric acid, or chlorate of potash, or with liquor potassae, or the alkaline carbonates, may be severally prescribed.

189. As an hepatic abscess advances externally, the diffuse swelling is gradually changed to a distinct tumour, which generally becomes softest at its apex or most prominent part. The tumour is attended by an expanded and firm base. If adhesions have formed between the inflamed surface of the liver and the abdominal parietes, the most prominent part of the swelling is soon after somewhat red and hot. When an abscess forms in the concave part of the liver, although much general swelling is evident in the region of the organ, yet a distinct tumour is rarely detected, unless the abscess be seated in or near the anterior edge of the viscous. When the symptoms indicate the existence of abscess, in connexion with prominent disorder of an adjoining viscous, no distinct tumour appearing externally, it may be concluded that the abscess is making its way towards or into that viscous. In most of such cases, little more can be done than to support the powers of life, without exciting vascular action, and to evacuate morbid secretions.

190. b. If the abscess point upon, or adhere to the diaphragm, dyspnea, thoracic oppression, anxiety at the praeordial, cough, hiccough,
LIVER—I N F L A M M A T I O N O F — T R E A T M E N T.

or a suffocating sensation, are generally present, and require the exhibition of anodynes, antispasmodics, and aperients. If pain be complained of, and the pulse has not become weak or irritable, a few leeches may be applied in the direction of the diaphragm or over the sternum. If the abscess open into the bronchi, after ales have been formed between the several surfaces intervening, the chief intentions are to palliate the several thoracic symptoms, and to support the strength of the patient. If adhesion of the pleural surface does not take place, the abscess may break into the thoracic cavity, and give rise to all the phenomena of Emphysema. (See Pleura.) Where an abscess of the liver finds its way to the bronchi, the sudden irritation of the matter is often attended by signs of impending suffocation. In order to relieve this, the patient ought to be raised up, and warm fomentations should be applied to the chest and region of the liver. When the abscess has burst in this situation, benefit will sometimes be derived from nitric acid solution, conjoined with laudanum, hyoscyamus, or cocaine. When the tongue is moist, the expectoration easy, copious, and purulent, and the patient does not complain of much pain, the pulse being devoid of hardness or sharpness, the infusion, or even the decoction of echinoma, may be tried, with the acid and narcotic, the bowels being duly regulated and evacuated. If night perspirations, with loss of strength and appetite, or with other signs of exhaustion, supervene, the same means, in still more efficient forms, or the mistura ferri composta, may be prescribed. Where it is requisite to exhibit an aperient in these cases, the decocum aloes compositum with the spirit, ammon, aconite, or the compound infusion of gentian and senna, are the more appropriate.

191. c. If abscess of the liver is apparently pointing upon the stomach, as indicated by some difficulty in swallowing, by great thirst, by vomiting soon after substances are taken into the stomach, or by general irritability of this organ, or a pumping up of its contents, sometimes by jaundice, and by the sitting or semi-recumbent position of the patient, little can be done beyond palliating the more urgent symptoms. Large or full doses of opium may be given, and the mineral acids may be taken in the patient's beverage. The compound infusion of rose, or the infusion of calumba, may likewise be tried with laudanum, or with other narcotics. Hydrocyanic acid and creasote may also be employed. In one case I prescribed the creasote with opium with temporary relief. The bowels should be evacuated chiefly by enemata. When the abscess pointing on the stomach is large, considerable tumefaction is observed in the region of the liver; and when it has its way into the stomach, death generally follows immediately afterward. In a case to which I was lately called in Montgomeryshire, this occurred; the swelling and bulging of the right hypochondrium and epigastrium being remarkable, in addition to the other symptoms, and to deep jaundice. When the abscess is smaller, death is less immediate.

192. d. If the symptoms indicate that hepatic abscess has opened into the large bowels, the indications are to palliate the urgent symptoms and to support vital power. In some cases, the abscess actually opens in this situation, without the event being detected, the occurrence being mistaken for the frequent complication of chronic diarrhoea, or dysentery, with inflammation of the substance of the liver. When, however, the abscess is large, the change observable in the hepatic regions, and the state of the abdominal viscera, is often a remarkable feature. In these cases, the chief intentions are, to support the strength of the patient, to soothe the irritation in the bowels, and protect their internal surface, by administering emollient and demulcent enemata. The warm bath, hot or rubefacient embrocations applied over the abdomen, and the nitric acid or nitro-hydrochloric acid, in demulcent and gently tonic vehicles, with laudanum, or with the compound tincture of camphor, &c., are also sometimes beneficial. In these cases, the abscess may refill, and open again in the same or in another part of the bowel, most commonly in the former; and although death follows in the great majority of cases, recovery sometimes takes place.

193. e. It is not improbable that one or more abscesses may form in the substance of the liver, and that, after having increased to a certain extent, or remained stationary for a considerable period, they may either partially or altogether be absorbed, without opening either externally or internally. The abscess may be drained out, and the patient entirely recovered. Proofs of this occurrence have been furnished by the history of cases, and by post-mortem examinations, where the liver has presented extensive cicatrices, or marks of the seat of old abscesses, from which the matter had been absorbed, and the internal surfaces had adhered, as described in another section (§ 212, 213).

194. f. This favourable result occurs chiefly when the powers of the constitution are not allowed to sink, and when the absorbed matter is freely eliminated by the kidneys before it accumulates in or contaminates the blood, so as to give rise to the severer forms of hectic and all its consequences. It is very probable that the chronic diarrhoea and dysentery attending abscess of the liver are owing to the effect produced upon the glandular apparatus and on the villous surface of the intestines by the purulent matter absorbed into the circulation, particularly when it is not sufficiently eliminated by the kidneys.

195. g. The diet and regimen of the patient should be carefully attended to, and should be so regulated, during the course of hepatic abscess, as not to excite or increase febrile action, or to impair the powers of life. The farinaceous kinds of food taken in sufficient quantity for the wants of the system and powers of digestion, as tapioca, arrow-root, sago, rice, rice-milk, bread and milk, bread-puddings, stale bread, biscuits, jelly, &c., are generally most appropriate, although cases occur in which other articles of diet, according as they are relished, digested, or agree with the patient, may be permitted. When animal food is allowed either to support the system, or during

* It is not unlikely, also, that certain depositors, assuming a semi-consistent or cheese-like appearance, and varying from one to several in number, occasionally found in the liver, particularly in Europeans who have resided long in the East Indies, are merely the more consistent and albuminous parts of pus, the aqueous portions of which had been absorbed.
convalescence, the lightest kinds of fish and white meats should be preferred, and taken in small quantity.

196. g. The external opening of hepatic abscesses, and the best modes of accomplishing this end, have engaged the attention of several writers, and very discordant testimony has been furnished by them of the success of the operation. There are numerous circumstances which influence the results of these cases: 1st. The age, diathesis, and constitutional powers of the person. 2d. The size and pathological associations of the abscess. 3d. The existence of two or more abscesses. 4th. The situation, particularly as respects the more external part of the organ. 5th. The existence of the surface of the abscess to the abdomen of the liver and the abdominal parietes. 6th. Redness and prominence over the seat of the abscess; and, 7th. The states of severe or advanced hectic and protracted diarrhoea, or chronic dysentery. Of these more important circumstances, external redness and prominence over the seat of abscess, as indicating the existence of adhesions and a somewhat external or superficial position of the purulent collection, and sufficient constitutional power to bear the more immediate and contingent effects of the operation, are the chief indications for entering upon it. Mr. Bell states that Dr. Dick, a physician of extensive experience in the diseases of India, found that the application of caustic to the part at which an abscess is pointing externally, with a view of opening it gradually, is sometimes followed by absorption of its contents, and by the recovery of the patient. This being the case, he was led to consider severe external irritation over the seat of the abscess as a most efficacious mode of favouring the absorption of the contained matter, and to recommend the application of caustic as the best means of procuring its external discharge. Dr. Graves advises an incision to be made through the integuments over the most prominent part of the external swelling, dividing the more superficial muscles, and keeping the wound open by a plug of lint. Mr. Annesley recommends the operation only when external redness, with some degree of pointing, indicates the adhesion of the surface of the abscess to the abdominal parietes, and prefers the lancet to the trocar in performing it. He objects to the latter on account of large flakes or curd-like matters being contained in some abscesses, which cannot pass through the canula, but are retained, while the more fluid parts only pass away. Having made the external excision large and with caution, until the peritoneum is exposed, fluctuation will be felt. An abscess lancet should then be introduced, and the abscess opened to the full extent of the external incision, which ought to be from two and a half to three inches in length. Care ought always to be taken that the opening do not extend beyond the limits of the adhesions which have been formed. Being fully evacuated, the cavity is directed to be filled with lint, in order to give a mechanical support to the excavated parts, and the wound to be dressed with compresses and bandages in the usual way.

197. Of these several modes of procuring the external discharge of hepatic abscesses, that advised by Dr. Dick, when aided by appropriate internal and constitutional treatment, is evidently that which is most congruous with pathological conditions, and with an enlightened experience of the cavity of the abscess with lint, as Mr. Annesley advises, is merely to admit the air, and to promote a more copious secretion of pus from the internal surface of the abscess: it cannot aid granulation and contraction of the cavity, but will increase the discharge, aggravate the hectic symptoms, and sink the patient with greater rapidity, as in all other cases where large internal abscesses have a free external opening, permitting the action of the air. In hospitals, and in low, damp, crowded, or unsanitary situations, this mode of procedure is particularly dangerous. I believe that, in whatever way the abscess may be opened, the orifice should be completely shut after the matter is discharged, so as completely to exclude the air, even although it may be necessary to reopen it often, or once, when matter re-collects. After the abscess has been opened, it is necessary to attend to the diet and regimen of the patient, to support the constitutional powers by means of mild tonics, or tonic medication with refrigerants, and to manage and correct the secretions and excretions by alternatives and restoratives.

[With respect to the use of mercurials in chronic hepatitis, as our author has passed them by, it is presumed that they do not, in his opinion, form a necessary part of the modus medicus in this form of the disease. And yet, if we mistake not, very minute doses of mercury, in some of its forms, especially when combined with iodine, will be found among the most successful remedies for this obstinate complaint. Dr. Dickson, of Charleston, S. C., who has had much experience in the treatment of this affection, remarks that mercury holds the first rank in the treatment of chronic hepatitis, after local bleeding by cups and leeches, and recommends that it should be introduced into the system slowly, and its influence upon the secretory vessels, as exhibited by a slight soreness of the mouth and gentle palsyism, kept up for some length of time, in the mean time keeping the bowels free, and promoting a due determination to the surface.] For these purposes, Dr. D recommended calomel in small doses, in combination with pulv. antin., with jalap, or rhubarb in sufficient quantity to affect the bowels moderately. This plan is to be persevered in for some time, employing, as useful adjuncts, the mineral acids, topical bleeding, blisters, exercise in the open air, flannel next the skin, &c.

We have seen that Dr. Chapman attributes the frequency of chronic hepatic affections in some parts of the United States to the extravagant use of mercury in the treatment of autumnal fevers and other diseases. The mode of procedure recommended by Dr. C. in this form of hepatitis, is moderate and repeated enemiation, cups and leeches over the liver, followed by a succession of blisters, or a caustic issue, aided by occasional purgings. To this end calomel is to be freely given every two or three nights, to be worked off the next morning with castor oil, Epsom salts, or magnesium, alone, or combined with colchicum, and this course to be continued for some considerable
time. Dr. C. also recommends the *Taraxacum* as a valuable deobstruent in these cases, as prepared after the following formula: B. Inflas. Tarax. viv.; Extr. Tarax. s. j.; Carb. Sod. 388.; Tart. Polas., Tinact. Khei., a., ziij. M. Dose, s. j. or more, three or four times a day. The fresh plant should be employed whenever it is possible to obtain it. Should this course fail in affording relief, Dr. C. next recommends a resort to a course of mercury, in order to restore the organ to its natural state by an alterative operation. For this purpose, minute doses of mercury, or bile of mercury, are to be given until some constitutional effects are perceived, as shown by an improvement in the state of the secretions, &c. This effect is to be kept up without abatement for several weeks, and in the more inveterate cases, with occasional intermissions, for months. There is, however, a great need of discrimination in the employment of mercury, for where it fails to promote the biliary discharge, it will not only prove of no benefit, but cause positive mischief, such as general irritations, or positive phlegmonis, with an irregular febrile movement. In every case, therefore, we must closely watch its effects, and immediately suspend its use if it does not appear to exert a salutary influence over the secretory functions generally. Where there are objections to the internal use of mercury, it may be employed byunction until the desired effect is produced, maintaining the same by repeated applications from time to time.

"That in these cases," says Dr. C., "reliance is placed mainly on mercury must be apparent, and in recommending it, having previously mentioned it as one of the causes of the disease, it may seem that I am guilty of an inconsistency. But such an imputation is not just, and cannot be sustained. It is against the abuse of the article I protest; and do not instances occasionally present where the same agent is the cause and remedy of the disease? This, indeed, is so true, that we have the old aphorism, 'Similia similibus curantur.' Take, for illustrations of it, delirium tremens, the attempts of it on the stomach from intemperance, &c. Do we not frequently resort to that very stimulant as a cure, which, improperly used, had produced the condition we are endeavouring to redress? Like the fabulous sword, the rust on which healed the wound inflicted by its point, mercury here cures the mischief it had occasioned. Even admitting that the case of hepatitis we are called to treat could be indisputably traced to the undue employment of that article, it would still be the appropriate means of relief. The liver being torpid, we should recur to mercury, from its well-known specific powers of exciting and restoring its healthy functions."

"It will not, I trust, be supposed, from what I have said, that I mean to lend any support to homœopathy, the leading feature in the doctrine of which is, that remedies are curative in proportion as they operate like the cause of the disease. The principle, as I have shown, undoubtedly is true to a certain extent; but what is to be received with many qualifications, they make of universal application, or without any limitation at all. False in theory, its disciples are still more so in practice, from the entire impotency of the means they profess to employ. Exceedingly absurd and mischievous as are many of the notions which disfigure the annals of our science more especially, none equal in these respects this recent phantasma, or had for its votaries such a collection of audacious charlatans or unmitigated impostors, and who, unrestrained by law or conscience, are spreading death in every direction."

"No longer ought it to be concealed that these mercenary miscreants, perceiving a loss of public confidence in the utter inactivity of the original practice, and particularly in the avowed inefficacy of every known expedient, are whirling around into the opposite extreme; now resorting to the most active, and in exorbitant quantities. The articles to which they are at present devoted, arsenic, veratrum, and aconite, are the most deleterious, when incautiously directed, of the whole Materia Medica. But"

"Fools rush in where angels fear to tread."

"From too feeble or energetic practice, I have seen, among other instances of disastrous results very lately, two individuals absolutely poisoned; by the inordinate use of aconite, the one thrown into violent tachypnoeic spasms, the other with incessant vomiting and delirious wanderings, and both cold, damp, and nearly pulseless. In a few words has been given my opinion of homœopathy and its followers, neither of which can have a wise or good man, and especially a physician, countenance in any way or degree for a moment. To consult with such arrant quacks is a degradation. To encourage them is to become *pariteps criminis*, and to employ them is wantonly to hazard life." —(Lecture on Therapy and Homœopathy. P. 335.)

We have derived great benefit, in the treatment of chronic hepatitis, from the use of the different preparations of iodine, and especially those natural mineral waters containing it. The sulphur springs of Virginia and of New-York (as at Avon, Richfield, and Sharon), the Saratoga waters, all of which contain more or less of this powerful mineral agent, have proved among the most successful means we have ever employed for the relief of chronic hepatic afebrile affections; and, in their joint resort, are recommended by a skilful and scientific physician, will be found adequate to the removal of many cases of this disease, which have resisted all other remedies.

198. F. Treatment of Chronic Hepatitis.—a. I have shown above that the chronic states of hepatitis are often similar to the acute, and differ chiefly in the activity or duration of the disease, in the structure chiefly affected, and in the more frequent association of organic lesions, which we do not so often meet with in the latter. The nature, however, of these lesions is seldom manifested through life, unless in as far as they may be attended with enlargement of the organ, and with deficiency of bile, or with jaundice; and even these are often equivocal. Although the bile is generally in smaller quantity, more remarkably changed from its healthy characters, and more frequently obstructed where the internal structure of the liver is chronically inflamed than when the surfaces are the seat of acute disease, yet the exceptions to this are so numerous as to forbid great reliance being placed upon it as a basis for indications of cure. The circumstances of chronic hepatitis being generally the cause of a great
majority of the lesions of structure found in the liver, and of itself being as frequently a sequela of the acute disease as a primary affection, ought to be kept in recollection, and the treatment that should be pursued. The forms of chronic hepatitis which are most readily recognised, and are most commonly treated as such, are those which are characterized by enlargement, by a scantly and dehydrated state of the bile, dyspepsia, and general ill health, low spirits, a sallow countenance and emaciation, particularly when they follow the acute disease, or periodic fevers, and occur in warm climates. In these cases the treatment should depend upon the previous disease, upon the duration of the acute treatment, and the duration of a residence in a warm climate. If much mercury has been already prescribed, if the constitutional powers are much reduced, mercurials, vascular deplications, and drastic purgatives are inappropriate, and recourse ought to be had to the nitro-hydrochloric acid bath, which should be steadily persisted in for a month or six weeks. While it is being employed, or previous to a course of it, a vapour or warm bath should be taken two or three times a day, followed by friction of the skin and surface; but the occasional recourse to the vapour or warm bath is preferable. At the same time, two or three drops of these acids may be taken in the patient's usual drink, and obstructions with mild aperients may be prescribed. It is in this form of the malady that the nitro-hydrochloric acid bath or lotion is the most beneficial; and in it the chlorides, the nitric acid, the tartrate, suptartrate, and acetate of potash are also beneficial. In the more chronic and obstinate states of the disease, I have found small doses of the iodide of potassium, uncombined with liquor potasse and with the decoction and extract of taraxacum, of great service.

199. b. When chronic hepatitis is a recent or primary affection, or follows the acute disease, owing to neglect or inactive treatment, or when it occurs in persons who live fully or who have not been reduced by previous disease, or by long residence in an unhealthy climate, then local vascular deplications, debasing or active purgatives, and mercurials are especially indicated. If this state of the disease be attended by congestion or enlargement of the organ, local deplications may be freely prescribed, and saline or other purgatives often repeated; but mercurials should, in most forms of chronic hepatitis, be given with caution. They are most beneficial in this particular state of the disease, where, however, they should be employed chiefly as debulcant purgatives. In other circumstances, experience has not demonstrated their utility, but shown that a frequent recourse to them only perpetuates the mischief for which they were employed. This seems to be the opinion of Clark, Dick, Saunders, Pemberton, Malcolmson, Martin, and others; and it accords with my own observation.

200. c. The nitro-hydrochloric acid bath was first recommended by Dr. Helenus Scott, who afterward ascertained that soaping the surface with a wash, containing the same acids, was as efficacious as the bath. Since 1796, when Dr. Scott published his first paper upon this subject, Sir James McGrigor, Dr. Pemberton, Mr. Bell, Mr. Annesley, Mr. Martin, and many others have shown the great efficacy of this treatment for chronic hepatitis; and, after all the acute symptoms have been removed, in cases of the more active states of the disease. It is more especially beneficial in cases attended by enlargement of the viscous, and a dehydrated state of the biliary and intestinal secretions. It should be employed daily for some time; and a trial of from two or three to five or six weeks may be given it, according to its effects. Even after its use has been interrupted for some time, its good effects will often continue. In an obstinate or extensive advantage from it should not be despaired of, although weeks may elapse without benefit being derived from it: and, although the first course of it may have been ineffectual, a second trial may be decidedly beneficial. A short time should elapse between the use of mercurials and a recourse to this bath, or wash; and purgatives should be occasionally given during the course, in order to carry off accumulated secretions from the liver and intestines. If heaviness or drowsiness occur after the treatment has been pursued for a few days, purgatives may be more actively prescribed. During the nitro-hydrochloric course, a change of air, especially to a temperate, and cool and pure atmosphere, will be of service. A feeling of cold, however, should not be occasioned by the change, as some risk of aggravating the complaint may be thereby occasioned. Sea voyaging, particularly when medical care may be enjoyed at the same time, is often of service, especially after the patient has resided long in a warm climate. HL should be exposed from a warm to a colder temperature, the clothing ought to receive due attention, and the night air should be avoided or guarded against.

201. The nitrous acid has been employed, in a very dilute state, as a common drink in chronic hepatic affections, in warm climates, chiefly as an alterative, and in order to promote the secretion and excretion of bile. When ta-

* Mr. Annesley gives the following directions as to the preparation of the nitro-hydrochloric solution, lotion, wash, or bath: "Into a common quart bottle put about eight ounces of pure water, to which add four ounces of the nitric acid and four of the hydrochloric acid, of the strength of the London Pharmacopoeia. The nitro-hydrochloric solution is thus formed. It can be in the form of a bath, from two to five ounces of it, according to the strength of the patient, is mixed with from two and a half to three gallons of warm water, of 96° or 98°, in a high and narrow vessel, and the wet and legs immersed in it for an hour, or two or half an hour every night before retiring to rest. If the bath does not occasion a pricking or itching sensation in the parts immersed, or to the parts touched by the water, the next bath should be increased in strength." Mr. A., however, states that, upon the whole, he prefers soaping the trunk of the patient with the nitro-hydrochloric acid lotion, as to absorb the excretion of the body and thelasts of the legs to be soaked, twice or thrice, or about a quarter of an hour daily, or occasionally night and morning. In torpor, and other chronic affections of the liver, he receved the wash to be used; also in the form of fomentation, or to be added by the application of warm poultices. "Occasionally much benefit will arise," he observes, "fromemploying the lotion in the form of fomentation; the water being made hot at 130° or 140° when the acid solution is added." Flannels soaked with the lotion may be applied to the head or to the face, to hypochondria and abdomen; and they may be covered with warm poultices, both the moistened cloths and the poultices being removed from time to time.
ken freely, and continued for a few days, it sometimes occasions salvation; but it is often of service without producing this effect. Sir J. McGrigor considered it equal to mercury in the cure of hepatitis. In the chronic states of the disease it is certainly a safer remedy than mercury, which ought not to be employed when this acid or the nitro-hydrochloric acids are being used. Issues, setons, or open blisters, or even the repeated action of blisters, a little below or over the region of the liver, are often beneficial in the more protracted cases, and when the foregoing means have proved unavailing. After a discharge from them has been established, poultices applied directly over them, and frequently renewed, are sometimes of service. Vapour baths, followed by frictions with a coarse towel, or by the flesh-brush, or hair gloves, and chlorine baths, are occasionally serviceable, and may be employed in the obstinate cases, in aid of deobstruents, alteratives, and aperients. Of other means, notice will be taken in the sequel, and after I have exhibited a view of the more chronic structural lesions of the organ.  

202. IV. Structural Changes in the Liver.  

Classif.: IV. Class; I. Order (Author). These changes are divisible into two classes, viz., those which proceed from primary vascular action, or are inflammatory, and those which depend upon the state of organic nervous power and nutrition, or are non-inflammatory. The former are generally more or less acute or active at their commencement, or are the consequences of acute or sub-acute disease; the latter are always chronic. Although both classes of lesions may originate in alterations of the organic, nervous, or vital condition of the liver, affecting the circulation and blood, and ultimately the structures of the organ, yet they depend upon very different states of the parts primarily affected; for while the one class seems to arise from an excited or exalted state of local nervous power and vascular action, the other apparently proceeds from a depressed as well as deprived condition—from very opposite states of power and of action; although the former may pass into the latter, when neglected, or in circumstances favouring the transition. Congestions of the organ, which may be independent of, or connected with either of these classes of lesions—both vascular and biliary congestions—have already been sufficiently noticed above (§ 59, et seq.), and need not, therefore, be again adverted to at this place.  

203. 1. Changes more strictly inflammatory, and consequent upon Inflammations.—4. The serous membrane or covering of the liver is liable to the same changes as are observed in other serous membranes. These are chiefly distension or development of the capillary vessels, effusion of lymph from the free surface of the part, and adhesion, by means of this lymph, to contiguous surfaces. The lymph thrown out upon the inflamed surface generally excites inflammatory irritation in the opposite surface, when brought in contact with it; and new capillary vessels are developed from the meshes of the old, and shoot into the coagulable lymph, and organize it. The membrane itself becomes slightly thickened, softened, and less tenacious than natural. These changes are common on the convex surface of the organ, are less frequent upon the concave surface, and are generally observed after acute or sub-acute hepatitis, affecting chiefly the surface of the organ, or membranous hepatitis. In these cases, congestion of the substance of the liver, well, and sometimes inflammatory appearances of the part subjacent to that chiefly affected, are also observed. In old or chronic cases the serous membrane is often thickened, opaque, and dense. It is sometimes, also, more readily torn, or less resistant. Depositions are also formed underneath this membrane in the chronic forms of inflammation of it. They consist of thin plates, presenting a cartilaginous appearance, and of an atheromatous substance.  

204. B. The substance or parenchyma of the liver (a), when inflamed, is more or less reddened, often deeply red, congested, and softened. If the inflammation is general, there is also great tumefaction from vascular distention. It is seldom, however, that the earlier changes connected with acute or chronic inflammation of the liver are observed, as the consequences and complications of the disease chiefly cause death. These early changes may occur in a part of, or more or less extensively throughout the organ. They are associated with inflammatory appearances in the serous surface, or with more advanced or other lesions.  

205. (b.) Softening of the structure of the organ is various in degree, and is commonly caused by the more acute states of inflammation, although it may also proceed from other causes. When produced by inflammation, there is not only friability, but also redness more or less deep. In some places, the redness is lessened by a sero-puriform or a puriform infiltration between the minute lobules. In these, abscess would most likely have been more fully developed, had the patient lived longer. In other cases, the softening has proceeded still farther in the centre, or in various parts of the inflamed tissue. In some instances, particularly in warm climates, the softened part is of a deep or dark colour, owing to associated vascular and biliary congestion (see Congestion or, §73). The most remarkable grade of softening is that which is sometimes observed after death from the more adhesive or malignant forms of remittent or marsh fever, and from scurvy. In these, the softening is not the result of inflammation, but of depressed vital power, causing extreme congestion with alteration of the congested blood. The congestion is sometimes so great in these cases, the blood so dark, and the tissues of the organ so softened or so much deprived of its vital cohesion, that the viscus assumes the appearance of a black, friable, or pulpy mass, which readily breaks when it is handled. Softening of the liver is often conjoined with tumefaction or enlargement, although not necessarily. Dr. Bailie has noticed softening of this organ in aged persons, the consistency of it approaching that of the spleen, and its colour being of a brownish red. Still more extreme states of softening have been observed by Portal, Bally, Jackson, Deveze, Montfalcon, Bailly, myself, and many others, in fatal cases of malignant remittent and other fevers, of scurvy, and
of purpura. In these the organ had hardly retained its form by means of the cellular framework of Glisson's capsule and of its vessels.

206. (c) Suppuration and abscess often follow softening of a portion or parts of the substance of the liver. Indeed, the softening may generally be viewed as the antecedent of suppuration, the sero-puriform matter diffused from the capillaries of the part breaking down or dissolving the vital cohesion of it, especially at its centre. If the constitutional powers be not sunk, and if the blood be not contaminated, lymph is diffused around the central softened and infiltrated part, and this lymph, as the infiltration and effusion in the centre proceeds, forms a cyst enclosing the matter secreted from its internal surface. (See art. Abscess, § 5, et seq.) If, however, the powers of life and state of the circulating fluids are such as not to form coagulable lymph, which may be thus condensed and stretched into a cyst by the matter accumulating within it, the abscess assumes a diffuse character, is not surrounded by any distinct cyst, the purulent matter at the margins of the collection infiltrating the surrounding lobules or structure of the organ. (See art. Abscess, § 13, et seq.)

207. Abscess of the liver may hence be divided into the converted and non-converted, either of which may be large and single, or numerous and small; or one large and several small may exist in the same organ; but it is very rare to find both the converted and non-converted in the same viscera. Abscesses frequently proceed from acute, and less frequently from chronic inflammation. They are much more frequently consequent of chronic or sub-acute inflammation in scrofulous persons. — a. Abscess, particularly when single and contained in a cyst, often attains a very great size, and converts the whole of the right lobe into a vast sac, stretching and condensing, and ultimately atrophying or destroying the lobular structure of the organ. It is usually situated in the right upper lobe or thorax, and bulging the hepatic regions. The cyst may be thin or thick, or more or less manifestly organized, and capable of containing from a few ounces to several pints. Locsi and ANDRAL consider that the internal surface of the cyst is analogous to mucous membrane.

208. b. The non-converted kinds of abscess are rarely very large, although I have seen them very large in one case, and others have been observed by Mr. ANNESLEY. They are rarely single, several or even many existing in the same organ. They are either cellular, in immediate contact with the structure of the organ, or partially infiltrating or diffused among the surrounding lobules. In many of these cases, little or no inflammatory appearances exist in the adjoining substance of the organ, while in others these appearances are either slight or equivocal, or are merely those of congestion. These abscesses are owing chiefly to phlegm, or to the passage of puriform matter into the portal circulation, that is either deposited in the part, or excites inflammation in the minute capillaries of the secreting structure. They have been also attributed, as noticed above (§ 20, 152, 153), to inflammatory action propagated along the hepatic ducts, according to some; and along the mesenteric and portal veins from the intestines, according to others.

209. The researches of M. CRUVELLIER (Novo Biblioth. Med., t. iv., et Anat. Pathol., liv. xi.), however, have thrown much light upon the formation of these abscesses, which I have denominated consecutive or secondary. (See art. Abscess, § 27) He ascertained that abscess of the liver from injuries, fractures, wounds, and surgical operations is always preceded or accompanied by purulent collections in the lungs, and always results from the same cause, namely, from capillary phlebitis in the neighborhood of the injury or wound; the globules of pus, which thus pass into the circulation, occasioning inflammatory irritation in the capillaries of these organs, in which the secondary suppuration is developed. When purulent or other morbid secretions are carried into the general circulation, the lungs, and frequently also the liver, become the seat of secondary abscesses, particularly when the powers of life are reduced, and the morbid matter is not excreted by the active functions of deputing organs. When these secretions pass into the blood of the portal system, consecutive abscesses or purulent collections generally take place in the liver. Hence, when ulceration occurs in the follicles or mucous surface of the bowels, in chronic diarrhea and dysentery, capillary phlebitis in the vicinity of the ulcerated parts sometimes supervenes, and the pus being carried into the portal circulation, excites inflammatory action of the capillaries of various parts of the liver. In like manner, secondary abscesses in the liver follow, as noticed above (§ 20), operations for hemorrhoids, fistula in ano, abscess, or ulceration near the anus, uterus, &c.

210. The changes which take place in the liver in these cases are stated by M. CRUVELLIER to be, in the first instance, effusion of bloody lymph and induration around the consecutively inflamed capillary vein; secondly, a secretion of yellow concrete pus into the tunnic veins, as among the lobules, giving the part a granite-like appearance; and thirdly, collections of pus, or small abscesses lodged in irregular cells, which increase in size by the continued secretion and extension into other cells. These purulent collections are surrounded by a narrow congested circle or margin, imparting to them a peculiar character. After they have existed a considerable time, their watery parts are absorbed, leaving concrete, whitish, and cheese-like masses, often resembling the matter of scrofulous tubercles.

211. (d) Gangrene of the liver has been very rarely observed, and then chiefly in connexion with non-converted or diffuse abscess. I have seen only one instance of it; and it has likewise been noticed by FORESTES, STEIDELE, Dr. CARSWELL, and Mr. ANNESLEY.

212. (c) Enlargement or hypertrophy of the liver is commonly consequent upon chronic inflammation, or upon the acute, after it has lapsed into the chronic state. It may be independent of any existing inflammation, and of all vascular or extravascular causes, although either or all of these, in some grade or other, may have preceded or may accompany it. The enlargement may be partial, or limited to any part or lobe of the organ, or it may be general. Mr. E. Wilson considers that it arises from irritation of the mucous membrane of the
ducts, occasioning, in the first instance, retarded circulation and venous congestion; or from impediment either in the circulation through the heart, or through the rest of the venous system; or, again, from impairment of the general powers of the system, as in the serofulous constitution. Without, however, dwelling on the causes of the lesion in some cases, I believe that it as frequently proceeds from an exudation of lymph between the minute lobules, or in the distributions of Gisson's capsule, that becomes more fine and dense, or more organized, the longer the period which has elapsed from its effusion; and that this lymph is the result of a sub-acute or chronic state of inflammatory action. Mr. E. Wilson states that the lobules are always in a state of partial congestion, resembling the second stage of hepatic venous congestion (§ 87); the congested portion presents a deep red tint, and the uncongested part is ramose or convoluted in appearance, of a dirty white, grayish, yellowish, or greenish hue, according to the condition of the biliary ducts and apparatus, and to the quantity and colour of the bile contained in the liver. Sometimes the organ is pale, and seems deficient in blood; at other times it has a generally diffused redness, or the congestion may be greater in one part than in others. The consistence of an enlarged liver is equally variable with its colour: sometimes it is hard, firmer, or denser than common, and even apparently granulated; the uncongested and granulated or denser parts projecting occasionally above the surface, and the congested portion sinking below the level of the former. As frequently, however, the organ is more or less softened, although often partially or unequally so. The enlargement of the liver may take place to a very great extent, the organ weighing twenty, thirty, or even forty pounds; its enormous bulk displacing more or less the other abdominal viscera. Hypertrophy is often associated with lesions of other organs, particularly of the lungs, spleen, mesenteric glands, pancreas, &c.; and with other maladies, as scrofula, rickets,dropical effusions, &c.

[One prominent cause, undoubtedly, of enlargement of the liver is the separation from the blood by the hepatic cells of some abnormal matter, which, instead of passing freely out of the liver in the bile, is retained there, adding to the size of the liver, and moreover, changing its texture and appearance. To understand how these changes are produced, we must bear in mind the intimate structure of the organ— that the lobules of the liver are spaces mapped out by the ultimate twigs of the portal vein, which, as Buon remarks, are hairy, as it were, with capillaries springing immediately from them on every side, and forming a close and continuous net-work, and that the inerstices of these capillaries are filled with nucleated cells, in which the vital chemistry of secretion goes on. We discover by the microscope that these cells vary in size in different livers; that in some they are almost transparent, in others opaque, and apparently more solid; that in some they contain but a few very small oil globules, while in others they are distended almost to bursting with globules of oil; that in some they are colourless, or nearly so, and in others, yellow with bile; and that in some instances they are broken down and destroyed. It is probable, too, that in some cases the cells are only slowly reproduced; that without complete destruction they become less productive of new cells, so that at length the number of active cells is much diminished. Now, corresponding differences in the size, colour, and texture of the liver are produced by these different conditions of the cells; sometimes these cells are completely broken down and destroyed, and this may result from long retention of the secreted bile from closure of the common duct, causing an enormous dilatation of the hepatic gall-duets, and occasioning the whole organ to assume a deep olive colour. Its tissue is flabby in these cases, but not readily broken down by the finger, and presents no appearance of lobules. Every part of the liver is affected alike, and exhibits under the microscope nothing but free oil globules, and irregular patches of solid biliary matter; the liver contains but little blood, and partly from this, but chiefly from loss of the cells, it may be smaller than in health, and its surface wrinkled, notwithstanding the biliary matter accumulates in it. But destruction of the hepatic cells may take place rapidly without any obstruction of the gall-duets, and instead of being consequent on jaundice, may be the cause of jaundice that proves rapidly fatal, apparently from disorder of the functions of the brain.

Several writers have described what they call serofulous enlargement of the liver, which is generally found connected with serofulous disease of the glands or of the bones. Portal supposes that it is an albuminous obstruction of the liver. Rokitansky calls it the "lardaceous liver," and describes it as follows: "Its anatomical characters are, considerable increase of volume, with striking development in breadth and accompanying flattening; very considerable gain in weight; a smooth, tight, stretched peritoneal coat; a doughy consistence, combined with a certain degree of resistance and elasticity; anemia; watery, pale-red appearance of the portal blood; grayish-white or grayish-red (mingled with yellow or brown) colour of the organ; smooth, homogeneous, lardaceous-looking section; scarce any fat on the knife-blade." The morbid appearances, he adds, depend on infiltration of the liver, with a compact, grayish, often transparent, albuminous, lardaceous, or lardaceous-gelatinous substance." Dr. Buon, as already stated, considers that, as in the fatty liver, the substance to which the liver owes its increased size and its other peculiarities is a product of secretion, which, instead of passing off in the bile, is retained in the liver. This affection, like the fatty enlargement, comes on without any pain, or even tenderness of the liver, which is supposed to be owing to the very gradual manner in which the foreign matter accumulates, and from its having no tendency to cause inflammation of the capsule of the liver or of the veins. It is worthy of note, that the passage of blood through the liver is much more impeded than in the fatty liver, probably from the foreign matter being firmer and less yielding than oil globules. — (Bouon.) The secretion of bile, however, may go on as in the fatty liver, at least the colouring matters of the bile; the complexion often remaining clear, but not so
often as in the fatty liver, as the matter deposited in its substance is firmer and more apt to interrupt the secretion, or the flow of the bile, and render the complexion sallow. Serosulous enlargement of the liver is met with in persons much emaciated, and in a state of serosulous cachexia; sometimes also in persons whose health has been broken by the conjoined effects of mercury and sulphur, or who have suffered from protracted intermitents.—(Reiphenbr.) Dr. Burns, however (p. 219), thinks that the liver is seldom much engorged from ague, and states that he has examined a large number of bodies in which the spleen was much enlarged from ague, but that in no instance did he find much enlargement of the liver. In this disease, as Dr. Graves has remarked, the stools are variously coloured with bile. "one part of them will be bilious, another part clay-coloured; they will be yellow to-day and pale to-morrow."—(Choragic Medicine, p. 506.) He infers from this that the office of the liver is interrupted by a temporary coagulation of this affection, then, as consisting of faulty nutrition of the hepatic cells, leading to the deposit of some peculiar matters, and unattended with pain, the diagnosis is, for the most part, obscure, but we shall be aided by the circumstances in which it commonly occurs, as in serosulous affections of the glands, or of the bones, or in individuals who have suffered from the combined effects of sulphur and mercury.

213. (f) Induration is occasionally attendant upon enlargement, and also upon the expression of the substance of the liver; but it sometimes is met with independently of these alterations, or with a normal size of the organ; the colour of the indurated portion varying with the grade of vascular or biliary congestion, from yellow to green, brown, or brownish red. The degree of density varies from a somewhat firmer state of the structure up to a cartilaginous condition. The highest grade of induration is generally observed in cases of arrested or decayed liver. Induration occurs in parts only of the organ, or is greater in some portions than in others. In rare instances it presents the distinct character of a fibrous or fibro-cartilaginous cicatrix, formed after the adhesion of the opposite sides of an abscess, the contents of which had been absorbed. The most hardened and granulated-like parts are also most deficient of blood.

214. (g) Atrophy of the substance of the liver is, like induration, one of the more remote consequences of inflammatory action. It may succeed depression, or even hypertrophy; and, as shown by Portal, is a much more rare occurrence than enlargement. As the viscus diminishes in bulk, the lobules become indistinct and variously congested, and appear intermingled and pressed upon by the cellular tissue with which they are surrounded. Mr. E. Wilson says that the proper lobular structure is sometimes entirely removed, and replaced by a loose or condensed cellular tissue. At other times the entire substance of the organ appears to have been absorbed by the pressure of a very large abscess, which has discharged its contents into the intestinal canal, and the parietes have afterward contracted into an atrophied mass. In rare cases, the atrophy is connected with a complete or incomplete cicatrix, remaining after absorption of the contents of an abscess, as noticed above (p. 213). These cases have been detected chiefly in India. Lieutaud found a liver that was shrivelled into a mass not larger than his closed hand. Portal met with this viscus, in a case of ascites, not larger than an ordinarily-sized apple. Atrophy of the liver may be general or partial. The latter, conjoined with hepatic venous congestion, is not an infrequent consequence of the practice of tight lacing; as Mr. E. Wilson has justly observed. The surface of the liver, in some of these cases, is marked by deep fissures into irregular polygonal divisions, resembling the lobulated appearance of the fetal kidney.

215. The Cirrosis of Lænnec is the most important form of atrophy of the liver. In it the organ is diminished to one half, or even one third of its natural bulk; the relative size of the right and left lobes is destroyed; and the surface is rendered shapeless by the projection of a number of ridges or granular points. The entire organ is wrinkled and shrivelled, is of a yellowish or greenish colour, varying from a bright yellow to a yellowish or greenish brown. Upon dividing its substance, it is found denser than natural; and the divided surface presents a number of patches of various sizes, but of a roundish form, resembling granules; and hence this state has been denominated granular by French writers. This alteration has been variously described by Lænnec, Boellard, Andræ, and Cruveilhier. Mr. E. Wilson remarks, that Mr. Kirwan first distinguished the true nature of cirrosis, which he called atrophy of the liver. In a case of granulated cirrosis, the liver being diminished to one half its natural size, Mr. Kirwan discovered, on injecting it, "that a collateral venous circulation had been established by way of the diaphragm." In another case, of a woman who had been tapped ninety times, he found, upon injecting the liver, that the same kind of collateral venous circulation had been formed. "The obstructions are thus circumvented by the development of condensed cellular tissue; and the greater part of the blood of the portal vein had made its way through dilated vessels upon the surface of the organ to the diaphragm, and from thence into the general venous circulation. In the latter case, there were numerous bands of adhesion between the liver and diaphragm, and between the intestines and the walls of the abdomen; and these also were traversed by large veins conveying blood from the portal vein into the general venous current.

216. M. Lænnec believed that the mottled and granular appearance of a section of the liver in a state of cirrosis arose from a morbid deposit, or from a special accidental tissue existing in the two states of crudity and softening. But somewhat more correct views were successively formed by Boellard, Andræ, and Cruveilhier, until Mr. Kirwan demonstrated that cirrosis is a partial atrophy of the liver—atrophy of the lobes with hypertrophy of the cellular tissue; complete atrophy of some of the lobules, partial atrophy of others, and biliary congestion without atrophy or hypertrophy of the rest. The small yellow grains, varying in size from a mullet seed to a pea or hazelnut, are not distinct lobules, in a variable state of hypertrophy, but small, unengorged patches,
composed of parts of several adjoining lobules, and having a single or several interlobular spaces for a centre.

217. Cirrhosis may follow enlargement of the organ; and it is manifestly the more remote consequence of chronic inflammatory action or irritation, during which the coagulable lymph exuded into the cellular tissue connecting the liver into lobules or organized, adds to the bulk and density of the cellular element of the organ, and thus hypertrophies it; the pressure thereby occasioned, together with imperfect nutrition of the lobules, producing more or less complete atrophy of them; while the varying states of vascular and biliary congestion, or of deficiency of blood and of bile in the vessels and ducts, occasion various tints of colour in different parts of the organ. When this lesion is far advanced, it produces ascites and jaundice, generally of that kind which proceeds from the accumulation of the elements of bile in the circulation. It is also sometimes preceded and attended by disease of the lungs or heart.

[Dr. BuDD supposes that the ordinary appearances in cirrhosis are the consequences of adhesions inflammation in the areolar tissue about the small twigs of the portal vein, by which serum and coagulable lymph are poured out. The serous part of the effusion is absorbed, and the fibrin contracts and becomes converted into dense fibrous tissue, which divides the lobular substance of the liver into well-defined masses, giving great density and toughness to the organ, and by compressing the small twigs of the portal vein and the small gall-ducts, and thus impeding the flow of blood and the escape of bile, causes the pale yellowish colour of the masses of lobules. The most frequent cause of this affection in this country, as perhaps in any other, is spirit drinking. The alcohol is absorbed by the portal veins, and carried directly to the organ, every fibre of which it permeates, and thus causes a change throughout its entire texture.]

218. ii. The second class of lesions of the liver, or those which seem more especially to depend upon impaired vital power and deprivation of the blood sent to the organ, differ from the foregoing in presenting no inflammatory character; in depending chiefly upon a constitutional vice, or proceeding from a diseased disposition inherent in the system; and in consisting chiefly of morbid deposits and of malignant formations. As most of these have separate articles devoted to the consideration of their nature and treatment, a brief notice will therefore be taken of them as they appear in the liver.

219. A. A deposit of fatty or oily matter is not infrequently observed throughout the liver. A certain portion of oily or fatty matter is one of the chemical constituents of the liver; but this may be so greatly increased, appearing in different forms, as the substance of the organ, as to constitute more than one half of its weight. M. Vauquelin analyzed a fatty liver which furnished 45 parts of oil out of 100 parts of the organ. This lesion is characterized by appearances resembling those exhibited by the livers of those fishes which furnish a large quantity of oil. The organ is of a cream or pale yellow colour, sometimes presenting deep orange or brownish spots on the surface. Internally, its appearance is nearly the same as that of its surface. It is generally enlarged, and sometimes softened; but it is occasionally firmer or much harder than natural. The fatty matter is commonly distributed equally through its structure, or infiltrated in the connecting cellular tissue. Sometimes, however, it is deposited in a mass, or forms several collections in various parts of the liver. This morbid deposit is readily recognized by the greasy feeling it occasions. A section of it appears like that of yellow soap. "The vessels seem pressed upon, and are scarcely perceptible; and the greasy deposit is divided into angular masses by a coarse and compressed cellular tissue."—(E. Wilson.) The quantity of fat deposited in the organ is sometimes very great, and it may exist even in a fluid state.

220. Portal found the liver quite white, and softened almost to the fluidity of melted fat, where no hepatic symptoms existed during life. He also met with this state of the organ in a female suffering a severe form of syphilis. Fatty deposit in the liver is similar to other morbid deposits. The fat is not owing to a degeneration of the structure of the organ, but to an undue secretion or deposit of the oily substance into the cellular connecting tissue of the organ, whereby its vessels and lobules are pressed upon, atrophied, or removed, in proportion to the amount of deposit. This lesion is found most frequently in persons who have died of scrofulous tubercles in the lungs, and of cancerous maladies. It has also been observed in connexion with hepatic and various chronic eruptions on the skin.

221. ANDRAL thinks that it may be owing to insufficient arterialization of the blood in the lungs, and diminished pulmonary exhalation; and he inquires if it can arise from an imperfect separation of hydrogen from the lungs, this element combining with the other element of fat, and being deposited in the parenchyma of the liver. This is not improbable, particularly during the low grades of vital power in which this change occurs, and in which nutrition is imperfectly accomplished.

[It was discovered by Mr. BowMAn (1841), and since this article was written, that this form of hepatic disease originates in an accumulation of oil globules in the hepatic cells. Dr. BuDD informs us that there is some uncombined oil or fat in every human liver, though small in quantity, and that it may be extracted from the liver by boiling, and may be seen through the microscope in the hepatic cells, in the form of very small globules of various sizes, having a dark outline. In the fatty liver, the quantity of oil in these cells is enormously increased, they being distended with very large globules, which obscure their nuclei. In some instances, the quantity of oil thus accumulated may equal in weight, and more than equal in bulk, all the other elements of liver put together. (For a minute description of this pathological condition, see BuDD on Diseases of the Liver, p. 227.)]

222. B. Deposits of true tubercle in the liver are rarely observed, and still more rarely independently of the presence of similar formations in the lungs or other organs; or of general indications of the scrofulous diathesis. They are met with in the liver of various sizes, from
LIVER—Structural Changes in.

that of a millet seed to that of a hazelnut. The tubercles are of a soft, cheesy consistence, and have a tendency to a brownish tint. They are deposited or infiltrated, according to Mr. E. Wilson, in the tissue of the lobules, which are compressed and congested by them. The obstruction to the circulation in the organ occasioned by them gives rise to more or less congestion.

224. Seirra, carcinoma, or cancer of the liver, appears in several forms, but most frequently in that of tubercles, tumours, or tubera of different size and consistence. They generally accompany manifestations of the malady in other parts of the body. At the commencement of their development in the liver, they resemble small, whitish, semi-opaque patches, occupying the tissue of one or several of the lobules. As they increase in size, they put on different appearances, and hence they have been divided into species and varieties.—(a) The simplest of these has been termed scirrous tubercle, and is well described by Mr. E. Wilson. It commences in a semi-opaque patch, and the outline of the lobules is for some time distinctly perceptible through its area; but at a later period the centre of the patch becomes quite opaque, and presents a cartilaginous hardness. The circumference is gradually diffused in the surrounding textures; and the progressive increase of the tumour seems to take place by the secretion of a milky, albuminous fluid into the meshes of the lobular venous plexuses. As the secretion increases, and becomes more consistent, the circulation in these plexuses is arrested, and the vessels obliterated. The obliterated vessels, according to Mr. Wilson, give rise to the appearance of small cells, in which the carcinomatous matter is deposited, and the larger areas are produced by the tissue of the capsules of the lobules variously distorted from their original form by the increased deposition. As the tumours become larger, white lines, formed by compressed cellular tissue, radiate from the centre to the circumference. Upon the surface of the liver, the scirrous tubercle appears flat, or slightly depressed in the centre.

224. (b) In a second variety, these carcinomatous tubercles, or tubera, are small and numerous, of a yellowish or brownish colour, and more rapid in their growth than those just described. The cells in which the carcinomatous matter is contained seem thicker, of larger size, and the contained matter or secretion is less firm than in the above variety. Occasionally they are redden in the centres by an effusion of blood, or by the congestion of unobliterated vessels, or by the passage of large or dilated nutritive vessels. When the latter variety of carcinomatous tubercles enlarge, they often coalesce, forming an irregular compound mass, divided into compartments, marking its original multiple form by septa of condensed Glisson’s capsule or by dilated vessels. This form of tubercle or tumour appears to be identical with the first variety of the tubera diffusa of Dr. Farre, and which he states to be “elevated at the surface of the organ, but not uniform in their figure, some rising with a regular swell into a round form, others acquiring a margin by being gradually depressed towards the centre, forming tumours without cysts, almost pulpy in their consistence, cellular in their structure, and containing an opaque white fluid.”

225. (c) A third variety of the albuminous carcinomatous tumours, the “large white tubercle” of BiiLIE, the “tubera circumscripta” of Dr. Farre, is well described by the latter physician. These tumours are of a yellowish white colour, and their projecting surfaces, slightly variegated with red vessels, deviate from a regular swell by a peculiar indentation at or near their centres, which are perfectly white and opaque. They vary much in size, according to their age or duration; for each tuber at its commencement is very minute, but during its growth it assumes the above character, and at its maturity exceeds an inch in diameter. These tumours commonly are distinct at the surface of the liver; but they coalesce internally, and form immense masses pervading the substance of the organ. Their cellular structure is so close, that a section of them appears solid and inorganie; but a white fluid of the consistence of cream is left on the knife by which they are divided, and a fresh proportion of this fluid adheres to it each time that it is passed over the surface of the section. The cellular structure becomes more apparent after long maceration.

226. (d) A fourth variety of carcinomatous tumour has been named the gelatiniform cancer, from the firm and jelly-like deposit occupying the cells of the tumour, instead of the albuminous secretion in the preceding varieties. The liver may contain a considerable number of tumours of various sizes dispersed through its substance. The smallest resemble the small patches in the inceptive stage of the other forms of carcinoma already noticed. The largest are equal to a walnut in size. They are distinctly circumscribed, and the lobules immediately surrounding them are flattened and compressed. In the smaller tumours the form of the lobules is more or less distinct; but in the larger the lobules have yielded to the characters of the disease. On the surface, the centre of the tumour presents an oval or irregularly marginal ring, around which it swells abruptly, and then subsides to the circumference. In a section of one of the larger tumours Mr. E. Wilson found a central area about two lines in diameter, transparent, dense, gelatinous, and bounded by a white marginal line. The portion of the section surrounding the central area formed the bulk of the tumour, was elastic, and rose above the central area, subsiding gradually to the mar-
LIVER—Structural Changes in.

227. (c) Medullary sarcoma is a fifth form of malignant disease occasionally found in the liver—the encephalocoele of several writers. The tumours produced by this morbid deposit are larger than serofulous tuberesces; and fewer, and more regular in form, than the scirrous variety (§ 223). They are originally developed the same way as scirrous, by infiltration into the minute capillaries, or into the tissue of the lobules, of a grayish white and opaque substance, which, as it accumulates, obstructs the circulation in the surrounding lobules. In their advanced state, the internal structure of these tumours is a loose mass filled up, with a soft and brain-like matter, often coloured with blood, or containing coagula from extravasation, in various stages of softening. As they increase in size, they become softer and more pulpy. This variety of malignant tumour seems to be identical with the second and third varieties of the "tubera diffusa" of Dr. Farre.

228. (f) Fungus hematodes, or the fungus-hematomatous tumour, is a sixth form of malignant disease met with in the liver, and is very intimate of the variety last described. In it there is a much more remarkable disposition to the development of new vessels, and to extravasation of blood, than in any of the preceding. As Mr. Wilson remarks, hard, cartilaginous, and scirrous tumours may exist with those of a softer texture, and of a medullary form; and both of these may be mingled together in the soft, elastic, and bleeding mass, constituting fungus hematodes. Fungus-hematodous tumours are infiltrating the cellular structure of the organ, and giving a general blackness to the substance of the lobules. 2d. As a morbid mass, composed of an acellular cellular net-work, in which the black coconis nature is deposed. 3d. As a melanous pigment accompanying tubereles or carcinomatous tumours, and imbuing the morbid structure with its colour. Melanosis varies in shade from a deep chocolate brown to a rich black. It rarely, or perhaps never, exists in the liver without being met with in other organs or parts of the body. (See art. Melanosis.)

231. E. Simple serous cysts are sometimes found in the liver, and are mistaken for hydatids. These cysts contain a watery fluid; their inner surface is similar to that of serous membranes; and their external surface is either adherent to the part in which they are imbedded, or is surrounded by condensed cellular structure, being very different from the fibrous cysts, which contain within themselves a number of detached smaller cysts or vesicles, and which are next to be noticed.

232. F. Hydatids or Acephalocysts are frequently found in the liver, enclosed in a fibrous cyst, and contained in a single parent hydatid vesicle. The hydatid cyst generally occupies the right lobe of the liver, and is most frequently situated very near the surface. It increases to a very great size, causing absorption of the structure of the organ, and opening into other viscera, after adhesions have been formed between them and the external cyst. Hydatids present the same characters in this organ as in other viscera. (See art. Hydatids.) When they are numerous, or when the cyst reaches a great size, a tumour is perceived or detected by touch in the region of the liver. The tumour is generally occupied by a watery, circumscribed, soft, and yielding mass, unaccompanied by the symptoms indicative of abscess; has not been preceded by indications of acute or sub-acute hepatitis; and is not attended by the constitutional evidences of cancerous disease. The external cyst is sometimes hardened by deposits of cartilagious or bony plates. The developing cyst may open: 1st. External through the abdominal parietes. 2d. Into the cavity of the peritoneum. 3d. Into some part of the alimentary canal, particularly the stomach, and yielding the adherent mem-branous cyst into the pleural cavity; and, 5th. Into the bronchi, whence the small hydatids may be expectorated. Some small cysts have occasionally been found in the liver containing a calcaraceous deposit, mingled with a membranous substance resembling fragments of hydatid sacs. These cysts are supposed to result from the spontaneous cure of hydatids.

[Some physiologists regard acephalocysts as true parasites, having independent vitality, and propagating by germs from without, while others suppose them to result from deprived nutrition of one of the normal constituents of the body. The celebrated comparative anatomist, Mr. Owen (Lect. on the Comp. Anatomy and Phys. of the Invertebrate Animals), has advanced the latter opinion, and supposes them to result from unnatural development of the nucleated cells. A French physician, M. Lisors, has lately discovered that acephalocyst are the dwelling-place of those microscopic animals to which Redolph gave the name echinococcus. It has long been known that echinococcus occasional exist in countless number in acephalocysts, but such instances have been considered exceptional, and the echinococcus have been regarded as parasites of the hydatids. The researches of M. Lisors, however, have led him to the conclusion that echinococcus exist in all acephalocysts. He]
states that among more than 800 hydatids from man and other animals, he did not meet with a single one without them. Dr. Bens also confirms this statement by his own observations (p. 332)."

233. G. Intestinal worms have, in rare instances, been found in the hepatic ducts, having passed from the duodenum along the common duct. It is very probable, however, that the worms have passed into the ducts after the death of the patient.

234. III. Diagnosis of Organic Lesions of the liver.—The symptoms of most of the structural changes of the liver are very equivocal, as many of them are common to several of these changes, as well as to certain states of functional and acute diseases of the organ. I shall therefore endeavour to determine the dependance which may be placed upon each of these symptoms, or signs, in estimating the seat and nature of the malady which occasions them.

235. A. Pain or uneasiness in any part of the region of the liver may arise not only from disease of this viscus, but also from diaphragmatic or costal pleuritis, or from partial peritonitis in the vicinity of the liver. It is a common symptom of disease of the pylorus or duodenum, or of the pancreas; from flatulence affecting the duodenum or the right arch of the colon; from feculent accumulations in the colon; or from disease of the substance or pelvis of the right kidney. Pain in its most severe states has been attributed above (§ 62), either to neuralgia of the nerves supplying, or connected with the liver, or to the irritation of gall-stones in the biliary passages. It should, moreover, be recollected that, during the absence of structural changes in the liver, little or no pain, or merely uneasiness may be felt in it, while symptomatic pains may exist in distant parts, chiefly, however, on the right side; the organic lesion not materially disturbing the sensibility of the nerves of the organ themselves, but exciting, through their medium, the sensibility of some portion of the spinal nerves of sensation. Next to the pain occasioned by gall-stones, neuralgia, and acute inflammation, that produced by malignant disease of the liver is the most painful. Hydatids, fatty deposits, hypertrophy, cirrosis, effusions, dilatations, inductions, and small secondary abscesses, are attended by little or no pain, especially in the hepatic region. The pain varies as respects its seat and extent. It may be limited to a particular point, or diffused over the whole hepatic region, affecting not only the right hypochondrium, but also the epigastrum, the back, the lower part of the right thorax, the right shoulder or apex, the left hypochondrium, &c. When it is limited, it may be centered in either of the parts, or it may change from one to another. It varies also in severity and in its character, as well as in its continuance. It is commonly more severe at one time than at another; or it presents exacerbations and remissions, or even complete intermissions. It may be felt only upon pressure, or in certain postures or positions. It is impossible to state any relation between the nature of the malady and the character of the pain or altered sensibility caused by it, as no such relation has been duly observed, or even perhaps exists. It is chiefly, however, in the more acute inflammations, particularly when seated in, or extending to, the surfaces of the organ, that pain is most continued as long as the inflammation is unshut. In all the other lesions, unless, perhaps, the sarcomatous form of carcinoma, the pain is remittent or inter-mittent, or developed only by pressure or by position.

236. B. Swelling, or tumour, has been already noticed, especially with reference to abscess (§ 140), hydatids (§ 132). In order to ascertain the existence of either, the patient should be carefully examined in the manner above described (§ 99). He should also be examined while standing up, leaning forward with his hands upon the table, and then the pain or abdominal muscles will thus be released, and the liver will fall more anteriorly. The changes with which enlargement or tumour of the liver is most to be confounded are, distended gall-bladder and tumours connected with other organs, as the pylorus, the pancreas, the duodenum, the omentum, or stomach. I have already shown (§ 145) how effusion into the right pleural cavity may so displace the liver as to occasion swelling or tumour beneath the ribs from the protrusion of the liver bed and the adjacent visera, just named, are often with great difficulty distinguished from those of the liver, while these latter are very readily mistaken for the former. Those which are situated in the hepatic region, or which are thus doubtful as to their seat and connexion, have been divided into two kinds, as they seem to contain solid or fluid matter. This distinction, however, is not very easily made, especially when they are deep-seated, or when the patient is corpulent.

237. a. Tumours containing fluid matters are generally more or less fluctuating; but cases occasionally occur in which the fluctuation cannot be detected, as in a case about to be noticed. Fluctuating tumours are chiefly hepatic abscesses, hydatid or serous cysts, and distended gall-bladder. 1st. Tumour caused by hepatic abscess, as shown more fully above (§ 140), is at first hard and diffused. Fluctuation is afterward detected with great difficulty; appears gradually, and only in the centre, extending to the circumference of the tumour in the more prominent and fluctuating part being surrounded by swelling and hardness. 2d. Hydatid, or serous cysts (§§ 231, 232), give rise, in most cases, to a circumscribed tumour, more or less fluctuating, elastic, but little or not at all painful, and unattended by diffused swelling or hardness at its base, or by redness of the surface, unless the cyst has reached the integuments, or has occasioned inflammation of the surrounding tissues.* 3d. Distention of the gall-

* A fibrous cyst, or sac, containing fluid or serous blood, was said to have been found connected with the liver in the case of a lady whom I saw in consultation with my friend Dr. BAKER. She was advanced in age, was corpulent, and had been more corpulent than she was then. A large tumour was found on the right side of the abdomen; it changed its position more or less with the change of position of the patient, and fell below the umbilicus. It seemed firm, and it evinced no fluctuation. Its mobility, situation, size, and hardness induced Dr. BAKER and myself to view it as a cartilaginous or solid tumour developed in the omentum. The patient complained of various gastric symptoms, but of little or no pain, until shortly before her death. Then she was suddenly and chiefly chiefly to the irritation produced by the tumour in the peritoneal surface of the bowels, and other visera with which it came in contact. This lady accompanied her hardness to
LIVER—Diagnosis of Organic Lesions of.

Blander has been described in the article on the diseases of the Gall-bladder and Ducts; and the diagnosis between it and hepatic abscess, fully stated (see § 22).

238. b. Solid tumours, in or near the hepatic region, generally appear with the liver when they partially extend under the cartilages, and when they remain near the same position. Tumours of the omentum, stomach, or pylorusgenerally admit of more or less motion. The swelling caused by congestion, or by induration, or by hypertrophy of the organ, is smooth and diffused. The enlargement, or tumours produced by cancerous deposits, when attended by inequalities of the surface of the organ, sometimes may be distinguished by these characters, which may be evinced through the abdominal parietes when the patient is emaciated, and when the liver falls below the ribs. The celerity or slowness of the development of the enlargement, or tumour, will also assist the diagnosis. Enlargements produced by congestion both appear and disappear the more quickly, while those caused by hypertrophy and malignant deposits are the most slow and permanent.

239. C. Jaundice has been so fully considered in the article devoted to that subject, especially in respect of its pathological relations, that no farther notice need be taken of it as a symptom of hepatic diseases. Intimately connected with this state of the cutaneous surface is the appearance of the urine evacuations. Generally when there is jaundice, the stools are more or less pale; and, when organic lesions of the liver are attended by this state of the skin, the evacuations are often of a light drab colour, approaching to white. But in chronic alterations of the organ, unattended by jaundice, the motions are very irregular, both as to frequency, consistency, and colour; they are often very unequal, or very different in colour, even the same evacuation exhibiting a great variety of colour, owing to the unequal discharge, and admixture of the bile in the stools. The faeces are generally pale and offensive, often yeasty, whitish, or clayey; and very rarely natural, either as to odour or appearance. In the more chronic cases, discharges of blood, of varying quantity, are observed in the motions.

240. D. The urine presents appearances connected with the nature of the hepatic disease, and with the degree of obstruction to the secretion and excretion of bile. In some cases it assumes a deep yellow hue before the skin itself is discoloured; and in other deposits lithate of ammonia of a bright pink colour on cooling. In most cases where the structural change has existed for some time, or is extensive, and the jaundice is deep, the urine is as dark as porter, and is often, also, of a greenish tint. It is often also scanty and turbid, especially when dropical effusions, particularly into the peritoneum, have taken place.

241. E. Dropical effusion is a frequent attendant on far-advanced structural lesions of the liver, and generally commences in the abdominal cavity, extending to the lower extremities only after the ascites has made considerable progress. When dropy proceeds from disease of the heart, it generally observes an opposite course, the effusion commencing in the extremities, and afterward extending to the large cavities. Cirrosis, or atrophy of the liver, induration, and the forms of degeneration which involve the principal part of the substance of the organ, and impede or arrest the circulation of the portal system, always, sooner or later, are followed by dropsy. Indeed, the abdominal effusion may be the first, and even the chief indication of the hepatic malady. (See art. Droopy, § 90, 96.)

242. F. Haemorrhages, as has been shown in the article upon this subject, often attended the more chronic and extensive organic changes of the liver. This circumstance has been fully insisted upon by practical writers; and the same dispositions place in the way of the portal circulation, to which, the more clearly described, is followed by ascites, in another class is productive of haematemesis, haemorrhoids, intestinal haemorrhage, or epistaxis. In the one, serious effusion takes place from the peritoneal surface; in the other, sanguineous effusion occurs from the digestive mucous surface, the tendency to either the one or the other depending much upon the vital condition of the membranes, in connexion with the state of the blood itself, and the condition of the vessels from which the haemorrhage proceeds. Haemorrhage, also, like dropsy, may be contingent upon the hepatic lesion either before jaundice has appeared, or at any period subsequently, but most frequently after some degree of discoloration has at one time or other occurred. Occasionally jaundice has been present and entirely removed, and at some period more or less remote from its removal haemorrhage from some part of the intestinal canal has taken place, proved critical for a time, or has recurred from the same part of the viscus and the diaphragm, and when the enlargement has been so great as to drag the latter downward, or to irritate the respiratory nerves.

243. G. Cough frequently attends enlargement of the liver, as well as acute, sub-acute, and chronic inflammations of the convex surface of the organ. It is most frequently observed when adhesions have been formed between the part of the viscus and the diaphragm, and when the enlargement has been so great as to drag the latter downward, or to irritate the respiratory nerves.

244. Besides the above, various other symptoms attend chronic lesions of the liver, and which, although not constantly present, are still very frequently observed, and deserve attention and due estimation. Of these the most common are, emaciation, sallowness, or pallor of the countenance, or a sickly appearance of the face and eyes; dilatation, and acrid or rank excretions, irritating the pharynx; slight acceleration of the pulse towards evening, heat and dryness of the palms of the hands, drowsiness, or pain, or heaviness over the eyes. Occasionally a fissured or lobulated appearance of the liver has been noticed in cases of jaundice.
of the tongue, which is sometimes also smooth and glossy, or loaded and foul, or more rarely furred in the middle and root, is observed. An irregular or partial perspiration often breaks out, and is frequently greasy and offensive, especially at night, or when it is copious. The existence of malignant formations in the liver may occasionally be inferred from the state of the stools and urine, in connexion with the general cachexia and anaemia attendant on the advanced stages of those maladies, and sometimes with manifestations of them in most external or superficial parts; but much uncertainty always attends their diagnosis.

244. 

245. iv. Treatment of the Structural Lesions of the Liver. — It is obvious that the treatment of these lesions must necessarily be a matter of difficulty and uncertainty, inasmuch as most of them cannot be ascertained with any degree of precision during the life of the patient. It is chiefly in cases of enlargement of the organ that admits of recognition, or of serous or hydatid cysts of considerable size, that means of cure can be appropriately or successfully employed. When fluid, semifluid, or solid matters are deposited in the liver, so as to enlarge or obstruct it, a reasonable expectation may be entertained of removing them, by the aid either of medicine or of diet and regimen. Hitherto, however, the means which have been considered most suitable for this purpose have not been such as could admit of a very successful application. Whatever means may be had recourse to should be directed with the following intentions: 1st. To the removal of the morbid lesion presumed to exist. 2d. When this object is unattainable, to retard its progress; and, 3d. To alleviate its effects. 

246. A. The first intention was formerly attempted to be fulfilled by courses of mercury, followed by mineral waters, &c.; and subsequently, and often less injuriously, by the nitro-hydrochloric acid baths. That mercurials were often injuriously employed in many cases of this kind, is evident from the circumstance that, if advantageously prescribed, if they had been directed with greater knowledge of the powers of the various preparations of this mineral, especially in various modes of combination, I have had sufficient opportunities of observing the error which has commonly characterized the employment of mercurials in organic lesions of the liver, is the exhibition of them, either in doses and forms, or with a frequency and continuance which are calculated to sink the vital powers, and to produce the resistance opposed by the constitution to the extension of the local mischief. Where, however, the organic lesions are the more immediate consequence of sub-acute or chronic inflammation, a judicious combination of the mild preparations of mercury with diaphoretics or antimonials, as Plummer's pill with soap and taraxacum, blue pill with antimonials, or with small doses of colchicum, &c., and a recourse to external derivations, as issues, setons, &c., are often of service.

247. As early as 1823 I had recourse to the preparations of iodine, especially to the iodide of potassium and iodide of mercury, in the treatment of those lesions of the organs attended by enlargement, or characterized by torpor of function, absence of fever, and dropsical effusion from impeded portal circulation; and since then, as stated in the early part of this work (see art. DROPSY, § 103). I have continued to employ this substance, in some one of its forms and combinations, more especially the iodide of potassium, for the removal of these lesions. Long subsequently to the period just named, this medicine has been resorted to by other physicians in the treatment of organic changes in the liver; but the preparations of it employed, or the doses in which they have been exhibited, or the modes of combining them, have been such as were little calculated to prove beneficial, particularly in the cases for which they were prescribed. In many instances they were exhibited in too large doses, and were inappropriately combined; in others, they were unsealed to the existing pathological conditions. In the first place, the preparations of iodine may prove injurious, by exciting or developing inflammatory action, where it already exists in a sub-acute or latent form, or where a strong tendency to it is present, especially when they are given in large doses, or when those which are more acrid are employed. Where inflammatory action implicates more particularly the surface or membranes of the organ, still greater caution in the use even of the milder preparations of this substance is requisite. It is chiefly when enlargement, obstruction, or torpor of the liver occurs after periodic fevers, or in the sequel of diahy sis, either alone or as a cause of dropsy, that iodine, particularly the iodide of potassium, employed either externally or internally, or both, and in conjunction with other debauchers, as the liquor potassae, or alternated with purgatives, has proved most beneficial in my practice. In these cases, the iodide of potassium, conjoined with liquor potassae, may be given in my preparations of taraxacum, or of sarsaparilla, or in mild, bitter, or stomachic infusions; whilst an ointment containing the iodide (3/5 of the latter to 2 of the former) may be rubbed over the right hypochondrium, or a plaster may be kept applied in this situation, consisting of equal parts of the emulsion ammoniacum hydrargyrum, and the emuls. picis compositum.

248. In those cases of enlargement of the liver which are attended by pain, or by sub-acute inflammatory action in some part of the surface of the organ, as well as in other cases where the above means either are inappropriate or have failed, the bi-tartrate of potash in mixture with the bi-urate of soda, in us large doses as the stomach and bowels will tolerate, has often proved remarkably beneficial, especially where the hepatic lesion has superinduced other dropsical effusion, or hemorrage, or jaundice. The nitro-hydrochloric bath, or lotion, or a course of these acids internally, or of the nitric acid alone, may be tried, particularly in enlargement of the liver, as advised above, and aided by debauchers purgatives or other appropriate remedies. As regards other means of removing structural lesions of the liver, it is unnecessary to add to what has been fully stated when treating, in the articles DROPSY, HEMORRHAGE, and JAUNDICE, of the most frequent consequences which they produce.

249. B. The second and third intentions of treatment comprise not only the means already
mentioned, which can, when they fail in accomplishing the first indication, sometimes fulfill the second, but also those remedies which have been more especially noticed with reference to those serious symptoms or consequences of organic lesions of the liver just referred to. It is obvious that, when we fail in removing these lesions, some one or more of these consequences will accrue—either dropsy, or jaundice, or hemorrhage, particularly from the digestive mucous surface, or any two or more of them; and that, either before they may have appeared, or subsequently, those means which I have advised, appropriately not only to either of these superinduced affections, but also to the original malady, should be employed. What these means are will fully appear on a reference to these subjects, especially at the places where they are treated of in connexion with hepatic lesions. 250. In most of the more chronic and extensive lesions of the liver, it is necessary, even while we employ means to remove them, to restrict in part the diet or to alleviate the depend- ences, to support the constitutional powers and improve the general health by medicine, by diet, and by air and regimen. In some cases, restoratives or mild tonics may be conjoined with alteratives, decoctums, and anodynes: thus the oxides or other preparations of iron may be given with iodine or some one of its preparations, or with the liquor potassae, and with narcotics or anodynes, according to the nature of the case, especially in the malignant alterations of the organ, when pain sometimes becomes a prominent feature of the malady. In other chronic cases, water impregnated with chloroform, or chloroform fumigation, as advised by Mr. Wallace, may be prescribed with temporary advantage, as tending not only to excite the functions of the liver, but also to promote the constitutional powers. With these views, certain of the chlorides may be employed, and more especially the chlorate of potash. When there is no tendency to inflammatory action, the bisulphate of potash may be given in the infusion of roses, either with or without small doses of quinine. In cases of enlargement of the liver consequent upon obstinate or repeated attacks of ague, the bisulphate of potash, prescribed so as to act freely on the bowels, is often most serviceable. [As Dr. Bovee has well remarked (On the Diseases of the Liver. Phil., 1816, p. 252), the treatment in cases of hepatic enlargement should have chief reference to the state of the system—the peculiar cachexia—on which the faulty secretion of the liver depends. When it depends on scrofula, our chief reliance must be on warm clothing, sea air, and bathing; a light, nourishing diet, comprising a liberal allowance of animal food and wine, and the preparations of iodine and iron, separate or combined. If the patient has previously laboured under syphilis and taken mercury in considerable quantities, the appropriate remedies are, warm clothing, a tonic regimen, iodide of potash, nitric acid, sarsaparilla, and quail. We are to bear in mind, in the treatment of these cases, that the original malady is faulty assimilation, and that the matter deposited in the liver does not become organized like the fibrin found out in inflammation, and that, by the use of proper means, it may all be removed by absorption, or pass off in the bile. To this end, repeated and long-continued frictions with iodine ointment, powerfully tend; and Dr. Bovee states (loc. cit.), that he has seen enlarged livers reduced to their natural size by iodide of potash, and frictions with iodine, or simply by these frictions and saline purgatives. Dr. Graves, also, in his Clinical Medicine, details several cases of a similar kind, successfully treated by blue pill and hydrate of potash.] 251. C. The Diet, in all diseases of the liver, should receive the strictest attention. The chief rules to be observed are, 1st. To allow only the most antiphlogistic diet and regimen, when any inflammatory action or any febrile symptoms are present; 2d. To recommend the most digestible food in small, or at least very moderate quantity, in all other cases; and, 3d. To advise the adoption principally of farinaceous articles of food, and to allow only a small quantity of the lighter kinds of animal food once in the day, even in the more chronic and least severe cases. A milk diet is generally of use, especially when the milk is taken with the addition of a small quantity of lime-water, or liquor potassae, or Seltzer water. A diet consisting of milk and the farinacea is very generally appropriate, especially when it is found to agree with the patient. 252. Regular exercise, particularly on foot or on horseback, sea-voyaging, and warm clothing, the general surface being covered with flannel, are also requisite aids to medical treatment. Change of air, especially to a cool, temperate, and healthy locality, and to a dry and elevated situation, is also of great importance. When a change of climate can be joined with the use of deobstructive saline springs, additional benefit will accrue. In torpid states of the liver, after a long residence in a warm climate, or in chronic affections of the organ, particularly those connected with congestion, enlargement, or inflammation, the deobstructive and purgative mineral waters are generally of service. The waters of Cheltenham, Leamington, Harrogate, or those of Carlisle, Kissingen, Marienbad, Honorg, of Pulsau, Sclauschitz, [Avon, Richfield, Sharon, Saratoga, Western Virginia], &c., and the artificial mineral waters prepared at Brighton, are several productive of benefit, when employed appropriately to the varying features of the case, or even of the same case,

LUNGS

Inflammation of the.

1. Inflammation of the Lungs.—Syn. Pneumonia, Peripneumonia (from πνευμόνα, the lung).

2. Defin.—Rapid, short, and sometimes oppressed respiration; cough and expectoration; general feverishness, and uneasiness referable to the lungs.

3. Pathol. Defin.—Inflammation and its usual consequences in the parenchyma of the lungs, often comprising the small bronchi and air cells on the one hand, or the pleura on the other, or either, more particularly or exclusively.

4. Of the numerous symptoms attending pulmonary disease, there are perhaps, none which are present in all cases excepting the above. The ascertainty vary with the stage and intensity or extent of the disease, and therefore are not comprised in the above definition. It was shown by me, in the article Bronchi (§ 41, 42), and subsequently by Dr. Stokes, that, although pneumonitis may originate in the cellular tissue or parenchyma of the lungs, yet it very frequently arises from an extension of the inflammatory action from the small bronchi to the air cells and substance of the organ; a mode of origin which had been generally overlooked until I insisted upon it, and contended that the inflammation, when thus originating, may not be confined to the parenchyma of the lungs and the minute bronchi and air cells, but be extended even to the pleura, producing the usual consequences of pleuritis, as will be more fully shown hereafter. It will be preferable first to consider the primary and simple form of pneumonitis, and afterward to notice its primary and simple form of pneumo...

inflammation of those affected with apices—b. Of those the lobar is the most common; it may be confined to an irregular portion of a lobe, or may extend to a whole lung, or to a great part of both lungs. When the inflammation is very extensive, it commonly exists in different degrees of advancement, as will more fully appear in the sequel.

7. As to the parts of the lungs most frequently attacked, Morgagni, Frank, Broissais, &c., judging from the post-mortem inspections, inferred that the upper lobes were often affected than the lower; while Lennec, Andral, Chomel, and others, comprising the slighter cases and those of recovery, considered that the lower lobes were most frequently inflamed.

M. Chomel found, out of 59 inspections, that the apex was attacked in 13, the base in 11, and the whole or central parts in the others. In general, the upper lobes are more frequently affected than the lower in the most dangerous cases, and when the disease assumes a low or adynamic form. M. Andral, found, in 80 cases, 57 of the lower lobe, 30 of the upper, and 11 of the whole lung. The proportion, however, in which the upper lobe is affected appears greater, according to this calculation, than obtains in this country.

8. b. In the lobular state of pneumonia, the inflammation is confined to a few isolated lobules, being limited by the interlobular cellular tissue, and appearing as lozenge-shaped or polygonal patches of red, engorged, or heaped tissue. This, however, is all that is contended for; the structure in which the inflammation is seated being such as gives rise to those phenomena when inflamed, other phenomena resulting from inflammation of the bronchial tubes. There can be no doubt, however, that inflammation of the air cells and minute bronchi will so fill up and obliterate them with the usual products of this state of morbid action, as to give rise to appearances similar to those consequent upon an infiltration of the same products in cellular or parenchymatous structures; and that, when the inflammatory action originates in the latter, it will give rise to changes similar to those produced by it when commencing in the minute tubes and cells; inflammation of these latter being rarely confined to them, but extending to the parenchyma or filamentous tissue of the organ; or, in other words, that the morbid action may originate and predominate in either series of structures, but that it rarely continues without implicating both.

6. The French pathologists, and after them several recent English writers, have distinguished the disease into lobar, lobular, and vesicular, according as it extends to the whole or continuous parts of lobes, or is limited to certain polygonal subdivisions of these, or to single bunches of vessels—a. Of these the lobar is the most common; it may be confined to an irregular portion of a lobe, or may extend to a whole lung, or to a great part of both lungs. When the inflammation is very extensive, it commonly exists in different degrees of advancement, as will more fully appear in the sequel.
hours. These are not, however, observed in all cases, or are so slight in some as to escape notice. Attending this state of febrile exirritum, and in addition to the usual concomitants of it, anxiety, difficulty of breathing, oppression in the chest; short, dry, or suppressed cough; general uneasiness, loss of appetite, are, are usually complained of.

13. The increment or development of the disease follows the disappearance of chills or rigours. Animal heat gradually increases until its assumes a marked character; and with it are developed vascular reactions, turgescence of the lungs and general organ of the circulation. The symptoms especially referrible to the afflicted organ now more particularly manifest themselves.

14. Respiration becomes short, frequent, anxious, and difficult; is attended with unusual expansion and elevation of the chest; with a frequent small cough, and increased warmth and moisture of the expired air; and as the disease advances, is performed chiefly by the diaphragm and diaphragm muscles. The chest, apparently remaining unmoved, especially on the side chiefly affected. The patient is unable to take a deep inspiration, the turgid and inflamed lung being incapable of farther expansion; nor is he able to expire freely, the organ being equally incapable of collapsing; and he lies, with preference, on the affected side, or, if both lungs are diseased, in the supine posture. There is a constant feeling of uneasiness rather than of pain complained of in the chest, with an unequally, a sense of constriction, fulness, internal heat, and of weight. There are constant restlessness, inquietude, and tossing, with frequent attempts to elevate the chest and shoulders, proceeding from the great vascular turgescence of the lungs, and obstacle to their farther expansion, to attempt which, the patient feels irresistibly called. The cough at the commencement is dry, troublesome, and short, accompanying almost each expiration, especially after a full inspiration, and constant: it afterward becomes more moist, and is attended with a scanty mucous, expectoration of a saffron hue, or streaked with blood. Still the dyspnoea is slight, respiration being quick, short, and frequent, but not difficult.

15. Sometimes a lancinating pain darts through either side of the chest, indicating irritation of the pleura, proceeding either from coeal and consecutive inflammation of a portion of pleura, or merely from the unusual degree of tension, a sense of constriction, fulness, internal heat, and of weight. There are constant restlessness, inquietude, and tossing, with frequent attempts to elevate the chest and shoulders, proceeding from the great vascular turgescence of the lungs, and obstacle to their farther expansion, to attempt which, the patient feels irresistibly called. The cough at the commencement is dry, troublesome, and short, accompanying almost each expiration, especially after a full inspiration, and constant: it afterward becomes more moist, and is attended with a scanty mucous, expectoration of a saffron hue, or streaked with blood. Still the dyspnoea is slight, respiration being quick, short, and frequent, but not difficult.

16. The symptoms which have a sympathetic relation to the disease are less constant, and are less to be depended on than the above and the physical signs (§ 48): they have generally more reference to the degree of sym pathetic fever than to the extent of local disease. They chiefly consist of turbidity of the countenance, with flushing of the cheeks, sometimes circumscribed, particularly towards the period of the evening; febrile excitation; gravitational headache, vertigo, suffusion and watering of the eyes; a humid tongue, covered by a thick mucous coating; constant thirst; anorexia; tension of the abdomen, with increased action during respiration, and peculiar uneasiness about the insertion of the diaphragm; costiveness; a scotch reddish, crude, or turbid urine, with scaling upon voiding it; palpation of the heart; great action of the arteries; a quick, full, and hard pulse—in children so quick as scarcely to be counted. The pulse is also sharp; but the hardness generally ceases early in the disease, and it often becomes soft, weak, or small. In some cases it is soft and small from the commencement. As the disease advances, lethargy or symptomatic delirium sometimes occurs; or more rarely, and in still more unfavourable cases, or in some cases more or less profound, supervenes. Blood taken from a vein is more thick and dense than usual, and exhibits a thick tenacious crust on its crassamentum, with little serum, or the coagulum is very firm and large.

17. The more severe the disease, and the more extended its seat, the more intense are all the symptoms, both local and general. They are always exacerbated towards evening and diminished in the morning. When both lungs are inflamed, all the foregoing symptoms are particularly marked, and vital power more pros trated or more readily exhausted, the constitutional symptoms assuming more of the adynamic character; but even when both are affected, the inflammation is generally limited to portions of them only.

18. When one lung only is inflamed, the sense of heat, tension, weight, &c., is chiefly confined to the same side as it, and on this side the patient lies with most ease, reclining on the affected side producing great anxiety and uneasiness. Respiration, also, is performed unequally, or only by one side of the chest, that containing the inflamed lung being nearly inactive during inspiration, but considerably elevated.

19. Circumscribed redness of the cheek of the same side is often observed, and frequently, particularly in children, the hand and wrist of the affected side are red and turgid, apparently owing chiefly to the pressure on the upper part of the arm, from constantly lying on the affected side.

20. The period of fully-developed disease occurs in from three to five days, according to the severity of the attack. The symptoms continue for some time afterward, generally for three, but seldom beyond five days, with slight exacerbations and remissions, especially when left to nature or insufficiently treated, and with occasional signs of a disposition to crisis. The dyspnoea is then more urgent, and the respiration short and rapid. The head and shoulders require to be raised. In the worst cases, inspirations are short, forced, and as frequent as from 40 to 50, or even 60, in a minute. The expectoration is then very viscid, tenacious, streaked with blood, or more deeply and in-
mately tinged by it. The pulse is quicker, weaker, and smaller; the strength more depressed, and the tongue more dry. In a few cases, where temporary ameliorations or exacerbations occur, the disease is protracted several days beyond the period just mentioned.

21. The disease may continue, or even increase, notwithstanding the treatment. In such very unfavourable or fatal cases, the thorax remains expanded, or scarcely acts, during respiration, which is chiefly diaphragmatic, or acts suddenly, forcibly, or convulsively; the patient is oppressed with the utmost anxiety, harassed by perspiration, which becomes more violent, and lapsing into a dreamy delirium, until the lungs have become nearly unfit for the office of respiration, or nearly impermeable to the air, he is entirely suffocated. This event is generally preceded by a bloated, pallid, or cadaverous countenance, which is bedewed with a cold sweat; by livid lips, dark or livid tongue, great difficulty and quickness of respiration; by suppression or change of the appearance of the sputa, which become greenish, dirty-red, rusty, or livery, crepitant and foetid; by a rapid, thready, irregular, or intermittent pulse; and by a groaning, convulsive, and rattling respiration. This unfavourable change often happens during the evening exacerbations, or perturbing efforts of nature to establish a critical evacuation.

22. A favourable result is sometimes preceded by a gradual disposition to a crisis, which is occasionally decided, and sometimes intermittent or abortive. This issue generally is observed to occur in the morning on the fifth, seventh, ninth, eleventh, or fourteenth day of the disease—very rarely so late as the twenty-first day. The evacuations which are most beneficial are, copious and general perspiration, hypostatic urine, a free mucous expectoration, epistaxis, and the catamenial and hæmorrhoidal fluxes.

23. In 93 cases, M. Andrall observed that the recoveries on critical and non-critical days were 14 to 3.

24. f. The decrement of the disease always follows the subsidence of the morbid condition of continual cough, dousing occasionally by the conservative influence of the vital energies or by art. The vascular turgidity, infiltration, and condensation of the parenchyma of the lungs gradually diminish, the functional disturbance decreases, and all the symptoms at first subside, and afterward some of them entirely disappear; but those which were first to manifest themselves, as cough and oppression at the chest, are the last to depart. Some degree of quickness of pulse and of breathing generally continues for some time. When these are removed, convalescence has commenced; but convalescence can never be confided in until these symptoms have entirely disappeared.

25. Acute pneumonitis, marked by no anomaly, complicated with no other malady, and occurring under favourable circumstances, generally proceeds as now described, and most frequently to a favourable issue. But it does not always observe this course. It is sometimes of much longer duration. In some cases it assumes, from the commencement, a more adventitious, or a complicated, or an otherwise unfavourable character. Occasionally, unwanted and accidental symptoms manifest themselves in its progress, owing to various contingent causes operating its continuance; and in other cases the whole tendency and character of the disease becomes changed, owing either to causes proper to the individual affected, or to a peculiarity of the nature and combination of the external agents which produced it, or to the state of the season or of the atmosphere, or to the epidemic constitution upon which it may supervene.

26. g. Relapses of pneumonia are not infrequent during some period of convalescence. They are indicated by a recurrence of characteristic symptoms—chiefly by slight dyspnoea, short, frequent respiration, oppression in the chest, cough, viscid or sanguinolent expectoration, and by increased frequency and weakness of pulse. In cases of relapse, the lungs often become more extensively affected, and the attendant fever assumes a less athermic form than the first attack—even an adynamic character. This is owing to the reduction of nervous power, and to the imperfect change effected in the state of the blood. Hence relapses are always more dangerous than the first seizure, and are more rarely attended by critical evacuations.

27. ii. Structural Changes marking the Stages of Pneumonia.—Laennec described three stages, with their corresponding symptoms and signs. In his first stage, the lung is engorged with blood, and a crepitating rule is heard. In the second, solidification takes place, and gives rise to its characteristic physical signs. In the third stage, interstitial suppuration occurs; or a state of softening preceding the formation of abscesses. I agree with Dr. Srokes, who contends for a stage antecedent to that which M. Laennec has called the first. He observes, that the existence of crepitation indicates that secretion has taken place in the cells and minute tubes, so that Laennec's first is, in reality, the secretive stage of the inflammation, and every analogy favours the opinion that a stage of irritation has existed previous to the secretion which caused the crepitus. It is obvious that this first stage of irritation and capillary injection can be but very rarely seen, unless death has been produced from other causes; but in these circumstances I have observed, as remarked by Dr. Stokes, portions of the substance of the lungs of a bright vermilion colour, and even drier than usual. It is sometimes met with in parts of the lungs where the first and second stages of Laennec exist; and I have seen in parts of the organ, after death from hæmoptysis and acute phthisis, with which, as I shall show in the sequel, pneumonia is not infrequently complicated.

28. The stages of pneumonia, therefore, are, 1st. Intense capillary injection—no effusion into the cells; 2d. The cells and parenchyma engorged with blood, without actual disorganization—sanguineous engorgement: first stage of Laennec; 3d. Solidification, with some degree of softening—red hepatization—the red softening of Andrall; second stage of Laennec; 4th. Interstitial suppuration—yellow hepatization: the third stage of Laennec. Abscess and gangrene are contingencies of comparatively rare occurrence.

29. A. In the stage of sanguineous engorgement, the substance of the organ is red, but of
LUNGS—Inflammation of the—Lesions.

different shades, is heavier than usual, and is still crepitant. The cells are not yet filled by effused fluid; or, if any infiltration into them or into the interstices of the filamentous tissue has taken place, it is only slight, unless, indeed, in cases of asthenic or cachectic pneumonia, or when the disease follows inhalation of noxious gases, or occurs in the course of low fevers or exanthematous maladies; and then this state of engorgement may pass very rapidly, and without any appreciable crepitation, into the stages of suppuration, or into a half-suppurative and half-gangrenous state. In the usual septic form of the disease, however, with capillary engorgement, there are some degree of thickening of the membranes between the cells, and slight, if any, infiltration of the part; the apparent thickening probably is chiefly owing.

30. B. The stage of solidification and softening, or of hepatization, presents the former stage in a more advanced state—in a state of more or less rapid progression to the next. In this stage the effusion of lymph, often more or less coloured by red particles of blood, has taken place into the parenchyma and air cells of the part affected. The density thus produced is generally so great that this part sinks in water. It is also more friable, from the interstitial infiltration of lymph having weakened the vital cohesion of the tissues, as shown in the art. Inflammation.

31. Dr. STOKES agrees with ANDRAL in supposing that this solidification arises, not from any deposition of lymph, but merely from excessive congestion of blood; and in proof of this he argues that the rapid appearance of this stage, and the rapid subsidence of the symptoms attending it, are evinced by no further change than congestion. But this is to assume that excessive congestion is attended by the same phenomena as accompany infiltration of lymph; and these occurrences are no disproofs even of effusion of lymph having occurred; for it is well known that absorption in the lungs is sometimes remarkably rapid.

32. The colour of the solidified portion of lung varies, according to the quantity of blood injecting the capillaries, from a red to a pinkish brown or reddish gray; but it is modified by the quantity of lymph infiltrating the part, and by the presence of black pulmonary matter. Frequently, when a portion of hepatized lung is divided, numerous little granulated points, the size of pins' heads, and of a lighter colour than the surrounding tissue, appear. LÁNNEC considered these to be the air cells converted into solid grains by thickening of their parietes, and by the obliteration of their cavities by a concrete fluid. ANDRAL viewed them as single air cells or terminations of the bronchi distended by a visceral runcus from their numerous linings. If this be the case, and if it be not coagulated lymph, the mucus must have become concrete during its retention. It is, however, most probable that these granules are produced by an infiltration of lymph into the cells or minute tubules, as well as into the connecting cellular tissue.

33. In some cases the solidified lungs are devoid of the granular appearance just noticed, and are of a more uniform and deeper red than the foregoing. M. ANDRAL attributes this state to a more uniform and complete obliteration of the cells; but if such is the case, there must have been also more intense capillary injection. Dr. WILLIAMS thinks that this non-granular form of hepatization may be ascribed to the circumstance of the inflammation having been confined chiefly to the intervesicular tissue. MM. HOURSCHMANN and DECHEMBRE have also distinguished the granular from the non-granular form of solidification, and have designated the former vesicular pneumonia, and the latter interlobular. Dr. WILLIAMS'S appellation of intervesicular is, however, more appropriate.

34. C. The stage of interstitial suppuration, or of puriform infiltration—of yellow hepatization—is merely the conversion of the affused lymph less than in the other stages, and that lymph opaque, pale yellow, soft, and semi-fluid matter, and ultimately into a purulent liquid, which infiltrates the inflamed part. This conversion takes place in the manner shown in the articles Abscess and Inflammation; but the matter rarely is confined in the form of a defined abscess, but is more or less diffused, owing to the structure of the organ, through the part affected. Owing to the organization of the lungs, a distinct abscess is rarely formed, because the lymph thrown out cannot concretize the matter, or prevent its infiltration of surrounding parts, by completely obstructing the minute tubes, cells, and pores permeating the inflamed part.

35. a. Abscess, therefore, cannot be considered as a stage of pneumonia, but merely a contingency of comparatively rare occurrence, but not so rare as LÁNNEC and some others have supposed. I agree with Dr. STOKES in believing that the rarity of pneumatic abscess has been much overrated; and it is most probable that LÁNNEC was partly deceived by trusting too implicitly to the physical signs, to the neglect of the rational symptoms, in his observations. Attention to the whole course of the case, and to the succession of both rational and physical signs throughout it, will alone guide the observer aright. The actual existing phenomena derive the chief part of their value, in forming a diagnosis, from a recognition of those which preceded them. Dr. STOKES states that abscess occurs more frequently in the lower part of the lungs. He is met with instances of its cure by cisternization. It may result from localized phlegmonous inflammation, or from the extensive and complete solidification above described. I have seen it chiefly after phlebitis, injuries, wounds, and operations, and in connexion with erysipelas; but in these the inflammation or solidification around the abscess, of which there were often several, was neither intense nor extensive.

36. Without reference to these purulent collections in the lungs which result from venous absorption, Dr. STOKES has seen acute pneumatic abscess under three forms: 1st. As an encysted abscess, with all the characters of true phlegmon; 2d. As purulent cavities communicating with the bronchi, and without any cyst, the walls of the abscess being formed of the solidified lung; 3d. The abscess is seated under the pleura, and external to the pulmonary tissue, dissecting the latter from the former, so as to show the structure of the lung.

37. b. Gangrene is another contingent result
of inflammation of the lungs. It is rarely observed unconnected with suppuration; but it may be rapidly caused by the inhalation of noxious gases, which may so impair the vitality of portions of the lungs as to favour the occurrence of gangrene before the suppurative stage can be developed. In other cases, it has not been determined whether it depends upon the intensity and suddenness of the congestion, or upon the cachectic state of the patient—most probably upon both. It has also been attributed to inflammation of a principal vessel supplying one or more lobules. In the interesting cases adduced by Dr. Stokes, the patients were long addicted to the use of spirits, a cause which operates upon the vascular system in a more direct manner than has been generally supposed; and likewise in all were evidence of extreme congestion, and typhoid, or, more correctly, asthenic pneumonia.

38. e. The state of the tissues adjoining the vascular plexus of the pulmonic parenchyma is deserving some notice. Dr. Williams states that the interlobular cellular texture is sometimes red, and sometimes singularly free from redness, or partakes of it in a much less degree. In the latter case, the hepatised lung presents somewhat of a marbled appearance. The interlobular septa retain their cohesion, and, in more chronic cases, are thicker and denser than usual. The mucous membrane of the large and middle-sized bronchi is generally more or less inflamed, presenting the same striated appearances seen in acute bronchitis. The smaller bronchi is commonly of a deeper red than in that disease. The bronchi in the inflamed part often partakes of the softening of the parenchyma. In some instances, they are plugged up with an albuminous exudation; but this arises from the extension or association of inflammation of one series of tissues to that intimately connected with it. More commonly the air tubes, as far as they can be traced, contain more or less of the rusty mucus or muco-puriform matter which has been expectorated. The pleura is very frequently inflamed. It may, however, be free from redness, or from lymph or liquid effusion, even when covering a hepatised portion of lungs (§ 30).

39. iii. Diagnosis of Simple Pneumonia—

A. By the aid of certain rational Symptoms—There is hardly one of the symptoms described above that may not be present in other diseases, or be absent in pneumonia. When it is considered that pneumonia is associated, in the very great majority of cases, either with pleuritis or with bronchitis, or with both; that it may be consequent upon, as well as give rise to either, it becomes the more difficult to determine what are the phenomena which distinguish the simpler states of the disease. Generally, local symptoms, especially cough, soreness of the sputum, or the suppression of the sputum; part of the chest, smallness and increased frequency of pulse, are complained of before chills or rigours occur, and before the constitutional symptoms are fully developed.

40. a. The cough in pneumonia varies remarkably. It is often slight, short, and occasional, and not such as gives much uneasiness to the patient. In other cases, particularly where the bronchi are affected, and in proportion to the extent of their affection, the cough is severe; at first dry, and subsequently attended by expectoration. If the pleura be at all affected, the cough is generally short, suppressed, sometimes infrequent, but it varies much according to the extension and amount of disease. The cough presents more or less fretful and oppressed features in the complications of pneumonia than in the simple disease.

41. b. The expectoration may furnish very decided evidence of pneumonia in some cases, while in others it can in no way assist the diagnosis. In children, especially, among whom pneumonia is a most frequent and dangerous malady, the expectoration furnishes no diagnostic aid. The viscid, muco-puriform, and sanguineous character of the sputum observed in many cases, is by no means constant. The disease may present all the kinds of expectoration, particularly during its early stages, and it may be even unattended by any until its most advanced stages, or until shortly before a fatal issue. The rusty sputum is generally found in the most acute cases, and in robust persons; but in feeble constitutions, or where the disease occurs as a complication of, or during convalescence from continued or exacerbatoua fevers, it is not often observed: indeed, in these circumstances, the sputum furnishes comparatively little information, or it may be altogether wanting or very scanty. Although it is generally true that the viscid and red sputum occurs only at the height of the disease, yet it may continue for some days after the subsidence of the more acute symptoms, or even after all signs of pneumonia have disappeared. Instances of this latter occurrence have been furnished by ANDERSON and STOKES, but in these cases it is evident that the inflammation continued to proceed in the bronchi after that of the parenchyma of the lungs had subsided.

42. In the suppurative stages, the sputum assumes a more characteristic form than in the preceding, and is either a purplish red muco-puriform fluid, or a homogeneous purulent matter, of a light yellow colour, and of the consistence of cream. These kinds of expectoration occur only in the far advanced or suppurative stage of interstitial suppuration and softening (§ 34). Dr. South, remarks that there are no differences in the local changes between the cases with prune-juice-like sputum and those in which there is a secretion of healthy pus; but he admits, with all other observing physicians, that in the former the disease exists in a lower, or more asthenic type, or in broken-down constitutions, while the latter is seen in the more asthenic cases, occurring in young or robust persons.

43. In pulmonie abscess, and as long as the matter continues pent up, or before it has found its way into the bronchi, the sputum presents no characteristic appearances. In many cases, nothing is expectorated but a little mucus: while in others it is muco-puriform, as in chronic bronchitis, and either devoid of smell or more or less foetid. If, however, an abscess form and burst into the bronchi, the expectoration becomes suddenly abundant and distinctly puriform.

44. Gangrene is attended by an expectoration of
of a dirty greenish, or brownish, or sanguine
mater, mixed with a mucous-puriform matter;
the whole being of a putrid and very offensive
odour, and occasionally mixed with sluggish
portions of tissue.
45. As the powers of life sink, the expecto-
ration in the advanced stages becomes scanty,
or is altogether suppressed. The suppression,
however, does not proceed from any diminution
of the secretion, but from the failure of the
respiratory acts, and of the vital manifestations
of the organ, both of which are insufficient to
procure its expulsion. Thus, in fatal cases, the
patient will, on occasion, increase death
approaches, until the accumulated secre-
tation mounts to the large bronchi and trachea,
when the rhonchus becomes tracheal, and
assumes the character to which the appellation
death-rattle has been given.
46. c. Dyspnoea, as remarked above (§ 14), is
more urgent in bronchitis, or even in pleuritis,
than in pure pneumonia; and, generally, the
amount of dyspnoea indicates in some measure
the extent to which the latter is associated
with the former, particularly with bronchitis.
However, extensive or double pneumonia will
increase the dyspnoea, but it will increase the
frequency and shortness of respiration more
than any actual sense of difficulty. This latter
often depends more upon an attendant irrita-
tion or spasm of the bronchi than upon actual
inflammation of them.
47. d. Pain is often but little felt. Uneasy
sensation is generally present, but it seldom
amounts to pain, unless the pleura becomes
involved in some way or another, or the
extension of this membrane consequent upon in-
flammatory turgescence of the parts underneath
hardly develop this symptom to any perma-
nent or marked degree. In the last stage of
the disease, the functions of the lungs, or arteri-
alization of the blood, is interfered with, but
not so early or so rapidly as in bronchitis, unless
when associated with it; an association which
will often mask pneumonia without the aid
of physical diagnosis.
48. B. The Physical Diagnosis of Pneumonia.
—It is chiefly upon the physical signs that reli-
ance is to be placed in determining the exist-
ence of pneumonitis. Dr. Stokes has enumer-
ated the following as the most important rela-
tions of these signs: 1st. Evidences of a local
excitation; 2d. Proofs of sanguineous conges-
tion; 3d. Evidences of a diminished quantity
of air in the affected lung; 4th. Signs of in-
creased solidity of the lung; 5th. Phenomena
of the voice; 6th. Phenomena referrible to the
circulating system; 7th. Evidence of accom-
panying lesion of the pleura; 8th. The dimin-
ished volume of the lung.
49. a. In the first stage of pneumonia, or that
of inflammatory irritation (§ 27), the physical
signs have not been observed with due preci-
sion. Dr. Stokes believes that it may be in-
ferred, by the occurrence of a local puerility of
respiration, combined with an excitement of the
respiratory system. It is evident that this sign,
namely, an unusually loud sound of respiration
in a part of the lung, in connexion with inflam-
mation of it, can be present only for a short
time, and often before the patient comes under
treatment; and that its chief value is in con-
nexion with disorder of the respiratory and
circulating actions, and with the succeeding
phenomena.
50. b. In the second, or Laennec’s first, stage
(§ 29), the crepitating rhonchus, and the grad-
ually diminishing vesicular murmur, are the
characteristic signs. Still, these signs derive
their value chiefly from their combination,
and partly from the accompanying, the preceding,
and the consequent phenomena.
51. Crepitation, which has been most accu-
ately compared by Dr. Williams to the sound
produced by rubbing a lock of hair close to the
ear, is not so invariable and positive a sign of
pneumonia as the whole lung becomes heard
be relieved on only when attended by increasing
dulness, and by the gradual cessation of the
respiratory murmur. If the disease be so ex-
tensive as to impede greatly the functions of the
lungs, the energy and frequency of the respira-
tory movements will be increased, and the
respiratory murmur in the sound side may be
thereby rendered louder than usual. The in-
creasing density of the congested and inflamed
lung will deafen the sound emitted by percus-
sion, so that the affected side will give out a
sound somewhat duller than that of the oppo-
site side; although not so dull as will be emit-
ted at a more advanced stage, as there is suf-
cient air still contained in the affected lung to
prevent complete dulness on percussion. The
increasing density of the diseased lung renders
it also a better conductor of sound; so that,
during this stage of extensive pneumonitis, and
while crepitation is still present, some degree
of the bronchial respiration and vocal resonance,
exist in the following stage. The more
advanced, the dulness increases, and the duller
lung is heard through the affected parts, while
of the unaffected part a dulness is heard
which is not so much dulness as mere
sensation of dulness. When the whole lung
begins to be dulled, the sound of the
bronchial respiration ceases; and, as the large
tubes remain pervious, “dulness of sound, bronchial respiration,
and a loud resonance of the voice are produced;
and within certain limits, the extension or inten-
sity of these signs furnishes an accurate meas-
ure of the extent or intensity of the disease.”
The bronchial respiration requires for its pro-
duction not only increased density of the lung,
but also a certain expansion of the side during
respiration; for when the whole lung becomes
solid, the side is fixed, and the bronchial respi-
ration ceases. In this latter case, the signs are
universal dulness, absence of respiration, and
resonance of the voice. If, however, the upper
portion begins to resolve, or even if an abscess
be formed, in either of which cases the bron-
chial tubes admit again a portion of air, the
bronchial respiration returns, it not being ne-
necessary that the permeable portion of lung
should be of great extent to reproduce this state
of respiration; so that the affected side will
become again resounding. When this change is
complete, particularly in the central parts of the
organ, the voice may be heard over a considera-
ble space in the thorax, and may be heard in
particular regions. The bronchophony, or vocal
resonance of the tubes, may be so loud as to be
mislaid for the pectorillogy of a cavity; but
it is distinguished from this latter by its diffusion over a large space, and by its being much diminished by using the stethoscope with its stopper. Dulness on percussion is generally complete when a whole lung is lepatised; but still it is seldom so uniform and general in the lower and middle portions of the chest as in cases of pleuritic effusion; for some of the lobules still continue to retain air, and the large tubes furnish some degree of resonance in the parts nearest to them. In proportion as the lung is solidified, so does it become inexpansible, and the corresponding part of the chest motionless, without their being distended or contracted, and without displacement of adjoining viscera or fulness of the intercostal spaces. When the left lung is solidified, it transmits the sounds and impulse of the heart to an unusually wide extent.

54. In the usual sthenic pneumonia, dulness of sound and bronchial respiration are preceded by crepitation; but in some cases of asthenic pneumonia solidification takes place so rapidly as not to be preceded by appreciable, or any form, or for a time sufficient to admit of their detection. In these cases the disease proceeds with great rapidity, and it becomes difficult to distinguish it from pleuritic effusion, unless the phenomena above alluded to be carefully observed; namely, the absence of displacement of viscera, and of fulness of the intercostal muscles, the resonance of the voice, the greater frequency of bronchial respiration, and the occasional occurrence of a rhonchus in parts of the chest. The disease rarely proves fatal in this stage, unless it be extensive, and both lungs are more or less affected.

55. d. In the fourth stage, or that of supplicative infiltration (§ 34), the physical signs are not materially altered until the effused matter accumulates in the bronchi, so as to occasion a sharp and peculiar mucous-crepitating rhonchus, the bronchial respiration still continuing, and the dulness of sound on percussion increasing; but these phenomena should be viewed in connexion with the previous history and existing state of the case. When, however, this peculiar rhonchus occurs in the circumstances described, and is connected with signs indicating an extension of disease in the lungs, it may be considered as truly the result of suppurative infiltration of the lung. Still, there are some cases in which this stage may be with more certainty inferred from the duration of the disease and from the rational symptoms than from the physical signs; in it the prune-juice expectoration sometimes occurs, and the purulent sputum may be expectorated in a very copious quantity. This stage is frequently passed by without taking place, in which case a sub-crepitation may then take place, and when this sound is heard, it is of a looser and less even character than before—a sub-crepitation merely. If solidification have advanced far and approached to suppurative infiltration, the restoration of the natural structure of the lung becomes proportionately difficult and prolonged to the extent of lesion. The cure may be eventually complete, but more frequently permanent alteration is produced, the pulmonic ventilation being obstructed by some of the cells and small bronchi, and dilatation of others. Bronchophony is most evident when dulness on percussion and bronchial respiration coexist, and it is always most evident in the superior and posterior parts of the chest. It is readily distinguished from pectorilogy by its greater extent, and by the absence of gurgling or cavernous respiration. It sometimes approaches the aegophonic character, when the pneumonia has passed into the fourth stage, and when resolution from the third is taking place.

56. When an abscess forms in this stage, a favourable result may take place nevertheless, and even more frequently than in the state of suppurative infiltration just noticed, inasmuch as the former change indicates more sthenic action and greater constitutional energy than characterize the latter. The signs of abscesses are nearly the same as those of a tuberculous cavity communicating with a bronchus. The diagnosis is to be inferred chiefly from the history of the case, a cavity from tuberculous excavation being of much slower progress, and preceded by much acute symptoms than that from abscesses. Nor is it attended by so great an extent of dulness as is observed in pneumonia. A cavity from an abscess occurs most frequently at the inferior portion, or about the root of the lung; and, owing to the quantity of fluid contained in it, upon its first communication with a bronchus, it gives rise, at that time, to a gurgling or bubbling sound upon a deep inspiration or coughing; and in some cases there is a patrid or festid odour with the expectoration, and bronchial respiration is palpable, chiefly when some degree of grangrene occurs or accompanies the abscess.

57. e. As to the more circumstantial diagnosis of true pneumonitis, it may be noticed that crepitation heard throughout the greater part or the whole of a lung shows extensive disease; if it be heard at the apex or root of the lung, or in the infra-clavicular and scapular regions, it evinces a more intense form of disease than if it were seated in the middle or lower lobes. The extension of crepitation to parts not previously affected by it shows the increase of inflammation; its cessation and the substitution of bronchial respiration and perfect dulness on percussion, are proofs of solidification; and the return of crepitation and resonance, where they had been replaced by bronchial respiration and dulness, indicates absorption of the effused lymph and the admission of air into the cells, and consequently a progress towards recovery; but a change from complete dulness and bronchial respiration to clearness and return of the noisy murmurs, without any crepitus of resolution, may take place; and when this sound is heard, it is of a looser and less even character than before—a sub-crepitation merely. If solidification have advanced far and approached to suppurative infiltration, the restoration of the natural structure of the lung becomes proportionately difficult and prolonged to the extent of lesion. The cure may be eventually complete, but more frequently permanent alteration is produced, the pulmonic ventilation being obstructed by some of the cells and small bronchi, and dilatation of others. Bronchophony is most evident when dulness on percussion and bronchial respiration coexist, and it is always most evident in the superior and posterior parts of the chest. It is readily distinguished from pectorilogy by its greater extent, and by the absence of gurgling or cavernous respiration. It sometimes approaches the aegophonic character, when the pneumonia has passed into the fourth stage, and when resolution from the third is taking place.

58. When pneumonitis is limited to a central or deep-seated part, especially near the base of the lung, without extending to the surface, the physical signs may be very obscure, and the
LUNGS—Inflammation of the—Asthenic.

Rational symptoms thus become more important. When the inflammation is very circum-
scribed, even although it may affect a more su-
perficial portion of the lung, it is detected by
the physical signs with some difficulty, particu-
larly when it is seated in the posterior and lat-
eral parts of the organ.

59. *f.* Pneumonia may be distinguished from
bronchitis by the crepitation being finer and more
equal than that of the latter; by the blood-
streaked or rusty appearance of the sputum; by
the dulness on percussion as the disease pro-
ceeds, and the bronchophony and bronchial res-
piration. In pneumonia, also, the skin is hot-
ter and less livid than in severe bronchitis;
while the cough and dyspnea are generally less
urgent, and the former less paroxysmal.

60. *g.* From pleurisy pneumonia is to be dis-
tinguished, in the first stage, chiefly by the
crepitation and sputa; and in the second and
third stages, by the bronchophony and vocal
vibration sensible to the hand; by the absence
of the signs of displacement of the adjoining
organs and of bulging of the walls of the chest;
and by change of posture causing no alteration
of the sound on percussion.

61. *h.* Pneumonia is sometimes not readily
distinguished from the hemorragic congestion,
or from pulmonary apoplexy, with both which,
however, as will be noticed hereafter, pneumo-
nia is occasionally associated. It is chiefly
the presence of febrile symptoms, the character
of the sputum, the absence of any real hemor-
rhage, the existence of crepitation, the progressive
dullness on percussion, and the course of the
disease, which distinguish pneumonia from
these.

62. iv. Varieties and Complications of
Pneumonia.—A. Asthenic Pneumonia—Con-
gestive Pneumonia—Typhoid Pneumonia of
various authors—Nervous Pneumonia of others.—
In this variety of the disease, the inflammatory
action assumes an asthenic form, and the at-
tendant fever the atypical type, owing either
to original weakness of constitution, to ex-
haustration, or a cachectic habit of body, or to the
nature of the exciting causes. Hence it is met
with chiefly in persons who are weakened by
exhausting influences, by insufficient or un-
wholesome food, or by residence in unwhole-
some localities and in an impure air [except
when it prevails epidemically, when it attacks
all classes]. Owing to these circumstances, and
to certain associated disorders, it has re-
ceived from modern authors not only the names
mentioned above, but also those of malignant,
purulent, suppurative, or sanguine pneumonia.

63. The general character of this form of the
disease is its occurrence during previous disor-
der or ill health; during a general morbid con-
dition; in a more or less latent form, and with
marked prostration of the vital energies. When
pneumonia appears in the course of, or in con-
exion with, continued or atypical fever, in-
fuenza, erysipelas, diffuse inflammation of the
cellular tissue, or phlebitis, it always assumes
this form. In these circumstances, however,
it appears more frequently complicated with
either bronchitis or with pleuritis, or with both,
than as a simple disease.

64. *a.* The rational symptoms of this state of
pneumonia are rarely well marked. There are
generally, however, a dusky hue of the counte-
nance, slight dyspnea, quick and short respira-
tion, slight cough, either with or without ex-
pectoration; oppression or weight at the chest,
but rarely pain, although the disease may be
more extensive and dangerous, or even extend
to the pleura. The constitutional affection is
severe. The pulse is rapid, weak, and small.
The skin is hot and dry, or covered with a
damnary sweat, particularly at the extremities;
the tongue is furred and brown; the bowels
are costive, and the evacuations offensive; the
urine is highly colored, scanty, sometimes
ammoniacal; and, as the disease proceeds, slow-
muttering delirium, coma, lividity of the lips,
cold, clammy extremities, &c., supervene,
and the patient sinks from interruption to the
functions of the lungs.

65. In this form of pneumonia the inflamma-
tory action is characterized by the asthenic or
diffusive characters pointed out in the article
Inflammation (§ 54, et seq.), and it possesses
many of the characters of active congestion.
When it occurs during continued fevers, par-
ticularly at a far-advanced period of their course,
it generally affects the posterior parts of the
organ, and extends to both lungs. In the ca-
chetic, and in most other complications, it is
similarly extensive. The parts affected are not
only engorged or hepatized, but also soft and
friable, readily breaking down on pressure or
exuding a dark grumous blood. The hepata-
tization, however, is seldom as complete as it is
in the sthenic form of the disease; but is irregu-
larly disseminated or extended through the pos-
terior and central parts of the organ, or in
points only, with marks of softening approxi-
mating the supplicative infiltration of the fourth
stage, already noticed, and with films of lymph
exuded upon the pleura. This partial or in-
complete state of hepatazation may, however,
occur in any part of the lung, but is more dif-
fused or extended than in the sthenic form;
and although one lung is generally more affect-
ed than the other, it is much less frequently
limited to one lung only than in that form. It
is commonly also, although attended by les-
ion; and, particularly when complicated, has
often advanced to an irreremediable state before
it has been detected.

66. *b.* The physical signs of this form of
pneumonia are more deceptive than in the pre-
ceding. For as both lungs are generally affect-
ed, and as the disease occurs in previously de-
bilitated or diseased persons, the patient lies on
his back, either altogether in the supine posture,
or with his head and shoulders much elevated,
this latter being usefully performed when the
bronchi are also much affected. This posture favours the congestion of the more de-
pending portions and the inflammatory reaction
in these parts, while the anterior, or more ele-
vated portion of the organ, remains compara-
tively unaffected. Hence, the anterior parts
of the chest do not evince the extent of exist-
ing mischief. In this situation but little dul-
ness on percussion is detected, and the breath-
ing is often distinct, although attended by sub-
stant or sonorous rhonchi. In the posterior,
and in some degree in the lateral portions of
the chest, dulness on percussion, and absence
of the respiratory murmur, are always found,
oncasionally with a whiffing or sibilous sound.
As Dr. Stokes has shown, crepitation does not
always attend the early stage of this form of pneumonia, or, if it occur, it is of very short duration, the structural change of the part causing obstruction to the passage of air through it soon becoming complete.

877. The terminations of asthemic pneumoni-tis are: 1st. In recovery, or restoration of the healthy state of the organ. This is, however, much less frequent than in the sthenic form; and, although the disease is formed and progresses with rapidity, its resolution is remarkably slow compared with that form; chronic hepatisation, with low hectic, or latent or more manifest congestion, continuing for several weeks. Recovery even from these states may take place under proper treatment; but more frequently atrophy of the lungs, with or without fibrosis, or other fatal changes, supervene.

2d. Fatal hepatisation or splenification—irregular, diffused, or incomplete, but more or less extensive in both lungs—takes place more frequently than any other lesion, and with great rapidity, and arrests the pulmonary functions.

3d. A sloughing or gangrenous abscess sometimes forms, and generally destroys the patient in a very short period. 4th. Chronic solidification of portions of the lung occasionally occurs, and commonly passes into a tubercular state. Such gangrene may elapse before the respiratory murmur is restored, and in many cases it is never completely re-established; and, even when recovery takes place, the contraction of the chest, which usually is observed, shows the slowness with which the disease is removed. However, a more rapid recovery may occur when an acute disease of another and distant organ supervenes.

The typhoid pneumonia prevailed very extensively in this country in the years 1812—13—14, and was called by different names in different places; as, *pneumonia notha*, *pneumonia typhoides*, malignant pleurisy, bilious pneumonia, malignant bilious fever, &c. For a particular account of the epidemic, and for various opinions relative to its nature, the reader is referred to the different volumes of the "Medical Repository," Mann's "Medical Sketches," and Gallup's "Epidemics of Vermont." The disease appears to have assumed somewhat different forms and types in different parts of the country, whence, undoubtedly originated the various opinions as to its nature which were held by medical men, as well as the various modes of treatment which were adopted by practitioners. On our northern frontier, among the United States troops, Dr. Mann states that it assumed a highly inflammatory form, accompanied with strong arterial action, and requiring free depletion with the lancet. In this city and vicinity the disease had less of a sthenic diathesis, and at Washington city it was regarded as typhus fever. The disease generally came on with great languor and lassitude, bluntness in the muscles, lancinating pains in the limbs, to which succeeded chillis, pain in the side, head, stomach, or region of the heart; pain in one side or other of the thorax was, with few exceptions, characteristic of the disease. The respiration was short and difficult; frequent cough, attended with bloody mucus expectoration; or there was an absence of cough and expectoration, the disease invading the serous membranes; pulse weak and frequent, or small and hard; the heat of the body and extremities generally below the standard of health. In most cases the tongue was coated in the commencement with a short, white fur, which grew darker as the disease advanced; diarrhoea was frequently present; in short, the symptoms partook of fever in general, connected with membranous inflammation of the internal organs, diversified according to the degree of irritability of the subject, the particular organs attacked, and the duration of the disease. According to Gallup, the local inflammation was not strictly phlegmonic, but of a membranous erythematic kind, not apt to end in suppuration, though sero-purulent dispositions containing flakes of lymph were often met with in the large cavities. The disease often terminated fatally within a few hours, reaction never taking place, while, as a general rule, it was protracted for many days, and recovery slow and tedious. In the most malignant cases the symptoms were somewhat modified, the temperature being much below the natural standard, respiration extremely laborious, and accompanied by a distressing sense of suffocation and oppression about the chest. On dissection the lungs were found excessively gorged with blood and hepatised, with much thrombosis, and adhesions in the bronchi, adhesions of the pleura to the ribs, and congestion of the cerebral vessels. Dr. Gallup estimates the number of deaths by the typhoid pneumonia in the State of Vermont (population 218,000), during the autumn of 1812 and winter of 1813, including five months, at 6400, 750 of which were among the United States troops. An equal mortality, at least, prevailed over the whole of New-England and portions of the Middle States.

69. Complications of Pneumonia. — These are more common than its pure or unassociated form, and are met with in both the sthenic and asthemic types of the disease; the latter, however, more generally presenting the complicated state.—a. The association of the bronchitis with pneumonia—broncho-pneumonia—is most common. Indeed, from what has been advanced above (§ 5), it will appear evident that pneumonia, especially its most asthemic form, can hardly exist without the small bronchi becoming more or less implicated. It is, however, when the disease extends to the larger branches that this complication should be considered as existing. It is sometimes material to mark the procession of morbid phenomena in order to ascertain the primary affection. In the great majority of instances, the bronchi are primarily affected, the morbid action extending thence to the parenchyma of the lungs, owing either to the nature of the causes, to the constitution and existing state of the patient, or to the treatment adopted at the commencement. I have observed in numerous cases, particularly among the children of the poor, living in low, damp, and close situations and rooms, sleeping in over-crowded apartments, and insufficiently or unwholesomely fed and clothed, that the disease has commenced in the bronchi, extended to the air cells and substance of the lungs, and thence to the pleura, with great rapidity. In this complication the quantity of mucus in the bronchi may mask the expectoration of pneumonia. Still, expectoration will generally be heard in the inferior and pos-
Lungs—Inflammation of the—Complications.

terior regions of the chest, while the mucous rhonchi will be evident in the more superior parts. The rusty or tinged appearance of the sputa, as the disease proceeds, the dulness on percussion, the increased dyspnea, the greater severity and more paroxysmal character of the cough, will also mark this association.

70. Broncho-pneumonia very frequently supervenes in the course of influenza. It was common and fatal in the influenza of 1837, particularly when it complicated, as it very often did, both lungs. In this epidemic the pulmonary affection generally assumed the asthenic form, the pulse being weak, quick, and small, the cough being severe, puriform expectoration abundant, the congestion more, and proportion to the vital depression the most energeic means were required to rouse the vital resistance to the extension and fatal tendency of the disease. Broncho-pneumonia is also frequent in the course of hooping-cough, and in the more unfavourable forms of croup; but in these it assumes a more sthenic character than in influenza. It also occurs in the course of cardiax disease, particularly when the valves are affected, and in connexion with hemoptysis; but in these circumstances it presents much of the congestive form.

71. The bronchitis which so very generally complicates measles passes very frequently into broncho-pneumonia, although the pneumonia may be the chief affection. In all cases of this association, the pulmonary disease partakes of the constitutional malady, being sthenic, asthenic, or malignant, as this latter may be. When the local disease is severe, it is readily recognised, as it is commonly attended by an impairment of the heart's action, and it follows immediately upon either the premature or the regular disappearance of it; the fever or constitutional disturbance being unaltered or increased.

72. The peripneumonia notba of several writers was frequently a broncho-pneumonia, occurring in aged, cachectic, or debilitated persons, in whom the disease assumed, from these circumstances, more or less of an asthenic form, and extended to both lungs; but the same term was often also applied to other states of bronchitis, sometimes to acute asthenic pneumonia, with extension of disease to the pulmonary pleura.

73. b. Pleuro-pneumonia—Pleurisy—Pleuritis—Pneumonia—Peripneumony—or the association of inflammation of the substance of the lungs with that of its investing pleura, very frequently takes place. The supervision of pleuritis upon pneumonitis, or the coetaneous occurrence of both, is attended by additional changes and phenomena to those mentioned above. Several of the alterations and symptoms described in the article Pleura are observed when the inflammation implicates the serous membrane; but when the substance of the lungs has been for some time, or is extensively affected before the pleura is invaded, this latter is very rarely so remarkably altered as in primary pleuritis, and effusion of lymph, especially from it, very rarely takes place to so great an extent. M. Laennec has shown that when the inflammation has been nearly equally severe in the substance of the lung and in the pleura, the effusion from the pleura, by its pressure, modifies the effects of the inflammation in the lung; this latter being often found after death more consolidated, and tougher and redder than in ordinary hepatchitation, and devoid of the granular texture. Its resemblance in such cases to the muscular substance induced M. Laennec to call this state that of car

74. As respects the pleura in these cases, the changes which take place consist chiefly, 1st. Of effusion of lymph; 2d. Of effusion of a sero-purulent fluid; and, 3d. Of the effusion of air, or gaseous fluid. The first is almost constant, although it may occur to a very slight extent, when the substance of the lung is extensively, deeply, and primarily affected. The second is comparatively rare in pleuro-pneumonia, and the third is very rare indeed, although it may take place in this complication of pneumonia, as in primary pleuritis, especially in the more asthenic cases.

75. The symptoms of pleuro-pneumonia are not materially different from those of simple pneumonia, unless much effusion takes place from the affected pleura. When this membrane is consecutively or slightly affected, pain may not be severely felt. Indeed, this complication is generally not so severe or acute as either simple pneumonitis or primary pleuritis; and the symptoms are very often more obscure than those of either. When lymph is effused on the pleura, it does not necessarily induce corresponding physical signs; hence the fro
temor rarely exists in this state. Of the effusion of pleuro-pneumonia, and is rarely observed in the advanced stages, or at the resolution of the dis-
case. It is observed chiefly in the early stages of some cases of extensive pleuro-pneumonia. At first crepitation may be heard; but it becomes indistinct as effusion from the pleura takes place and is considerable. Dulness on percussion is greater than in pneumonia, especially in the lower parts of the affected side. As Dr. Williams states, bronchial respiration and bronchophony are soon produced, in the central regions of the chest, by the condensed lung being pushed against the walls; and if a thin layer of liquid intervene, the bronchophony acquires a buzzing accompaniment, the sound secretions of the bronchial tree probably arising from the vibrations being modulated into a buzzing or bleating by passing through the thin layer of liquid. The vocal resonance is generally louder in pleuro-pneumonia than in either simple pneumonia or pleurisy, owing to the greater condensation of the vesicular structure, and to the closer application of the inflamed lung to the walls of the chest, circumstances, also, which explain the occasional appearance of the tracheal or aphoramic sound on percussion in the mediastinal region, while other parts are dull. In cases inefficiently treated at their commencement, and become chronic, solidification of a portion of the lung having become permanent, and the fluid diffused from the surface of the pleura having been in great measure absorbed, respiration is often quite tracheal in this region, and resonance of the voice as loud as that of cavities, especially if dilatation of the bronchi have taken place, as frequently occurs in these circumstances.

76. c. During the course of tubercular disease of the lungs pneumonia often occurs, and is either partial or limited, or more or less extended, especially in one lung. Inattention to this fact, and the consequent non-detection of the superinduced inflammation in such cases, are often the causes of their more rapidly unfavourable termination. Either simple pneumoni- tis, or pleuro-pneumonitis, or even still more frequently broncho-pneumonitis, may thus supervene; and the great frequency of their occurrence should induce the physician to watch for them, and to combat them on their first appearance.

77. d. When treating of hemorrhage from the lungs (§ 114), I remarked upon the frequent connexion of this pathological condition with inflammation of some portion of the organ. It is not unusual for active congestion of the lungs to give rise to slight, or even copious hemorrhage, and then pass on to either simple pneumonia, or to broncho-pneumonia. Generally this congestion precedes tubercles, this latter being the primary malady; but, in many, the consequent inflammation is more immediately dependant upon the hemorrhage and congestion than upon the tubercular disease; and this is more especially the case when hemorrhage takes place in the form of pulmonary apoplexy. Whenever, therefore, hemoptysis occurs, partial or more general pneumonia or broncho-pneumonia should be suspected, and its existence or non-existence ascertained by a careful examination; this probably infrequent causes of pneumonia of a peculiar, insidious, and latent kind, which sometimes does not manifest itself until shortly before death, and then chiefly by oppressed, quick, and short breathing, and maceous rattle. In some of these cases, portions only of the lungs are found inflamed in the first and second stages; in others, there are numerous circum- scribed hepatizations, varying somewhat in their characters; and in several, purulent de- posites are met with in the parenchyma of the organ; these deposits being circumscribed, and the tissue surrounding them either inflamed or almost healthy. These are, however, to be viewed as infiltrations of puriform or other morbid secretions into the pulmonary tissue, inducing asthenic inflammatory action in the parts with which they come in contact and contaminate; and, perhaps, in some situations, as asthenic inflammation of the more extreme capillaries through which these secretions circulate, the capillaries of mucous and cellular parts being most prone to be affected by them. Those small abscesses, or deposits, which are more obviously due to puriform inflamma- tion, present the matter in contact with, and infiltrating the margins of the surrounding tis- sue, which is hardly or not at all inflamed; while those which are manifestly connected with inflammatory action present a red or livid margin, with a more or less distinct coat of lymph in some instances, but only in those in which this action approached the nearest to the sthenic form. These consecutive abscesses or deposits are more particularly noticed in the area. Abscess (§ 27, et seq.) and Liver (§ 505, et seq.).

79. f. A complicated and congestive form of pneumonia, complicated most frequently with bronchitis, is often consequent upon eruptive fevers, upon cholera asphyxia, or pestilential chola, and upon asphyxia from whatever cause, and especially when produced by foul exhalations. It sometimes also occurs in the course of continued endemic, remittent, and intermittent fevers. In all these circumstances, the pneumonia is generally more or less asthenic and obscure, or even more, sometimes not manifesting itself until shortly before death, or before the lungs had become extensively impervious to the air, or even not until it is detected after death.

[Pneumonia may also be complicated with pericarditis, which is supposed to coincide more frequently with inflammation of the left lung. The heart should frequently be examined in cases of severe pneumonia of the left lung, in order to detect this complication, if it exists. It is not obvious in pneumonitis occurrence to meet with fibrinous concretions in the heart and large vessels after death from pneumonia, which are supposed to be indicated during life by dull, obscure, and veiled sounds of the heart, with intermittent pulse. Icterus is also a frequent complication of pneumonia, having occurred in 27 out of 70 cases reported by Gruolle. Its occurrence has been attributed by some writers to the extension of the inflammation to the convex surface of the liver.

7. g. Bilious pneumonia is a not unfrequent form of the disease in this country, and occasionally takes on an endemic, or even epidemic
character. It is that form of pneumonia under which the late President of the United States, Gen Harrison, sunk, and it prevails every winter, to a considerable extent, in some portions of our country, under the name of bilious pleurisy. It generally attacks adults, coming on suddenly, with nausea and much derangement of the digestive organs; a soft, feeble pulse; hot and dry skin; severe pain in the head, particularly the frontal region, and very great prostration of strength. The gastric and biliary derangement are indicated by a foul toad, it being covered by a thick, yellowish, fetid fur; a bitter taste in the mouth, nausea, and vomiting; variable thirst, constipation, yellowness of skin, and tenderness at the epigastrium, &c. It is very apt to assume the typhoid type if improperly treated, under which there is great danger that the patient may sink, especially if the epidemic form of the disease prevails.]

V. CAUSES OF PNEUMONIA.—Inflammation of the substance of the lungs, in some one of its varieties, whether severe or slight, is apt to result from either a constitutional or local state of the system, which may be exposed to some injurious influence.

Pneumonia is most frequent in winter, and after those seasons, which are attended with an ascendant, impetuous climate. It is a disease, which, in its most severe forms and complications, destroys more of them than all other inflammatory diseases. Delulity from whatever cause, whether original or from previous disease, remarkably predisposes to pneumonitis. The eruptive fevers, especially measles, hooping-cough, and previous attacks of either pneumonia, bronchitis, or pleuritis, exert a similar influence, as I have shown under these heads. The greater disposition of pneumonia to occur during this season of the year, is such as the present description of our climate, and the various moral and political changes, which have occurred, can be used to the account. These effect is shown in various facts, that, in proportion as the high temperature of summer makes an impression on the system, do the lungs become susceptible to the morbid agency of the opposite seasons. In the United States, for example, as cold predominates, and no decided impression is made upon the animal economy by the short summer, the annual ratio of pleuritis and pneumonia is not only low, but there is little difference in the ratios of the seasons; on the other hand, in the Southern States, which are remarkable for high and long-continued summer heats, the annual ratio is about twice as high as in the Northern States, while the difference in the seasons is very considerable, the ratio of the third quarter being less than one ninth of the annual average. The statistics of the United States army, then, show that pneumonia, pleuritis, and phthisis pulmonalis are most prevalent in the middle districts of the United States, and these diseases are of a more fatal tendency in the southern than in the northern regions. In the latter, the ratio of mortality from phthisis pulmonalis is 32, and in the former 42 per 100 cases; and, as regards pleuritis and pneumonia, the difference is much greater, the average mor-

"The remarkable prevalence and fatality of pneumonia among infants and children are shown by the returns to the registrar-general."

1. In Manchester, in 1839, 501 deaths from pneumonia, 213 were infants in the first year, 150 in the second year, and 44 in the third year of age.

2. In Liverpool, of 655 deaths from pneumonia in 1839, 216 were infants in the first year, 212 in the second year, and 68 in the third year of age.

3. In the counties of 335 deaths from pneumonia in 1839, 169 were in the first year, 130 in the second year, and 26 in the third year of age.

In persons far advanced in age, asthmatic and complicated pneumonia becomes somewhat more prevalent than at middle age, and very much more fatal.
tality in the northern being 9, and in the southern 26 per 100 cases. Much credit, we believe, is due to the lamented Farr for first developing the important fact above mentioned, and calling the attention of the profession to the predisposition to pulmonary diseases, induced by the high temperature of summer, contrasted with the low temperature of winter. — (Loc. cit., p. 216—7.)

82. Inhalations of acid, chemical, and other noxious gases; public speaking, and all exertions of the voice; the use of wind instruments; concussions of the chest; prolonged swimming, or immersion in water; and removal into a very warm air after prolonged exposure to cold, and the inhalation of atmospheric cold, are powerful exciting causes of the disease. Other maladies not only predispose to, but often excite an attack of simple or complicated pneumonia, but more frequently the latter, in either a phthisic or asthenic form, and either during their progress or upon convalescence from them. This is especially the case in respect of eruptive and continued fevers; of hooping-cough, bronchitis, and pleuritis; of diseases of the heart; and of croup and laryngitis. The greatest liability of pneumonia to occur after the disappearance of cutaneous eruptions, or upon the sudden cessation of an attack of gout or of rheumatism, has been noticed by most writers; but much more importance has been attached to this cause than it deserves, for pneumonia is very rarely produced by it.

83. The incautious exposure to cold or wet, and to the night air, after breathing for some time the foul and depressing air of a confined or crowded apartment, or ill-ventilated quarter, bedroom, or barrack-room, is perhaps the most productive cause of pneumonia, particularly in large towns, and in armies and fleets, and explains the greater prevalence and mortality of the disease in these circumstances than in open, healthy localities.

84. C. The endemic and epidemic prevalence of pneumonia has been admitted by most writers.—— It is sometimes endemic in elevated, cold, and dry localities, either in its simple or in connexion with pleurisy, as a pleuro-pneumonia. It is also prevalent in low, cold, and humid localities, but less so than in the foregoing places, and is most commonly associated with bronchitis, as a broncho-pneumonia. Although pneumonia prevails chiefly in cold countries, yet it is often observed in the more temperate climates of the south of Europe, especially where cold northerly winds blow from high ranges of mountains. In both Milan and Madrid pneumonia is very prevalent. Accini states that, in the hospital of the former city, there were 142 cases of it out of 175 patients. It is also said to be prevalent in the vicinity of Vesuvius, probably owing to acid or otherwise noxious exhalations or gases from that volcano. Mr. Farr has shown, in his tables of mortality, drawn up from the returns made to the registrar-general, that the deaths from pneumonia in cities and large towns in England are much more numerous than in the same amount of population in country districts—are so much so as to indicate both a greater prevalence of the disease, and a greater rate of mortality from it, in the former than in the latter.

85. b. Epidemic pneumonia has been described by many authors; as a complication of influenza, pneumonia of an asthenic form, and broncho-pneumonia, may be said to have been predominant in the epidemic of 1837. When this disease is epidemic, it is most frequently asthenic. It is not infrequently, also, epidemic among horses and cattle. Lænnec attributed the epidemic occurrence of pneumonia to deleterious minims in the atmosphere; and others have imputed it to swarms of minute insects in the air—a subject of much importance, and most ably considered by Dr. Holland, in the chapter on The Hypothesis of Insect Life as a Cause of Disease. (Medical Notes and Re- flections, p. 282.) All owing to the temperature, in the hygrometrical state, in the weight or density, and in the electricity of the atmosphere, may account for the increased prevalence and varied forms of this and of many other diseases, still they are insufficient of themselves to cause the more devastating epidemics sometimes observed, and, as respects this disease, most remarkably among some of the lower animals. Even when occurring epidemically, situation, weather, and seasons materially influence the characteristics and prevalence. Thus, Huson states, that during an epidemic it assumed more of the bronchitic character in low and humid places, and most of the pleuritic form in dry and elevated situations. (See articles Endemic and Epidemic Influenzes.)

In 1838 and 1839, were 3954 males and 3177 females: total, 7131.

The deaths from this disease in the about the same amount of population in the counties of Cornwall, Devonshire, Somersetshire, and Wiltshire, during these two years, were 1898 males and 1558 females: total, 3456, or less in one half the deaths from pneumonia in the metropolis.

2. The deaths from pneumonia in 1838 and 1839, in twenty-four town districts, including the metropolis, were 1819 males and 8674 females: total, 10,493.

The deaths from this disease in the same two years in twelve country districts, containing about the same amount of population as the town districts, were 3392 males and 2920 females: total, 6312, or in the proportion of about 3 to 23.

3. The deaths from pneumonia in the metropolis, in January, February, and March, 3071 days, 2328 but less than 1447.

3. During April, May, and June, 273 days, 2454.

3. During July, August, and September, 275 days, 1827.

3. During October, November, and December, 275 days, 2300.

The greatest number, and nearly double that of the preceding three months, in which the number is least. From these data, pneumonia appears to be most prevalent and fatal during the cold and humid weather following the third three months of the year. This agrees with my observation in respect of children. (From 1819 to 1834 inclusive (16 years), the were 83,783 deaths in the United States, 51,086 of which were of the diseases of the lungs, 4906 being acute affections, and 11,385 were from pulmonary phthisis. Besides these, there were 2513 cases of death from croup, 1416 from hooping-cough, and 183 from asthma, all of which might, with propriety, be added to the list. In some years the mortality among the aged, from diseases of the lungs was of the greatest magnitude; in others a general catarrhall inflammation has rendered children peculiarly subject to inflammation of the thoracic organs, produced by atmospheric exposure. (Statistics of the City of New York, by the Editor, in Am. Jour. Med. Sci., vol. xix.) Of 5715 deaths which occurred in Massachusetts during the year ending April 30th, 1813, 14th Report of the Registrar and Registrar of Births, Marriages, and Deaths in Mass., by J. G. Aliffen, 15. 242 were of the respiratory organs, 9 of asthma, 12 of bronchitis, 5022 of complicated, or indeterminate, pulmonary diseases, 250 of pneumonia, 11 of phthisis. 14 diseases of lungs. From diseases of the nervous system there were 791 deaths; from diseases of the organs of circulation, 130; of the di-
86. vi. Terminations, Duration, and Prognosis.—A. The chief terminations of pneumonia have been noticed when describing the usual course of the disease. But in addition to these it may be stated, that the supervision of pleuritis with very copious effusion may supersede or resolve the inflammation of the substance of the organ, that of the pleura and its consequences becoming the chief or only lesion. This is, however, comparatively rare. Much more frequently the acute attack of pneumonia subsides or is subdued, and the patient continues short-breathed and feverish. The pulse remains quick, and dullness or crepitation is still detected in parts of the chest, with or without uneasiness. Chronic hepatization of portions of the lungs thus not infrequently follows neglected or improperly treated pneumonia, or premature exposure or neglect during convalescence, especially among soldiers and sailors, or the poor, who are exposed to vicissitudes of weather. It is not improbable that tubercular disease of the lungs may originate in these states as chronic pneumonia, especially after repeated attacks, or even from local changes, as supposed by MM. Broissas and André; and when occurring in scrofulous constitutions, it is not unlikely, however, that many of the cases in which the inflammation has been supposed to lapse into the chronic state, and to give rise to tubercles, have been tubercular from the commencement, the pneumonia being merely an intercurrent disease, which has more rapidly developed the tubercular formations; and these have tended to keep up a state of chronic inflammatory action, with more or less engorgement or solidification of the lung; for pneumonia very rarely degenerates into a chronic state, unless in connexion with tubercles or haemoptysis, a circumstance which probably induced Bouillard to infer that tubercular formations in the lungs is merely a chronic form of inflammation of them.

87. B. The duration of pneumonia is very indefinite, and varies with the age of the patient, with the state of vital action characterizing the inflammation, with the complications and the treatment adopted. In general, the asthenic states are more rapid in their progress than the sthenic; and the complications of the disease with exanthematous or other fevers, or the occurrence of it during early convalescence from these, not only accelerates the progress, but increases the danger from it. Debility and advanced age also accelerate its course. In some instances of its occurrence in these circumstances it may run its course in from thirty-six to forty-eight hours, or even in a somewhat shorter period. M. Lazenec attempted to assign periods to the different stages of the disease; but these can be viewed as approximations only to the truth, which numerous causes may vary, more particularly the violence of the attack, and the circumstances just adverted to. He states that the average duration of the stage of engorgement is from twelve hours to three days; of the stage of hepatization, from one to three days; and of the stage of suppurative organs,

88. C. The prognosis is, equally with the duration of the disease, dependent upon numerous circumstances, and more particularly upon those just named (§ 87). Pneumonia is fit to every form, but more particularly its asthenic and complicated states, and when epidemic, is a very serious malady, requiring a cautious prognosis even in the more favourable cases; for these may superinduce a most dangerous pleuritis, or become otherwise aggravated in their progress; or a relapse of a most dangerous kind may occur during early convalescence from them. The "numerical method" of estimating the danger has been extended to pneumonia as well as to other diseases by several French pathologists, as well as by a few British writers. But it must be obvious, on reflection, that the danger and rate of mortality must necessarily vary with the situation and climate; with the prevailing epidemic; with the age, constitution, and other circumstances of the patient; and with the severity, stage, and complications of the malady. Hence the mortality from this disease has been differently estimated; and, among soldiers during service, and in civilians, and more especially among persons engaged in crowded or overheated or ill-ventilated factories, and in other unfavourable circumstances, it is generally high. Dr. Many states, that during the last war in the United States of North America, pneumonia was both very prevalent and very fatal. Sir J. MacGregor states that the disease was prevalent among the troops in Spain during the last war, and that it often assumed an insidious, latent, or low form. The disease, however, does not appear to have been very prevalent or fatal in the United States, and in pneumonia, only 225 died, or rather less than 1 in 14. The treatment of it appears to have been energetic, early, and judicious. In some of the hospitals in Paris the mortality has varied from two fifths to one tenth. The loss is still greater than the highest of these rates among the aged.

89. The danger from an attack of pneumonia is remarkably increased by previous ill health, or attacks of pulmonary disease; by preceding eruptive fevers; and by original debility or constitution. Although recovery may take place from any stage of the disease, the chances diminish rapidly with the supervision of the advanced stages, and become very few after suppurative infiltration takes place. The very rare occurrence of gangrene or abscess is a most dangerous, but not hopeless event. A violent attack, a great extent of the disease, and particularly the implication of both lungs, and its complications with double bronchitis; the affection of the ribs, in particular the ribs of the organ; the operation of causes of a depressing and contaminating nature, as foul air, and partial asphyxia from foul exhalations; the occur-
rence of the disease during influenza and eruptive fevers, during the purer peripheral states, and after prolonged snickering; all the severe complications noted above, and the progressive advance of the disease, notwithstanding early and judicious treatment, are extremely unfavourable circumstances.

90. The symptoms more particularly evincing danger are those indicating the progress of the disease to suppurative infiltration of the lungs, or even to extensive hepatization; very quick and short breathing; frequent dilatations or a working of the alee nasi; a feeling of a want of breath rather than a desire of breathing; of blood sweat; of nervous or restlessess; a rusty or peuce juice appearance of the sputa; cold sweats; anxiety, and sharpened, pale features, with lividity of the lips and tongue, and the other symptoms noticed above (§ 21, 55).

91. vii. Treatment.—The treatment of pneumonia should be conducted with strict reference, 1st. To its stages; 2d. To the states of vital action and power; and, 3d. To the complications and peculiarities of each case. To each of these circumstances the indications of cure are usually directed.

92. A. Treatment of Throatic Pneumonia.—a. In the first and second stages, or those of incipient inflammatory action and engorgement—the first stage of LAENNEC (§ 49-51) —the disease may be much shortened, if not altogether arrested by energetic means. This, therefore, should be the first and chief intention. —a. If, at this period, the local and constitutional symptoms and appearance of the patient indicate thistic reaction either commencing or established, selection from the usual remedies is indispensably practised; and the blood should be abstracted in a full stream, and until a marked impression is made upon the pulse, while the patient is in a sitting or semi-recumbent posture, as directed in the article Blood (§ 64); but, for the reasons there stated, and since adopted by the ablest writers and practitioners, it should not be carried so far as to produce full syncope. In the young and robust, and where there is evidence of unimpaired constitutional power, blood-letting may be resorted to as early as any signs of inflammatory action can be detected, if it be performed in the way I have advised. This having been performed with the effect just mentioned, means should be prescribed to prevent the return or increase of the vascular reaction; and with this view I have for many years directed, immediately after the blood-letting, from 5 to 15 or 20 grains of calomel, with from 3 to 5 of JAMES'S powder, and from 1 to 3 of opium, to be taken at one dose: saline diaphoretics, with antimony, more particularly the liquor ammonii acetatis and boracic acid, in full doses, with the spiritus aethers ni trici, in camphor water, being given every three or four hours. In many cases this prompt and large blood-letting will arrest the farther progression of the disease, and in all tend remarkably to shorten it.

93. The patient ought to be seen again in about eight or ten hours, or twelve at the farthest; and if the symptoms are not abated, or if they have become exacerbated, and if vascular reaction or perspiration has been so reduced by the blood-letting as to which it had been reduced by the blood-letting have taken place, the pulse having increased in strength, venesection must again be resorted to, if the patient be robust or p lethoric, and blood abstracted, as soon as to affect the pulse and system as before, and in the manner already advised, and it should be instantly followed by the exhibition of the same medicines which I have recommended above (§ 92) after the first bleeding. In many cases, as in the less robust or p lethoric, or where the increase or return of the vascular action is slight or hardly manifest, or where there is merely a persistence of the morbid action, either in the same or in a decreasing degree, local depletion by cupping or leeches, or local hyperemia, or blistering will be adopted with advantage; the amount of local depletion having reference to the circumstances of each case. The chief advantages of this plan, which I have long pursued in this and in other thistic inflammations, is, that the means employed immediately after a full blood-letting are such as will promote all the effects which it is calculated to produce, and as will prevent a return of the vascular excitement, which is prone to return as long as the latter morbid action continues, and even after it is subdued, when the blood-letting has been copious.

94. The practice of prompt and copious vascular depletions, so very generally and long observed in this country, has been recently adopted by M. BOUILLAUD and a few others in France, and with the success which has followed it in this country, although it has been decried by M. LOUIS, who has aducd his "numerical method" in proof of the little benefit produced by it. But, as I have elsewhere commented, this method is a delusion, unsupported by any of the best of all tests of medical doctrine, common sense; for it must be manifest, that if a mode of treatment be empirically followed in all cases said to be nosologically the same, although different or even opposite as respects vital power, complication, and stage of advancement, it must be injurious almost as frequently as beneficial. The quantity of blood abstracted by M. BOUILLAUD is certainly large, but not larger than has usually been taken in this disease by the most liberal practitioners.

95. It is unprofitable to follow the French physicians in their arguments on this question, as some of our recent philo-Galic writers have done; as their lucubrations tend only to overlay a plain, common-sense view of the subject with a load of flat, stale, and inapplicable numerical, vainly called statistical, details. From what I have advanced, it may be inferred, that nothing can be said with propriety as to the precise amount to which blood-letting should be carried in this manner than in any other inflammation. It should be practised so as to

* [The numerical system of M. Louis has never obtained many advocates among the enlightened members of the profession in this country. Its failure, indeed, is too obvious to need pointing out; but we may allude to one well-known fact, which must render it entirely nugatory in the estimation of all who are governed by truth and positive observations. The fact to which we refer is, the great difference in the duration of diseases in different years, in some requiring a longer prophylactic course, while others of the same diseases do not bear a similar course. This has been particularly noticed in the treatment of typhoid fever in this country, and in the French manner. In the case of typhus fever, in the latter, the additional examples, allude to the pneumonia of 1812 and that of recent years, the former being of a low typhoid type, and not bearing the signe of the lancet, while the latter is invariably benefited by the abstraction of blood.]
make a full impression upon the pulse and system, and with but little reference to the quantity. I have taken as much as fifty ounces at one time, in the manner I have advised, from a strong, plethoric man, the early stage having been fully developed, and vascular reaction being energetic; and, having had recourse to the additional means above mentioned (§ 92), no farther blood-letting was required. In similar circumstances, I have not unfrequently had from forty to fifty ounces taken at the first venesection, and with the same result. In this, as well as in other inflammations, although vascular reaction is the chief remedy, it ought not to be attempted unless it should be aided by other means. What these means are I have already partly indicated; but they require to be noticed more in detail, for the chief of them have been individually laddled with all the zeal which partisanship generates, and with all the exclusiveness which a one-sided view or an adopted doctrine never fails to produce.

96. b. Tartarized antimony has been long employed in emetic and nauseating doses in the treatment of pneumonia; and, independently of these effects, by Dr. Madevak, and more recently by Dr. Balfour. Rassori of Genoa, however, first demonstrated the great extent to which this substance might be prescribed for inflammatory diseases; and Laennec, more especially, elucidates its effects in the treatment of pneumonia, but, in estimating it above blood-letting in this disease, rated it much too highly. He gave this medicine in doses of from one to two and a half grains in three ounces of sweetened weak infusion of orange leaves, withholding it afterwards, as by the third dose, one would be too strong in regard to the violence of the attack. It was chiefly to this remedy that he attributed the great success of his treatment, which he rated as high as 2 deaths only in 57 cases: a success, however, which has not been attained by other practitioners who have used this substance. Since 1819 I have given it an extensive trial in pneumonia, chiefly in dispensary practice; and, although I do not think so highly of its efficacy as Laennec, I believe it to be a valuable medicine, but subsidiary to blood-letting, and appropriate chiefly to the first stage of the disease. It is by no means a safe medicine for young children or infants; for I have seen large doses of it, particularly when too often repeated or continued too long, produce most dangerous and even fatal collapse, which was sometimes mistaken for the unfavourable course of the disease. In this class of patients, therefore, it should be given with caution, and its effects ought to be carefully watched. For adults it may be prescribed, after sufficient blood-letting, in doses of from half a grain to two grains in any agreeable vehicle, and repeated every two, three, four, or five hours, according to the severity of the disease; but I have found it equally beneficial in smaller doses, when conjointed with the other medicines noticed above in connexion with it (§ 92). The first doses usually cause vomiting, which ceases after the second, third, or fourth, and which should be arrested if it continue after the second or third, by one or two doses of hydrocyanic acid. If it produce purging, a few drops of laudanum or the sirup of poppies should be given with it. Tartar emetic, when given in large and repeated doses, operates chiefly upon the organic nervous energy and the vascular action, lowering both, or the latter chiefly through the medium of the former, in a very remarkable manner, when neither of them is much excited, but much less manifestly when either or both are greatly increased.

97. c. Mercury with opium, in large doses, has been much employed, both with and after blood-letting; and calomel, in doses of from 5 to 20 grains, is the preparation which is most to be preferred. If the bowels have not been sufficiently evacuated, the first dose of it may be given without the opium, with four or five of JAMES's powder, or with one or two of the extract of colchicum, or even with both; but when the bowels are free from fecal accumulations, from one to three grains of opium should be combined with these, and given immediately after the first blood-letting, as noticed above (§ 92). The doses of these, and frequency of exhibiting them, should be regulated according to the severity and progress of the attack and the circumstances of individual cases; but they should not be of such an extent as to make them contraindicated, unless the disease is arrested. In children very generally, and in adults not infrequently, the disease will be either much mitigated or altogether arrested before the effect upon the mouth is produced by the mercury. The application of the mercurial ointment to a blistered surface, and rubbing it on the sides of the thighs and arm pits, have been likewise recommended; but the exhibition of calomel internally, particularly with the remedies here advised, is much more efficacious, these remedies accelerating the operation, and securing or promoting the beneficial effects of the calomel upon the local disease as well as upon the constitutional disturbances. In some cases, the hydrargyrum cum etra may be given, particularly when the bowels are irritable, with opium and ipecacuana; but it is not so entirely to be depended upon as the calomel.

98. The good effects of calomel, prescribed as now advised, are less immediate than those of tartarized antimony, but more certain and permanent; it should, therefore, be preferred, particularly when the disease is advancing to, or has far advanced in, the stage of hepatisation. It is also a much safer treatment for children than that by antimony in aid of blood-letting; but for them, JAMES's powder or ipecacuana should be given with it, in preference to other medicines, and opium should be omitted, unless the child is several years of age. The great advantages of this treatment are its influence in reducing the local area and general vascular excitement; in relaxing the cutaneous surface, and equalizing the circulation; in preventing the effusion of lymph, and in promoting the absorption of whatever may have been already effused.

99. d. In the early stages of pneumonia, venesection, as above advised, local bleeding according to circumstances, tartar emetic, mercury, &c., are the means which ought to be depended upon. Other remedies may, however, be employed, either in aid of these or with a view of preventing a return of the inflammation. Blisters and other external derivate should be employed only after the treatment advised above has been carried sufficiently far, when
they will aid in removing existing congestion. *Purgatives* are not of much service; still, the biliary and other secretions should be promoted, and the bowels duly evacuated. Ends which the patient already desires will seldom fail to accomplish. *Diaphoretics* and *diuretics* should be viewed as adjuvants merely, and are but little required where either the tarry emetic or the mercurial treatment has been prescribed with due activity. Of these medicines, the liquor ammoniae acetas, of the spiritus aeth., nitric, and ipecacuanha are the most beneficial, and are generally valuable adjuncts to the more energetic means previously mentioned. *Expectorants* are seldom required in the earlier stages of either pneumonia or influenza; but even after the inflammatory action is removed, unless in old persons, or when the treatment has occasioned considerable exhaustion, and is followed by a difficult expectoration. They should be employed with caution, or they may favour a relapse. The decoctum senega, camphor, and ipecacuanha should be preferred; squills and ammonium carbonicum should be prescribed only in small doses. In this stage too much should not be attempted by expectorants. Nature will generally perform her own work the best when not impatiently driven. If she require aid, the means just named, blisters, or the embrocations hereafter to be noticed (§ 110), will be sufficient. A recourse to other *sedatives* than the opium, in the manner above advised (§ 97), is seldom either required or beneficial.

100. e. In the third stage—the second of *Lænæc*—when solidification has taken place, or is far advanced or extensive, the chief intentions are, to procure the absorption of the effused matter, to remove the attendant engorgement, and prevent the extension of irritation or inflammatory action around the hepatised part. Blood-letting is now no longer of service, unless it has been previously neglected or very insufficiently practised, and the patient is still plethoric, the veins evincing considerable fulness and the pulse much power. A general or local bleeding, or both, may be cautiously employed in these latter circumstances, particularly if crepitation be still heard in any part of the lung; but the chief dependance should be placed upon *cataplasma* and *opium*, which may be conjointed with colchicum or *Jame’s* powder, or with digitalis, according to the peculiarities of the case. When this stage becomes advanced, or has continued for some time, blisters, rubefaciency embrocations (§ 110), and salines, with mild expectorants, digitalis, camphor, &c., according to the state of the pulse and the presence of fever, are often beneficial. In this stage of the disease, the decoction of *senega*, in small or moderate doses, with orange-flower water, and full doses of the *liquor potassae*, or the *liquor ammoniae acetas*, with the ammonium in excess, or with camphor, and spirits of nitric aether, or with these, or with digitalis and small doses of squills, are the most appropriate medicines. When there is much cough or irritation, *alkalies*, particularly the liquor potentiae, or the liquor ammoniae acetas, should be given freely with sedatives, especially opium or henbane; or the *hydrocyanic acid* may be prescribed with *demulcents* and *diaphoretics*. When fever is removed, but the lung still remains partially hepatised or much engorged, I have found small doses of the *voda* of potassium, with the liquor potassae, in a weak decoction of *senega*, or with *arsenaria*, of great service, frequent recourse being also had to blisters, or to rubefaciency embrocations on the chest. If the vital energies become much depressed in the course of this stage, our chief reliance should be placed upon full doses of camphor or of ammonia, with the decoction of *senega*, upon stimulant embrocations on the chest, and the other means advised for the next stage.

101. f. In the fourth stage—the third of *Lænæc*—or that of suppurative infiltration (§ 55)—the chief indication is to support the powers of life, in the meanwhile to prevent the entrance of mischief and to repair that which has been done. This, however, cannot frequently be accomplished, but it ought always to be attempted; for well-directed efforts will sometimes succeed in procuring the expectoration of whatever puriform matter may pass into the small bronchi, or in limiting the extension of the suppurative infiltration, and subsequently in procuring its absorption and the repair of the lesions which have been produced. The means with which these efforts should be made must be adapted to the circumstances; digitalis, camphor, *asafoetida*, ammonium carbonicum, squills (pilula *scille comp.*), *senega*, ammonia, musk, myrrh, sarsaparilla, iodide of potassium, the mustard *ferri composita*, *liquor potassae*, may be prescribed, in various forms or combinations, according to the peculiarities of the case, and aided by stimulating embrocations applied to the chest (§ 110).

102. g. If *abscess* occur in this stage, the treatment need hardly be varied from that just advised; but the state of the pulse, the expectoration, the state of vital power, and the physical signs should guide the physician. When the symptoms of *pangrene* (§ 44, 56) appear, the treatment should depend much upon the state of vascular action and vital power attending it. In most cases, quinine, with camphor and opium or henbane, or the decoction of bark with soda and ammonia, and inhalation of the vapour of cresates, are more or less serviceable. If vascular action still continue much excited, and vital power not materially impaired, local depletions, especially by cupping, may be prescribed, even while the tonic and antiseptic means just mentioned are being employed. *Dr. Stokes* prescribed, in these cases, the chloride of lime with opium, as an antispetic; and *Dr. Williams*, the nitro-muriatic acid. I prefer camphor in full or large doses, conjointed with the other substances just mentioned, or with expectorants and alkaline carbonates. *Lænæc* advised quinine or cinchona, either of which may be given with the camphor, as above.

103. h. There are various circumstances, some of them only of occasional occurrence, which require attention during the treatment of pneumonia.—*a*. A female may be seized with pneumonia without the catamenia disappearing, or they may appear early in the attack; but this occurrence is not to paralyze the treatment; for, unless this discharge occur at an advanced stage, or after active means have been employed, and unless it be attended by marked abatement of the disease, blood-letting, general or local, or both, should be adopted, according to the circumstances of the case.
LUNGS—Inflammation of the—Treatment of Asthenic.

104. b. The occurrence of delirium during pneumonia, a circumstance long and justly considered as very unfavourable, and as generally prognostic of a bad issue, ought not to forbid a recourse to this treatment, particularly if the delirium occur only in the night. In several instances I have prescribed venesection with marked benefit, although this symptom was present, the other symptoms indicating the propriety of it. Two of these were persons between seventy and eighty years of age, and in one of them venesection was twice performed. They both quickly and perfectly recovered.

105. c. In persons far advanced in age, inthose addicted to the excessive use of spirituous liquors, in the ill fed and badly clothed, in females during the puertal states, blood-letting is often but ill tolerated; and it should, therefore, be resorted to with caution. In many of these cases, even a moderate sanguinaceous depletion is followed by increased oppression, collapse, and extended congestion and infiltration of the lungs. For these, the treatment recommended for the asthenic disease (§ 109) should be immediately adopted; and camphor, the hijims, senega, asefetida, musk, ammoniacum, squills, &c., ought to be prescribed in such forms and combinations as the peculiarities of the case may suggest, and be aided by rubefacient embrocations, blisters, &c.

In the cases of persons addicted to drunkenness or to the excessive use of spirituous liquors, due regard to these habits should be had during the treatment, especially in the advanced stages of the disease.

106. Calomel and opium were first recommended by Dr. Hamilton, of Lyme Regis, and subsequently by Reil, Thomann, Weight, Vogel, Hufeland, Schmidtman, and several contemporary writers. In severe asthenic cases, it will be often preferable to combine them with the tartarized antimony, or to give them in much larger doses and at longer periods, and the camphor emetic during the intervals, commencing with them immediately after the first bleeding, as advised above (§ 92).

107. No dependance can be placed upon the plan of giving a large dose of opium alone after the first blood-letting, as recommended by Thilenius, Kor tum, Horn, and Michaelis, and more recently advised by Dr. Armstrong. Other preparations of opium, as the acetate or moriate of morphia, the bi-meconate of morphia, or the liquor opii sedativus, may be used instead of the pure opium, or the watery extract; but they should be given either with calomel, or with antimony, or ipecacuanha, in order to secure a beneficial effect in this disease.

108. As long as the pulse continues hard or sharp, the tongue dry, and the skin hot and unperspirable, the heating expectorants ought not to be prescribed, nor should blisters be applied. These symptoms, however, do not preclude having recourse to the turpentine embrocation, which may be applied over the chest in the manner about to be described (§ 110), and which generally, especially when employed in aid of the treatment by calomel and opium, or by antimony, or by both conjoined, reduces the frequency and force of the heart's action, and promotes the free inspirations.

109. b. Treatment of Asthenic Pneumonia (§ 62).—This form of the disease seldom admits of more local vascular depletions, and even these should be prescribed with caution. Where they cannot be applied, dry cupping on the chest or between the shoulders, as suggested by Celsius, may be substituted for them. Camphor is one of the most valuable remedies that can be given in this form of pneumonia. It was much employed by Thomann, Reil, Bayler, Horn, Schmidtman, and Willen, and has been frequently prescribed by the author in this state of the disease. It may be taken in doses of from two to six or eight grains, every four, five, or six hours, and conjoined with calomel and opium, or with antimony and henbane, according to the character of the attack. The latter combination may be preferred when the inflammation approaches the asthenic form, and then the camphor may be given in the smaller doses; the quantity of it being increased as the asthenic character predominates. This may be further combined with digitalis, which is not contra-indicated in this form of the disease.

110. Embrocations with spirits of turpentine, applied over the chest or between the shoulders, are the most valuable remedies that can be used in this form of the disease, and in the advanced stages of the asthenic variety (§ 30, et seq.). The best mode of resorting to them is by means of two or three folds of flannel, of sufficient width to cover the greater part of the chest. These should be worn as dry as possible on the skin. The linen or the skin, or other matter which may prevent or much impede evaporation. This embrocation should be kept applied as long as the patient will endure it, or be renewed from time to time. Instead of the spirits of turpentine, an embrocation consisting of equal parts of the compound camphor liniment, and of the turpentine liniment, with a little eucalypt oil, may be reduced to a strength well adapted to the warm flannel, and applied as thus directed. I believe that the inhalation of the vapour from this embrocation is partly influential in producing the benefit which accrues from it, and which I have witnessed in many cases.

111. In this form of the disease, and particularly in its advanced stages, the warm expectorants may be severally employed. The senega, which was praised by Thilenius, Hufeland, Beulam, Oberteuffer, and others, is among the best expectorant remedies in this state of the disease, particularly when aided by other appropriate medicines; as the athers, hydrocyanic acid, the paregoric elixir, &c. Arnica has been also much recommended, particularly by Fischer, Hufeland, Rat, and other German physicians. I have had no experience of its effects in this malady. Conchoa, or the sulphate of quinine, is advised by Williamson, Laxner, and others. I have given the quinine with camphor and henbane, and the infusion or tincture of eucalyptus is prescribed by Horn and Thomann. I have tried it in a few
cases combined with ammonia, and with narcotics and sedatives, and have found it most beneficial in the complication of pneumonia with the adynamic states of the eruptive fevers, or with hooping-cough (§ 70). *Ammomaccum, asafetida, myrrh,* or *squills* may severally be advantageously combined with soap, or with an alkali or an alkaline carbonate, or with other substances suitable to this state of pneumonia. *Musk* was much praised by *Reil* and *Horn.* *M. Krcamier* has more recently employed it in very large doses, and has viewed it as almost specific in this variety of the disease. *Phosphorus* was prescribed many years ago by *B. B. Barchewitz* and *Lunsford,* the last of whom stated that he had a sufficient trial, either then or since, in this form of pneumonia, the only one to which it is appropriate.

112. In the typhoid or asthenic states of pneumonia, as well as in the advanced stages of the stemic, when the disease has assumed the former character, and when diffusive infiltration of the cells and small bronchi has manifestly interfered with the functions of the lungs, benefit sometimes results from prescribing the decotition of scirpus so large as to induce *vomiting,* or from giving along with it the sulphate of zinc, in sufficient quantity to produce this effect. In some of the complications of pneumonia, particularly those with hooping-cough, croup, and bronchitis, the *emetic* effect of these medicines is often very beneficial.

113. In the more *malignant* forms of asthenic pneumonia, more especially in those complications of it sometimes met with in adynamic or decotitous cases, the treatment of the posture of the patient should be changed as often as possible, as justly advised by *Mr. Gerdy* and *Dr. Stokes,* in order to prevent the more depending portions of the lungs from becoming irreparably infiltrated or congested, from a protracted retention of the same position. (Typhoid pneumonia is one of the most fatal diseases which the American practitioner is called upon to treat. This arises from excessive depression of nervous energy, and a consequent depression in the pulmonary system; so that, as *Dr. Williams* has well observed, we might empty the great blood-vessels, and stop the heart's action, before the congestion of the lungs would be relieved, and their vessels enabled to contract. In this condition, the weight of medical authority is decidedly opposed to the abstraction of blood from the general system, although local depletion is regarded as highly beneficial and necessary. Our own experience and the true effect of the disease leads us to believe that the local abstraction of blood by cups and leeches, while at the same time the nervous power is roused by the internal administration of diffusible stimulants and tonics, and mustard cataplasms to the external surface, will be found the most effectual mode of relieving that congestion or engorgement of the pulmonary structure which is the leading phenomenon of the disease. To this end, wine, camphor, snake-root, quinine, and ammonia should be freely given; but our great dependence, after all, except in the very malignant form of the disease, must be on mercury, which, beyond all other agents of the materia medica, is best calculated to restore tone to the capillary system, and to arouse the dormant energy of the cerebro-spinal axis. This should be given so as to produce slight swelling of the gums, and its action should be maintained by small and repeated doses, in combination with camphor and Dover's powder. In the typhoid pneumonia of 1812, general bleeding was practised to a considerable extent by many physicians, and, according to *Drs. Gallup* and *Mann,* with very satisfactory success. The former states that the first indication is, to restore warmth and activity to the surface as quickly as possible; which he effected by the warm bath, or by wrapping the patient in several blankets dipped in warm water, or in warm alcohol. The next remedy is *blood-letting,* which is to be practised early, and in proportion to the pain and distress, without much regard to the pulse. Regarding the low and feeble state of the circulation to be owing to torpor and congestion, *Dr. G.* maintains that bleeding relieves this condition by unloading the congested vessels, and thus imparting nervous energy; and that it should be practised early, and carried to a sufficient extent, and repeated even to seven times, if necessary, without regard to the apparent depth of the "own case," says this writer, "I was bled four times, and never gained ease that was any how tolerable until the last time, when I perceived by my feelings instantly that I had gained the point of relaxation from pain; the blood was stopped, and this was the end of extreme distress."—("Epidemics," p. 299.)

*Sudorifics,* particularly *senega* snakeroot, are also highly recommended as adjuvants in the treatment of this disease. *Emetics,* we are told, were found very useful when the bronchial vessels were loaded, and expectoration not very free. In other cases, they proved injurious; rich animal broths, of an agreeable taste, were beneficial, while cathartics were employed cautiously, but often with benefit. As a stimulant, *Dr. G.* speaks highly of a preparation of Peruvian bark, allspice, sugar, and alcohol; while calomel, or mercury in any shape, except as a cathartic, is ranked last in our scale of medicine. In the treatment, *Dr. G.* states that he proceeded in from 150 to 200 cases of typhoid pneumonia, and lost but two patients (p. 311). *Dr. Mann,* in his "Medical Sketches of 1812-13-14," also speaks highly of small and repeated bleedings in this disease, which he says proved more effectual than all other remedies in rendering the pulse fuller and slower, and increasing the heat of the body. Stimulants were found almost inviable in the treatment.

114. C. Treatment of *complicated Pneumonia.*—The complications of the disease require not merely strict attention to their nature, but also to their characters, as respects the states of vascular action and of vital power. The treatment must be based more especially upon these latter, upon their *stenic* or *asthenic* states, and upon the grades in which either of these characters may be manifested; but also with due reference to the nature of the complication.

115. a. The association of pneumonia with *bronchitis,* or *broncho-pneumonia* (§ 69), requires general or local blood-letting, or both, commonly in moderation, and a free recourse to tartarized antimony; afterward camphor, ipecacuanha, and the milder expectorants, with sedatives.
and rubefacient embrocations or blisters applied on the chest, are generally of service, and accelerate or ensure recovery. When pneumonia is associated with double bronchitis, it most commonly assumes an asthenic character, and requires the remedies advised for that form of the disease (§ 109).

116. b. Pleurao-pneumonia, or the complication with pleuritis (§ 73), requires a free and prompt recourse to general and local blood-lettings, in the manner advised above, and to the exhibition of calomel and opium, sometimes with colchicum or digitalis. In this association calomel and opium, in large or frequent doses, are especially beneficial in promoting the effusion of the serous pleura, and in procuring the absorption of what may have been effused; and although the tartarized antimony is useful in addition to these, it is less so in this complication than in broncho-pneumonia, for which it is a principal means of cure, and to which the calomel and opium are not so appropriate. If the dulness on percussion, buzzing, bronchophony, and other signs (§ 75), indicate considerable interstitial infiltration of lymph, and effusion from the pleural surface, calomel or other mercurials should be continued, or prescribed so as quickly to affect the gums; and blisters ought to be repeatedly applied to the side. After inflammation is removed, and pleuritic effusion only remains, the hydroiodate of potash, with liquor potassae, may be prescribed internally, a mercurial being given at bedtime; and the terebintinate embrocation, alternated with blisters, should be applied to the chest. If the effusion is so great as to endanger collapse or partial obliteration of the effusion, the application of the lungs, paracentesis thoracis, and the means advised for this state in the article Pleura, may be resorted to.

117. c. The complications of pneumonia with eruptions or continued fervers (§ 71) are frequent, and require close attention, not merely in detecting them, but also in recognising the exact states of vascular action and of vital power by which they are characterized. Upon these states will depend the treatment which should be adopted. When the fever, and consequently the pulmonary affection complicating it, assumes much of the sthenically inflammatory character, blood-letting, general or local, but more frequently the latter, will generally be required; but in large towns, and during the epidemic prevalence of these maladies, unless they assume a decidedly inflammatory or phlogistic diathesis, vascular depletions should be cautiously practised; calomel and opium, tartarized antimony, camphor and benzene, rubefacient embrocations, blisters, and similar means being more generally appropriate. If these complications, particularly with eruptive fevers, assume an asthenic or malignant form, the means recommended for the treatment of this form of the disease (§ 109, et seq.) should be promptly resorted to, more particularly camphor in full or large doses, with tonics, stimulants, or antiseptics, or with these and antimony, according to the peculiarities of the case. In these complications more especially, the asiduous application of the warm terebintinate embrocation to the chest (§ 110) will be found remarkably beneficial. The complications of pneumonia with fervers, both continued and eruptive, are fully considered in the articles Fever, Measles, Scarletina, and Smallpox, to which the reader is referred.

118. d. Of the association of pneumonia with hooping-cough (§ 76), it is unnecessary to say more than I have advanced in that article. The treatment should depend chiefly upon the character of the disease and circumstances of the patient. In most instances, however, after moderate vascular depletions, most frequently local, anodynes, anti-spasmodics, emetics, rubefacients, and external derivatives, will be found most beneficial. During hooping-cough, pneumonia rarely occurs in a pure form, but chiefly in that of broncho-pneumonia (§ 69). In the early stage, when the paroxysms of cough are not followed by vomiting, the occasional exhibition of an ipecacuanha emetic will be of great service; and, as the disease advances, conium, hyoscyamus, or hydrocyanic acid, if the patient be not too young, may be added to demulcents or diaphoretics, in order to soothe the cough and allay local and general irritability. In the cases of infants, however, these and other narcotics should be used with caution. In this complication, the terebintinate embrocation (§ 110) applied to the chest, or the embrocant rubbed along the spine, for a few minutes, night and morning, will prove very beneficial.

119. e. Croup, particularly when it is fatal, is generally complicated with pneumonia. After local depletions, the means advised for the complication with hooping-cough (§ 118) are most appropriate, aided by emetics of the decoction of senega with ipecacuanha or sulphate of zinc, and rubefacient embrocations or blisters applied to the chest, when the paroxysms of cough are not followed by vomiting, the occasional exhibition of an ipecacuanha emetic will be of great service; and, as the disease advances, conium, hyoscyamus, or hydrocyanic acid, if the patient be not too young, may be added to demulcents or diaphoretics, in order to soothe the cough and allay local and general irritability. In the cases of infants, however, these and other narcotics should be used with caution. In this complication, the terebintinate embrocation (§ 110) applied to the chest, or the embrocant rubbed along the spine, for a few minutes, night and morning, will prove very beneficial.

120. f. The association of pneumonia with influenza (§ 70) occurs, as in hooping-cough, in the form of broncho-pneumonia, and the treatment should depend chiefly upon the character of the existing epidemic. In most instances, both of such epidemics and of individual cases, vascular depletions should be resorted to with great caution. In the many cases of this complication which I treated in 1837, even local bleeding was not required; and in a very few instances, where only a few ounces of blood were taken by cupping, no benefit resulted from its abstraction. The treatment should not, in this state of disease, be different from that which I have advised for the asthenic form of pneumonia (§ 109). See, also, article Influenza (§ 42).

121. g. The occurrence of pneumonia in connexion with ruborities or pulmonary hamorrhage (§ 76) requires vascular depletions, but generally local, more especially by cupping. Tartarized antimony, digitalis, external derivation by blisters and rubefacient embrocations, issues, &c., are the chief means which may subsequently be prescribed.

122. d. The remarkable prevalence and fatality of pneumonia among infants and children (see § 80) require a few remarks. It may be asked, to what causes are the prevalence and fatality owing? The former is manifestly owing chiefly, 1st, To the greater susceptibility of the organs, in infancy and childhood, to the impression of external agents, and to their more marked disposition to react upon or after the impression of sedative agents, such as cold,
if the sedative operation be not such as to overpower vital reaction; and, 2d.—a. To the circumstance of this class of patients being frequently subjected to the depressant influence of cold, without the beneficial influence of making those exertions which may enable the circulation to resist this influence. A child, before it can run about, is often carried out and exposed during too long a period to the cold air in a state of perfect quietude; and, although the surface of the body be warmly clothed, still the cold air paralyzes the organic nervous influence of the lungs, and causes congestion and engorgement of them, which are soon converted into inflammatory action, as soon as removal into a warmer air—often rapid or suddenly effects—develops vascular reaction. A certain grade of cold, relatively to the state of susceptibility and of vital action, is followed by inflammation; a greater degree of cold produces inflammation, which rapidly passes into disorganization.

123. b. The fatality of this disease in young children is chiefly owing to the frequently latent form it assumes, to the circumstances of the patient being unable to express his feelings, or to express them in a way readily intelligible to the complaint being often mistaken for a common cold, and to the consequent neglect of a suitable treatment until the disease has advanced beyond the reach of remedies. Hence the importance of an early attention to pectoral symptoms during infancy and childhood. A neglect of these, and allowing the slightest attacks of pneumonia at this epoch to lapse into a chronic state, or altogether leaving them to nature, are frequent causes of tubercular formations, in their incipient or early stages, which may remain for years latent, or be slowly developed, to burst forth in more open disease at some future period.

124. c. The treatment of pneumonia in children is not different from that in adults, due reference being had to the age, constitution, nutrition, and strength of the child; to the character or form of the disease, and the stage to which it has advanced. Very frequently the disease has advanced far before it is seen by the physician, and the period for vascular depictions has entirely or almost elapsed; and then mercurials and external derivants are chiefly indicated; and these are very frequently unequal to the control or removal of the disease. At an early stage, blood-letting, calomel, James's powder, or other antimonials, with suitable anodynes, are required; but tartar-emetic should be given with great caution at an advanced stage; calomel, with extract of poppies, the liquor ammonice acetatis, with vinum ipecacuanhae, and a few drops of the spiritus ammonice aromatica of his ailments embrocations, particularly the terebinthinae (§110), are then the most efficacious remedies. If blisters be applied, they ought not to remain on the part above four hours, and they should be replaced by warm bread and water poultices, which may be renewed every two hours. Blister are very apt to be followed by severe sores, or by sloughing, when applied at an advanced stage of pneumonia, if these precautions be not attended to; and the tartrametic ointment often produces no less unpleasant effects. The embrocations here recommended are never productive of injury. Pneumonia in children most frequently exists as a broncho-pneumonia, but this circumstance does not materially modify the treatment now advised. When the bronchitis is double, the attendant pneumonia is generally asthenic, and requires the remedies recommended for that variety (§109, et seq.).

125. E. Although pneumonia generally assumes an asthenic form in aged persons, still this does not always obtain. In a few instances, copious blood-letting may be prescribed even in very aged persons. I have directed it in a person aged about eighty years, and have mentioned above (§104) instances of a successful recourse to it at nearly as great an age, even when delirium had supervened, the symptoms indicating high phlogistic action. In most cases, however, it should be most cautiously, or only locally, or even not at all prescribed; and chiefly at the very commencement of the attack, for the period at which it is beneficial soon passes away. I have, however, found tartar-emetic alone, or with calomel and opium, well borne at a far-advanced age; and expectorants especially the discaccharides. Blister, embrocations, and other external derivants are generally useful; and even at an early stage, when the pneumonia is complicated with bronchitis, which is often the case in aged as well as in very young patients, they may be prescribed.

126. F. In the dark races, and particularly among individuals belonging to them who have recently migrated to cold countries, or to highly-elevated regions, and to changeable climates, pneumonia generally assumes an asthenic form. In the tropical countries, also, negro races do not bear copious blood-letting, even when the subjects of pneumonia. It should, therefore, be resorted to among them with great caution, in small quantity, only at the very commencement of the disease, or it should be entirely omitted, and the means advised for asthenic pneumonia be had recourse to. This inability to tolerate vascular depictions characterizing these races depends chiefly upon the greater laxity of their soft solids, and the nature of their diet, habits, and modes of living. A negro race born in the northern states of America, and much better fed than those living within the tropics, and obtaining only poor or scanty vegetable food, bear blood-letting better than they.

127. G. Diet and Regimen.—The diet ought to be strictly antiphlogistic in the athenic states of pneumonia and their complications. Mucilaginous or farinaceous fluids only should be taken, and in small quantity. In the athenic form of the disease, light milk, water, or milk given, at rather short intervals, and in very small quantity. Persons addicted to the excessive use of intoxicating liquors may be allowed, in this form of the disease, and particularly in its advanced stages, certain quantities of the beverages to the use of which they had become habituated. Children affected by the asthenic form of the disease may be allowed asses' milk, more or less diluted according to the circumstances of the case. If the disease in them be associated with gastro-enteric irritation, as is not infrequently observed, this should be the chief or only diet.
128. If gangrene or extensive suppuration take place, jellies, beef tea, wine, &c., may be allowed. As convalescence commences and advances, weak veal, or mutton or chicken broth, may be given in small quantity, with boiled rice or with toast; and subsequently the lightest baked puddings, water-souchee flounders, and the white kinds of fish, &c., may be cautiously ventured upon. Attention should be paid, during convalescence and the course of the disease, to the preservation of a free state of all the secretions and excretions.

129. During the treatment the patient should be kept out of currents of cold air, in a large apartment, the temperature of which should not vary much above or below 60°. In asthenic, prolonged, or severe cases, the position of the patient ought to receive attention, with the view of preventing hypostatic congestion. Respiration and expectoration will be favoured, particularly when both lungs are affected, by raising the chest by a bed-chair. During convalescence great care should be taken at first irregularly to ferment, and subsequently in exposure to the open air.

130. VIII. CHRONIC PNEUMONIA.—Chronic Inflammation of the Lungs.—Primary and consecutive Chronic Pneumonia.

131. Dr. Stokes correctly remarks, that it is difficult to define the exact meaning of the term chronic pneumonia, or to draw the line of distinction between it and that low irritation of the lung which is followed by tubercular infiltration; and he seems to infer that there are two forms of the disease, the one producing the iron-gray and indurated lung, and the other forming, or ultimately passing into tubercular solidity. The first he calls the simple chronic, the second the serofulous pneumonia. Many of the cases of senile phthisis may be referred to the second variety. These forms of disease differ remarkably in their liability to produce suppuration. Dr. Stokes contends, that in the serofulous affection, suppuration, though slow in its occurrence, is almost sure to supervene; whereas in the simple form abscess formation is rare. The one producing in that hard and semi-cartilaginous condition termed "induration gris" by M. Andral.

132. Chronic pneumonia, in a primary form, is, very rare. It is commonly observed as a sequel of the acute disease, and as a complication of other lesions of the lungs, and in connexion with prolonged organic lesion of the heart. The gray induration constituting the more simple form of the disease varies in its aspect like acute hepatisation, according to the tissues chiefly affected. It may thus assume a granular or orange aspect, owing to the thickening, as Dr. Williams contends, of individual vesicles. In some cases it appears streaked and veined, from the hypertrophy of the interlobular septa and cellular tissue around the vesicles; in others it is more uniform and of a darker colour. In this last variety, the cellular tissue between the lobules is sometimes thickened to the extent of several lines, and is of a light drab or grey colour, like that of miliary granulations; if they exist, they have almost the density of cartilage.

133. These changes are chiefly consequent upon acute pneumonia which has been imperfectly subdued, but they are frequently also

found complicating tuberculous states of the lungs; the solidifications, so frequently met with in these states of the organ, being entirely identical with the changes now described as being a sequela of acute pneumonitis; and hence it may be inferred, as noticed above (§ 67), either that chronic pneumonia may give rise to tuberculous formations, or that tubercles may occasion a state of chronic irritation of the substance of the lungs followed by solidification. Probably both modes of morbific succession may obtain in different cases, more particularly the latter. These chronic solidifications of portions of the lung are met with in connexion, not only with tubercles, but also with irregular dilatation of the air cells; hence the organ often presents a knobby surface after death.

134. A. The symptoms and signs of chronic pneumonia are chiefly the continuance, in a less severe form, of those attending the acute disease. The cough, dyspnoea, or oppression at the chest, quickness of respiration, &c., are still felt, affecting the general or local functions; probably induced, even by slight exertion. Quickness of pulse and heat of skin occur towards night, and the improvement following the acute attack is either slow, or, after a time, altogether checked. Partial dulness on percussion, with some bronchial respiration, and vocal resonance, may be detected near the seat of inflammation.

135. I agree with Dr. Williams in his remark, that several cases of consumption appear to originate in this way, independently of any distinct tuberculous disease or diathesis; and I have at this time a case of this kind under my care. In these, the previous health has been good, and the chest free from any indication of disorder, before the attack of acute inflammation, which, afterward lapsing into a chronic state, has laid the foundation for consumption, which has ultimately proved fatal. This form of disease, however, is slower and less intractable than the true tubercular consumption; it is more local, and less constitutional; and of circumstances do not promote its extension, nature, aided by art, may ultimately effect partial or complete restoration of the organ.

136. B. The treatment of chronic pneumonia, when consequent upon the acute disease, consists of a mild course of mercury aided by external derivation, by means of open blisters, or of tartarized antimonial ointment, or of rubefacient emulsions (§ 110), or of issues or setsons. Either after the mercurial has very slightly been applied, although it is urgently, and are read-
of the air cells, or upon inflation of air into the connecting cellular tissue, or upon both.

138. Previous to the time of M. LAENNEC, emphysema of the lungs was viewed as an infiltration of air into the cellular tissue of this organ. That pathologist, however, extended the application of this term so as to embrace simple dilatation of the air cells or vesicles, and divided emphysema of the lungs into two varieties, namely, vesicular emphysema, and interlobular emphysema; the former being dilatation of the air vesicles, the latter infiltration of air into the cellular tissue which is contiguous to them. A third variety, that those authors have been added by some French pathologists, particularly M. BOUILLAUD, consisting of an extrication of air immediately beneath the pulmonary pleura, which is elevated in the form of a cyst, varying in size.

139. Vesicular Emphysema.—Dilatation of the Air Cells.—A Description.—The lesion described by M. LAENNEC under this appellation essentially consists, as I have just stated, of dilatation of the air vesicles, with some degree of change as respects their form. The dilated air cells vary most commonly from the size of a millet seed to that of a bean. Those of the largest bulk probably are sometimes formed of several cells, owing to a rupture of the partitions which separated them. Occasionally the dilated vesicles are not observable at the surface of the lungs, but sometimes they are considerably in relief upon it, and even are, in some cases, elevated much above it. More rarely, single vesicles are observed on the surface of the lungs, and sometimes are of a cherry-stone, or larger, generally globular, and apparently pediculated, owing to a constriction at the point where the cell begins to rise above the surface of the lung. Cases of this kind may be distinguished from infiltration of air beneath the pleura by the circumstance of the air not being displaced, or caused to pass or circulate beneath this membrane when the vesicle is pressed upon, as may be done when the air is infiltrated in that situation.

140. When the air cells are extraordinarily distended, and when this change takes place suddenly, rupture of them, and a consequent infiltration of air into the cellular tissue connecting them, are not infrequent. This constitutes the true emphysema, and is nearly allied to that which takes place from wounds or laceration of the lungs. In this case, vesicles of an irregular form are found on the surface of the lung, which may be displaced by pressure with the finger. These vesicles vary from the size of a hemp seed, or smaller, to that of an olive. M. LAENNEC remarks, that sometimes the air, although truly extravasated under the pleura, cannot be displaced by pressure, as now mentioned. This is observed when the air is infiltrated at the point of reunion of the partitions which divide the different groups of air cells. In this case the projection has usually a triangular form, and is small in size.

141. The infiltrated air seldom penetrates to any considerable extent into the substance of these interlobular partitions, nor into the cells of the lungs, but is often seen to the sides of larger ramifications of the bronchi; but the interior pulmonary substance is sometimes lacerated by over-distention of the air cells. When this is the case, an irregular projection is observed over the site of laceration, and is proportionate in size to it. When the projection is divided it is found to contain air, and sometimes a minute quantity of blood, either fluid or coagulated; and the surrounding air cells, forming the immediate walls of the cavity produced by the rupture, are loose, flabby, and deprived of their natural globular form.

142. Accompanying this dilatation and occasional rupture of the air cells, the bronchial tubes, particularly those of a small caliber, are sometimes displaced, and occasionally are dilated in those parts of the lungs where emphysema exists. They are more frequently inflamed and partially obstructed.

143. When a lung affected with this kind of emphysema is dried and afterward cut into slices, the air cells are generally found much more dilated than they appear externally; and some of the cells are observed simply dilated, while others are ruptured, the partitions of several being more or less completely destroyed.

144. This form of emphysema may be met with both lungs at the same time, or one only, or a part of one or both. When vesicles of a considerable size exist not on the surface of the organ, the disease may be overlooked during post-mortem examinations. M. LAENNEC considers that the lungs of persons who have long suffered from dyspnea, from whatever cause, always present, upon accurate examination, dilatation of the air cells, to a greater or less extent.

145. When the lesion exists in a very high degree, and occupies one or both lungs, the appearance is very striking. When exposed, the lungs seem confined in the thorax, and instead of collapsing, as usual, often project beyond the margin of its divided parietes. They feel at the same time firmer than natural, and are flattened or depressed with greater difficulty. They are also less crepitant than in health, and the air escapes from them more slowly upon pressure, and with a sound resembling that produced by the slow escape of air from a pair of bellows. When the lung is detached, crepitation is still less perceptible; and when pressed, it produces a sensation similar to that occasioned by handling a pillow of down; probably owing to increased difficulty of communication between the air in the cells and that in the bronchia, together with diminished elasticity of the structure of the lung itself. When a portion of emphysematous lung is placed in water, it is observed to float more lightly than a part which is healthy. It is also lighter even at its roots, and less morbidly affected by the sero-sanguineous infiltration often observed after death. When a single lung is affected, it becomes much more voluminous than the other; sometimes so much so as to press aside the heart and mediastinum, and even to occasion an increase of the size of that side of the chest.

146. Emphysema of the lungs, which consists of dilatation of the air cells, is, therefore, often consecutively accompanied with infiltration of air from rupture of some of the cells, but not always nor necessarily. M. LAENNEC considers the latter lesion to be of less consequence than dilatation of the cells, inasmuch as the air will be absorbed and the rupture oc-
LUNGS—EMPHYSEMA OF THE.

casionally be cicatrized, while the dilatation is a permanent change.

147. B. CAUSES.—This kind of emphysema of the lungs is generally produced by extensive or severe bronchitis, and particularly by those modifications of it termed by Lænne, dry, suffocative, and latent catarrhs. He conceives that, in the dry catarrh, the smaller bronchial ramifications are obstructed either by pearly spita, or by tumefactions of the lining membrane; and that, as the muscles of inspirations are much more powerful than those of expiration, air will be drawn into the cells through the obstructed bronchi, without being expelled, succeeding inspirations, which are forcible or energetic, introducing a fresh supply of air into the cells, occasioning their distention; and, when the obstruction of the bronchi is of considerable duration, rendering the dilatation permanent. There can be no doubt that one of the most common antecedents of this form of emphysema is chronic bronchitis, particularly when it is seated in the smaller ramifications of the bronchi. The obstruction of these vessels, as well as the share the air cells themselves have in the inflammatory state, will so far injure their elasticity as to render them more susceptible of dilatation than in the healthy condition.

148. Other causes may also conspire to produce this lesion of the air cells, such as long retenion of the breath, as in the case of players on wind instruments, and reading or speaking aloud for an unusually long period. Violent exertions of any kind, which require the long-continued retention of the breath, are also causes of this kind of emphysema, although more frequently of the kind next to be considered.

In rarer instances, this lesion may be produced by tumours obstructing or pressing upon the bronchi, whether those developed in the lungs themselves, as cysts, tubercles, polypi of the bronchi, &c., or those produced externally; as in the aortic aneurisms, enlargements of the bronchial glands, tumours in the mediastinum, &c. It may be also consequent upon the spasmodic affections of the large bronchi sometimes attendant upon asthma, bronchitis, croup, and hooping-cough, and upon tuberculous formations, and the solidifications attending chronic pneumonia.

[Rokitansky believes that emphysema usually results from the forced inspirations in croup, hooping-cough, &c., &c., Loris denies

"["Lænne's views," says this pathologist, "hold partially true in emphysema from catarrh. Still, we do not believe the retention of the air which causes the forcible expansion of the air cells, but, much rather, the very deep and powerful inspirations which finally follow the retainer expiration; this view gathers confirmation from the effects of the laboured inspirations in croup, bronchial catarrh of children, and hooping-cough. Besides the forcible dilatation, they may also cause paralysis of the contractility of the lungs, and consequent stagnation of air in the diiled cells.

Still, emphysema undoubtedly develops itself in some cases without the presence of bronchial catarrhs of any kind, and in fact, in slow persons who lead a sedentary life. In these, the less frequent, but so much the deeper, inspirations probably cause the respiration to take place without the aid of the diaphragm, as the occupation of these persons generally requires a bent position, by which the diaphragmatic cavity is compressed. The paralysis of the diaphragm is of the greatest importance here, for the prevented abdominal respiration is compensated by the laboured action of the other great respiratory muscles; and hence we find an evident dilatation of the superior portions of the chest, while emphysema is primarily and most fully developed in the anterior portions of the upper lobes of the lungs.

"The thickening of the walls of the diiled air cells arises, doubtless, from the final coalition with them of the adjacent tissues, which have become atrophied from the compression. The thickness of the wall of these dilated vessels increases, atrophy of the contiguous walls of the cells will ensue, from the persistent pressure which the adjacent opaque mucous membroa, one another, and several of them will unite to form larger cavities, as is also the case in rare instances with contiguous bronchial sacs."

The dyspnoea in emphysema arises from a complication of causes.

"a. The excessive accumulation of air in the lungs prevents the circulation in the capillary vessels which ramify on the walls of the air cells, by the pressure which it exerts upon them, and hence renders the arterIALIZATION of a sufficient quantity of blood impossible.

"b. The pressure of fatuousness of emphysema numerous capillary vessels become obliterated, not only in the walls of the air cells, but also in the adjacent atrophied pulmonary parenchyma, and produces the above consequence in a still greater degree.

"c. The diminished contractility of the lungs, and the frequent and laboured inspirations to which the lungs are constantly urged, allow of only a very imperfect evacuation of the air cells, and occasion a permanent accumulation of highly carbonized air in them, which in its turn prevents the absorption of the oxygen of the blood.

"The impermeability of numerous capillary vessels leads to an accumulation of blood in the pulmonary arteries, and hence to their dilataion, and to the formation of the right auricle and both ventricle cavities, and finally of the venous system generally. The predominant venous impotency will prevent the excretion of the enormous quantity of humoral and phlegm in persons suffering from tuberculosis.

"The impermeability of the capillary vascular system also occasions the anaemic condition of emphysematous lungs, and produces atrophy of the corresponding mammae, sternum, humerhage, and pulmonary in them impossible.

"It proves fatal by final paralytic of the lungs, by asphyxia, from the accumulation of highly carbonized air, by paralysis of the heart, and vascular apoplexy of the brain."

```
earthly hue, and the lips become violet, and somewhat tumbushed. The difficulty of breathing is constant, but is increased by distension of the stomach and bowels, anxiety, exercise, ascending heights; by indigestion or a loaded stomach, catarrh or bronchitis: it also presents exacerbations or paroxysms, occurring at irregular intervals, and continuing an indefinite time. The dyspnea and cough, however, should be considered as being less the signs of emphysema, than of the disease of which emphysema is the consequence.

150. This form of emphysema of the lungs seems to occur in infancy. It may even continue, when slight, from that period of existence through life, without materially abridging it, if the person so affected live in an easy, regular, and abstemious manner. It, however, more frequently tends to aggravate, modify, and induce other diseases, so as greatly to diminish the probabilities of life. The disordered state of respiration always attendant on it particularly affects the functions of the heart, and ultimately its organization, giving rise, at last, to dilatation and hypertrophy of the cavities of the organs.

151. When vesicular emphysema is confined to one lung, or is much greater in one than the other, the side thus affected is perceptibly larger than the other, its intercostal spaces are wider and fuller, and it yields a clearer sound on percussion. If both sides are equally affected, the parietes of the thorax are depressed much less than natural during expiration, while the efforts to accomplish the depression are very much greater, and the spongy chest, instead of its natural compressed form, is more rounded and globular, swelling out both anteriorly and posteriorly; and yields a more hollow or clearer sound on percussion than usual. Dr. Stokes thinks that the symptoms are more severe when the lower lobes of the lungs are chiefly affected.

152. The only diagnostic or pathognomonic symptoms are, however, furnished from a comparison of the indications derived from auscultation and percussion. The respiratory sound is greater, and over the greater part of the chest, and is very feeble where it is audible, a very clear sound being, at the same time, produced by percussion. At intervals, also, particularly when the patient coughs, a slight sibilous rattle, or a clicking or cracking sound is heard, occasioned by the displacement of the mucus in the bronchi. These signs, together with the rational symptoms already enumerated (§ 149), and the history of the case, will generally enable us to form a diagnosis. When one lung is principally affected, the increased size and sonorousness of this side will sufficiently discriminate the disease from all others, excepting pneumonia, from which, also, it can readily be distinguished, as shown in the article Pleura. When vesicular emphysema exists in a very high degree, Laennec considers that it may be accurately ascertained by the presence of what he calls the crepitous rattle with large bubbles. In this case, the sound during inspiration and coughing is like that produced by blowing into half-dried cellular membrane. It differs from the common crepitous rattle, in conveying the idea of dryness, and of being connected with bubbles which are at once large and unequal, the other rattle having qualities exactly the reverse. This phenomenon is, however, not frequent, not of long duration, and occurs only in points of small extent. It is more common and more permanent in the interlobular emphysema. In rare instances the patients are sensible of a cracking in the spot where this rattle is heard. Dr. Williams has sometimes observed a sound of friction, seemingly produced by the rubbing of lobules or cells against the costal pleura.

153. Emphysema in the bronchial vesicles takes place only in a gradual manner. When it has reached a certain point, it may continue for an indefinite period, or afterward increase, or it may even diminish slowly, and disappear altogether. This last result is, however, of comparatively rare occurrence, and only takes place when the causes of the lesion have entirely ceased to act. When the dilatation of the vesicles is extreme and general throughout one or both lungs, the obstacle to respiration is then very great and the danger considerable, inasmuch as this change indicates the existence of an antecedent affection of the lungs of great importance from which it proceeds and with which it subsequently becomes complicated. But when the vesicular emphysema is moderate, it is not to be considered, in itself, as a dangerous affection. According to M. Laennec, it is, of all the forms of asthma (of which disease he considers it, but too generally and indiscriminately, as the proximate cause), that which admits the most of expectations of length of life. There can be no doubt that it constitutes one of the most frequent pathological images existing in early and late age. It is especially frequent, particularly in the chronic forms of the disease, and in persons advancing in years who have been subject to the occasional causes of this kind of emphysema. In general, it may be remarked that this affection is a consequence of another disease of the respiratory organs, to which even more regard should be paid, both as respects prognosis and treatment, than to itself, and more particularly of those noticed above (§ 148); and that it often supervenes upon and attends pulmonary enlargements, the thickening of the substance of the lungs, consequent upon repeated attacks of pneumonia, or upon the chronic states consequent upon the acute form of that disease.

154. Dr. Stokes, among other conclusions, arrives at the following respecting the vesicular form of emphysema: 1st. That the disease consists essentially in an enlargement of the air cells; 2d. That the rupture and coalescence of several cells is not a constant occurrence; 3d. That the disease increases the volume and rarefaction of the lung (when it is far advanced); 4th. That it may occur uncomplicated with any other affection except bronchitis, or it may exist along with other diseases, which are generally chronic; 5th. That it may coexist with great dilatation of the tubes; 6th. That it may be partial or general; 7th. That percussion gives a morbidly clear sound when the disease has attained a certain extent; 8th. But that the cells may be so enlarged as to evince the dryness of respiration without change in percussion; 9th. That the physical signs of bronchitis which occur, though indicating disease in the smaller bronchi, are not character-
istic of the affection; 10th. That the stethoscopic indication is the want of proportion between the sound of vesicular expansion, the results of percussion, and the efforts of inspiration; 11th. That the increased volume of the lung is the source of an important physical sign; this increase being ascertained by measurement of the chest, by displacement of the mediastinum, by depression of the diaphragm, and by the lateral displacement and the depression of the heart; 12th. That the physical signs from asphyxia cutis are much modified by the degree of yielding of the thoracic parietes; the characteristic feebleness of respiration appearing to be directly as the amount of resistance to the increased volume of the lung; 13th. That the intercostal spaces are not protruded in this disease; 14th. That cases of it may be divided into two classes, viz., those in which the diaphragm is unaffected, and those in which it is depressed; 15th. That in the first class the abdomen is collapsed, and without tumefaction in the epigastric or hypochondriac region, the heart being in its natural position; 16th. That in the second class the reverse occurs; the liver is depressed, and the heart so displaced as to be found pulsating as low as the ninth intercostal space; the postero-inferior portions of the chest sounding clear even to the last rib; 17th. That the volume of the lung varies remarkably at different periods; 18th. That when it is greatest, all the physical signs are most evident; 19th. That the cause of its increase is a return or exacerbation of bronchitis; 20th. That under treatment calculated to remove bronchial irritation the vesicular murmurs may return, and the volume of the lung be diminished.

155. ii. Interlobular and Sub-pleural Emphysema.—The infiltration of air into the interlobular cellular tissue, or under the pulmonary pleura, is the consequence either of a sudden and immediate laceration of some of the bronchial vessels, as in cases of external injury, or of rupture of these vessels from previous inordinate dilatation of them (§ 140) of some duration—a consequence of the emphysema already described.

156. A. Anatomical Characters.—When the air is infiltrated into the compact cellular tissue forming the partitions between the pulmonary lobules, small bubbles or vesicles are formed at the surface of the lungs, and disposed in the form of transparent bands, penetrating more or less deeply into the opaque substance of the organ, and becoming narrower the more deeply situated. These small bubbles of air are occasionally, also, found in the cellular tissue in the course of the pulmonary blood-vessels. Sometimes the interlobular bands of emphysema run parallel to each other, with sound portions of lung intervening. More rarely, they cross one another in such a manner as almost to isolate several of the pulmonary lobules. The transparency and want of colour of these bands, by which they are readily distinguished from the opaque pulmonary structure, are chiefly owing to the infiltration of the air, and to the drier state of the cellular tissue into which the air is passed.

157. The infiltration of air into the sub-pleural cellular tissue gives rise to bubbles or vesicles, sometimes of very considerable size, and, in rarer cases, the pleura is elevated into very remarkable bladders. Upon pressing the bubbles of air extravasated in this situation, they are readily displaced and made to pass along the surface of the lungs. When interlobular emphysema is in the vicinity of the roots of the lungs, it frequently extends to the mediastinum, and thence to the neck and to the whole subcutaneous and intermuscular cellular tissue.

158. Although this kind of emphysema necessarily supposes the rupture of certain air vesicles, the rupture are seldom or ever been satisfactorily demonstrated. It has, therefore, been believed by some that the air is secreted in the cellular tissue from the blood-vessels of the lungs, and not extricated from rupture of the cells or smaller bronchi, and others suppose that it is exhaled into this tissue from the obstructed cells and minute bronchi.

159. The different kinds of emphysema now described—the vesicular, the interlobular, and sub-pleural—may coexist in the same person; but the interlobular is the most frequent. The vesicles arising from morbid dilatation of the air cells may, in such cases, be distinguished from those occurring from the infiltration of air into the cellular tissue, by means of pressure and insufflation, by which the air is not made to circulate, or pass from one part to another, in the former as in the latter.

160. B. The causes of this kind of emphysema are those of the vesicular emphysema, particularly when acting in a very marked manner. Infants and children are more subject to this lesion than adults, especially during attacks of croup, in the advanced stages of pertussis, and in severe attacks of bronchitis, where there is much obstruction of the air tubes; and from fits of anger, or from struggling and crying, owing to the violent inspirations taken in such circumstances. Forcible retention of the breath during powerful or long-continued exertions; wounds, injuries, or laceration of the lungs; lifting heavy weights, straining at stool, and the advanced state of the acute fevers. Catarrh or bronchitis, are the most efficient and frequent causes of this kind of emphysema in adults. The spontaneous secretion or exhalation of air into the cellular tissue of the lungs may possibly be a cause of the disease; but this has not been satisfactorily shown. M. Laennec remarks that interlobular emphysema is very seldom consequent upon the vesicular form of the disease, owing to the great density of the cellular tissue intervening between the air cells and lobules, as shown by Laennec, and perhaps to some degree of thickening of the parietes of these cells during the continuance of their dilatation. Extravasation of air into the cellular tissue connecting the pleura with the lungs is much more frequently met with as a consequence of the vesicular species of the disease.

161. C. The symptoms and diagnosis of this species of emphysema are, dyspnoea and shortness of breathing suddenly following violent exertion, or continuing in a marked degree after croup, suffocative catarrh, or any other disease which may have occasioned obstruction for a time of the bronchi. In some cases the patients are sensible of a kind of crepitation in the part affected. On percussion, the chest generally sounds well over the site of the emphysema,
unless an engorged state of the lungs from peripneumonia exists with it. Asxomeration de-
tects "the dry crepitations rattle with large buble-
bles," which LAENNEC considers pathognomonic of
this lesion, particularly when this sign is
very distinct and continuous. It is never want-
ing, and is always more marked than in the ve-
sicular emphysema. Together with this sign, a
sound or sensation as of one or more bodies
rising and falling, and rubbing against the ribs,
is usually perceived during inspiration and ex-
piration. The dry crepitations rattle with buble-
bles, and very friction of asceptic during inspira-
tion, and of crepitations during expiration, with
the occasional production of the crepitation by
pressing the intercostal spaces over the affected
part, are the signs of this lesion most to be
depended upon, and are the least liable of the
other stethoscopic signs to temporary interrup-
tion from obstruction of the bronchial tubes.
Should an external emphysema appear at the
same time with, or subsequent to, the above
symptoms beginning in the neck, the nature of the
disease then becomes perfectly evident.

162. III. TREATMENT.—A. OF PRIMARY Em-
physema.—Care should be taken to avoid the
exciting causes, more especially all exertions of
the voice, and exposure to the inhalation of dust,
or of particles of any kind which may float in
the air that is respired, or of delerious gases or
vapours. Violent mental emotions, and the
influence of cold and humidity, or other causes
of catarrh, coryza, &c., should also be shunned.
Attention ought to be directed to the state of
the digestive organs; the secretions and excre-
tions being preserved in a plasrer state, and
fullatent distention of the stomach and bowels
being prevented. These objects ought to be
kept in view, particularly as respects those who
have had parents affected by the disease, even
although they may not themselves have experi-
enced an attack; for it would appear, from
what M. Louis has advanced, that the parents
of more than one half the patients which he
has treated had been similarly attacked; thus
indicating
an hereditary predisposition to the dis-
ese in a very large proportion of those affected
by it. In entering upon the treatment, we
shall endeavour to distinguish the cases which
are simple from those which are complicated, or
consequent upon or associated with organic or
other affections. Most of the means of cure
recommended for chronic bronchitis (see art.
BRONCHI, § 91, et seq.) are more or less benefi-
cial in this affection. The medicines which I
have found the most serviceable, particularly
when the complaint is exacerbated by cold, &c.,
are camphor, myrrh, asafoetida, and the bal-
sams, with hellebore, or extract of poppy, or
opium; the decoction of senega with an aro-
matic water; the liquor potasse, and small
doses of the iodide of potassium; the mixtu-
raeferi composita, with the alkaline sub-carbon-
ates and anodytes or narcotics; the compound
decocitio of saraparilla, with an alkali and an
anodyne; the sulphate of zinc, with the com-
pond ippecacuanha pill; and the compound
squill pill, with soap, and the compound galba-
nurn pill. Rubefacient limenvis and embrocations
(§ 110), or a blister or warm poultice, applied
to the chest, or any of the stimulating limenvis
prescribed in the Appendix (F. 296, et seq.), rub-
bed along the superior parts of the spine, will
also materially contribute to the relief of the
patient. The inhalation of various balsamic
fumes or terebinthinate vapours, or the vapour
of tar, of cresosote, or of iodine, when much
diluted in the steam of warm water, as advised
at another place (see art. BRONCHI, § 100); or
smoking stramonium, opium, or tobacco, or
other narcotics, is generally very beneficial in
the more urgent cases.

163. It has been supposed that vesicular em-
physema, when once established, cannot be
altogether removed. Dr. Ossoryk and Dr.
Stokes, both fully stated, that the disease is sus-
ceptible of very great amelioration, if not of
complete cure. In this opinion I concur. As
the disease is a consequence of hooping-cough,
bronchitis, chronic pneumonia, and the dry
catarrh of LAENNEC, much of the treatment
which is appropriate to these maladies is also
suited to it. When symptoms of congestion in
the lungs still continue, or when the complaint
has recently followed these or other affections
of the lungs, local dejection by means of cup-
ping, or manual de-cupping may prove useful.
If local dejection be adopted, it should be re-
sorted to before expectorants and the means
just mentioned are prescribed. It has been
suggested by Mr. Martin and Dr. Stokes to try
the effect of strychnia in this disease; but the
contractility of the air cells and tubes can hard-
ly be restored by other means than by those
which will promote the general tonicity and
health of the frame; and of these, residing in a
pure, dry, and moderately warm atmosphere,
and attention to all the digestive and assimil-
ating functions, are the most influential.

164. B. When the disease is complicated
with some other lesion, as congestion, inflammation,
or obstruction of the minute bronchi, with
chronic bronchitis or dry catarrh, or with
chronic pneumonia, tubercular infiltration, or
solidification of portions of the lungs, the treat-
ment should be chiefly directed to those in the
first instance, and subsequently to the resto-
ration of the tone of the pulmonary cells, by
the several means above suggested, and by those
more fully stated in the articles Asthma and
BRONCHI, and more especially by those recom-
manded for the chronic states of bronchitis.
In some instances I have found a residence in as
dry and mild an air as the sea-coast can furnish
of great service. In two or three cases re-
moval to Ramsgate, Brighton, Worthing, or
Hashtings has been advantageous. The sea air
being invigorating to the lungs, voyaging may
prove of service, particularly in the cases of
young persons affected with the slighter grades
of the condition.

105. C. The treatment of interlobular and sub-
pleural emphysema requires few remarks. When
air is infiltrated in the cellular tissue of the
lung, it is soon absorbed. When it continues
or increases, it is probable that the passage of
the air from the minute bronchi into the cellular
substance is not interrupted by the closure
of the minute laceration through which the air
passed; but the laceration generally closes by
means of the lymph effused, as these cases,
with few exceptions, recover, whatever means
may have been prescribed.

III. Edema of the Lungs.—Pulmonary Edema.
Classif. IV. Class, II. Order (Au-
thor).
LUNGS—Hypertrophy and Atrophy of the.

166. Deppt.—Infiltration of a serous fluid into the cellular tissue between the cells of the lungs, and probably also into the cells themselves, occasioning dyspnoea, cough, and short breathing.

167. A. The anatomical characters of oedema are, the pitting of the organ on pressure, its greater gravity and paler colour than in the healthy state, its imperfect collapse or subsidence upon opening the chest, and a copious exudation of a frothy serum when it is divided. Oedema of the lungs occurs generally as a consequence of disease of the heart, particularly of the valves and orifices, causing obstruction to the return of blood from the lungs; of the exanthematos fevers; of other diseases of the lungs; and of obstructions of the kidneys, liver, &c.; it thus arising from the same maladies which occasion other dropsical exudations or effusions, and being often associated with serous effusions in other situations. This lesion, although previously noticed by Albertini and Barrere, was first correctly described by M. Laennec; by whom, as well as by other writers, vesicular blood was rendered visible, increased effusion from interrupted circulation, and impaired absorption of the serum poured out to facilitate the vital functions of the lungs, owing to excessive vascular plethora, impeded circulation, or impaired vital power. Laennec believed that a certain degree of oedema attends the resolution of most cases of pneumonia. From this it will appear that it can rarely be a primary or idiopathic affection. Slighter grades of it not infrequently occur in the advanced stages of asthma or typhoid fevers, particularly in the posterior or more depending parts of the lungs, but generally in connexion with hypostatic congestion in the same situation; and are not to be distinguished from this condition, or from inconstant congestive pneumonia.

[It is a frequent attendant upon Bright’s disease of the kidney, and very often the immediate cause of dissolution in this complaint. In 100 cases of death from albuminous nephritis, oedema of the lungs has been observed in 31 instances.]

168. B. The symptoms of oedema of the lungs are very equivocal, and vary greatly with the pathological states from which it arises. When it becomes extensive, it causes dyspnoea, short breathing, cough, and serous or thin mucous expectoration. The physical signs are a crepitant or sub-crepitant rhonchus, with the breathing less fine or even than in pneumonia, and indicating the presence of more fluid in some of the larger tubes by the mucous rhonchus. The natural vesicular sound is rendered indistinct, particularly at the lower and posterior part of the chest; and percussion is followed by a duller sound, especially in those situations. These symptoms are not very different from those of the early stage of pneumonia; but the absence of fever and of the characteristic expectoration, and the presence of oedema of other parts, and of other signs of the organic lesions usually preceding edema of the lungs, sufficiently distinguish the nature of the disease. There can be no doubt of edema occurring much less frequently in the lungs than the external cellular tissue; and it probably is never, or is very rarely seen, but consequentely upon anasarca or external oedema.

169. C. The treatment of oedema of the lungs should be based entirely upon the pathological conditions which occasion it. That which attends or follows low eruptive or continued fevers, particularly scarlatina, should be treated by dry cupping, frequent change of position, by purgatives, digitalis, senega, camphor, and the means above advised for asthenic pneumonia (§ 109, et seq.).

IV. Hypertrophy and Atrophy of the Lungs.

Classification.—(See § 166.)

170. 1. Hypertrophy of this organ is rarely met with in a true or unequivocal form. A spurious form of it arises in consequence of chronic pneumonia and emphysema. A state of the organ, which has been described by Dr. Clesdenning in connexion with disease of the heart, and which consists of a denser, heavier, and more developed condition, without any apparent obliteration of the vesicular structure, and either with or without congestion, closely approaches hypertrophy. It occurs chiefly in consequence of hypertrophy of the right ventricle of the heart, with difficult circulation through this organ. It is evident that this associated disease of both lungs and heart will be attended by shortness of breathing, more or less dyspnoea, particularly on exertion, and slight dulness of sound on percussion.

["The various differences," says Rokitansky, "in the size of the lungs depend, for the most part, upon the number of the air cells, and their capacity. Enlargement of the lungs may depend upon the presence of a greater number than usual of air cells, which are at the same time larger; or, under opposite circumstances, the lungs are reduced in volume. The first state is generally connected with a great development of the muscular and osseous systems, and a comparative smallness of the abdominal organs; hence it is most frequent in the male sex. The second is generally found when the muscles are less large and firm, the bones more slender and delicate, and the abdominal organs large; hence it is most frequent in females.

"The lungs may appear large, either within or beyond the bounds of normal development, when any given number of their air cells are dilated; under an opposite condition of the cells, the lungs will seem small. The lungs may even appear larger with a smaller number of air cells, than in other examples in which a large number of air vesicles are crowded into a small space. In the first case, the tissue of the lungs is rarefied; in the second, it is denser and compressed."

"Hypertrophy in forming an opinion of the size of a lung, the density of its parenchyma requires especial attention. The two extremes of excessive rarefaction and extreme density of the lungs constitute very important diseases, of which we shall treat more fully when we come to the consideration of the alterations of the texture of these organs.

"Hypertrophy of the lungs doubtless results from a remarkable combination of dilatation of the air cells with simultaneous thickening of their tissues; it is at times observed in the vicarious development of one lung, when the other, from any given cause, has become unserviceable. This variety does not depend upon an increase in the number of the air cells,
but in a dilatation of the existing ones, the walls of which have also become more massive and thick, while their capillary vessels are enlarged in caliber, or even increased in number by the addition of vessels of new formation. The tissue of the lung is thus rendered more dense, but in particular more firm, and the lung itself resists the pressure of the air in a remarkable degree; it has, in fact, become larger, and its thoracic cavity wider."—("A Treatise on Path. Anatomy," translated by J. C. Peters, N. Y., 1845)

171. A survey of the lungs, or a state opposite the foregoing, takes place as a consequence of age: the cells becoming larger, apparently from the absorption or wasting of their intermediate parietes or septa; the substance of the lungs being softer, paler, more flaccid, and less dense than natural. A similar change is rarely observed in cases of chronic emaciation and debility. Partial atrophy is often observed as a consequence of bronchitis, tubercles, pneumonia, and pleuritis. Amrhal and Strokes have argued that, when a portion of the lungs does not admit the air, owing to obliteration or obstruction of the bronchi supplying it, atrophy of it is the result, the consequent deficient circulation of blood to it, and impaired nutrition, naturally causing this; and it has been even further supposed that an impaired state of function of the lungs, or any limitation of the function, may have some effect of the same kind as respects the whole organ.

[Rokitansky remarks of atrophy of the lungs, that "it is exactly the opposite of the preceding condition; it occurs in the most marked degree in old age, under the form of atrophy seniles of the lungs; whenever it is found at an earlier period, it depends upon a premature involution of the respiratory organs, and comes more properly within the limits of pathology. It consists in a dilatation of the air cells (emphysema), with an alteration of their normal angulo-concave form to a roundish or elliptical; and this dilatation is the consequence of an emaciation and thinning of their walls, the vessels of which finally become obliterated. In extreme cases, the walls of the air cells are atrophied to such a degree that several of them coalesce and form a larger cavity; the interlobular cellular layer has disappeared, and hence the lobular structure is destroyed; the parenchyma of the lung resembles an irregularly perforated net-work, while the lungs themselves are blanched, pale-gray in colour, but spotted with much black pigment; they are soft and downy to the feel, light in weight, small in size; they collapse as the thorax is opened; when cut into, the air exudes sluggishly, with a dull, diffused sound, and their tissue is dry and bloodless.

"This marasmus of the pulmonary organs is generally connected with an equally marked emaciation of the tracheal passages, dilatation and thinning of their walls, and dryness of their mucous membrane, and the proximate cause of both is essentially the same. As a rule, it attains its maximum of development in the peripheral portions of the superior lobes, and hence often occasions a remarkable dislocation of the interlobar tissue, which gradually assumes a vertical position."—(Hufmann.)

"The walls of the chest sink downward upon the atrophied lungs, become flattened laterally, and take on a conical form; the spine bends backward with a bow-shape; the sternum is thrust forward; and the vertical diameter of the chest is diminished by the spinal curvatures, the consequent absorption of the intervertebral cartilages, and even of the vertebrae themselves. The soft parts of the chest, but especially its muscles, are pale and emaciated; the diaphragm is thin, lax, and ties in folds; the heart is small.

"The difficulty of breathing, the greater part of the weakness, pallor, and lividity of the tissues, and the general atrophy of aged persons, are owing to the above condition of the lungs. The small size of the respiratory muscles renders every inspiration imperfect; the loss of contractility of the lungs, together with the above condition of the muscles, makes each expiration equally laborious and imperfect; while so large a portion of the capillary vessels of the lungs are obliterated, that but a small quantity of blood is offered for arterialization.

"If an abscess of the lung resists evacuation for a longer period of life, and be far advanced, while that of the rest of the body is but little so, then the disease will acquire fresh importance from the superaddition of active dilatation of the right side of the heart.

"A remarkable enlargement of the lungs is present in emphysema; lesser degrees, and in part only apparent increase in size, take place in hepatisation, high degrees of tubercularization, and in cancer of the lungs, &c.

"A diminution of the size of the lungs may be induced by contractions of the thorax, but in particular by accumulations of air or fluid within the chest, as in pneuma-thorax, hydro-thorax, empyema, &c., or by obliteration of the bronchii."—Loc. cit.]

172. V. ABSCESES PERFORATING THE LUNGS. An abscess may form, or purulent matter may collect, in any of the following situations, and, by perforating the tissue of the lung, pass into the bronchi, whence it may be evacuated: 1. In the thoracic or abdominal parieties, perforating either through the parietes or membranes of the membrane or membranes; the third is also rare; 2. In the pleural cavities, and thence directly passing into the lungs; 3. In the anterior or posterior mediastinum, through the pleura and lungs (see Mediastinum, Abscess of); and 4. In the liver, thence passing through the diaphragm and pleura, as shown in the article Liver (§ 111). The first of these rarely occurs, the second still more rarely, unless the purulent collection in the pleura is limited by adhesions of the opposite parietes or by adhesions between the surfaces of this membrane; the third also rarely occurs, but I believe more frequently than generally supposed. In a case recorded by Dr. Proctor (Medicinische Zeitung, July, 1834), an abscess of the anterior mediastinum communicated both with the lung and the vena cava. The fourth mode in which abscess may perforate the lung is not infrequent; sufficient notice of it and of the phenomena consequent upon it has been taken in the article Liver, Abscess of.

173. VI. GANGRENE OF THE LUNGS.—a. Gangrene in this organ is always a consequence of inflammation; but whether or not it be always caused by inflammation seated in the substance of the lung itself, or in a large vessel conveying blood to a portion of the organ, causing ob-
literation of this vessel, and consequent inter-
ruption to the circulation in that portion, has 
not been fully determined. It is not improba-
ble that it may arise from either, or from as-
themic or congestive inflammation of a portion 
of the substance of the organ extending to the 
blood-vessels. Dr. Stokes seems to believe 
that it may proceed from the suddenness and 
completeness of the congestion occurring in a 
morbid state of the patient; and the cases which 
he has instanced support this view. In all these 
the patients were long addicted to the use of 
spirits: a cause, however, of arteritis as well 
as of phlebitis. In one case there was chronic 
circumscribed gangrene, with an isolated slough 
in one lung, followed by acute phlebitus in the 
other; in another an enormous gangrenous abscess, 
succeeding to contused injury of the 
chest; in a third, a gangrenous cavity occurring 
after causes likely to produce intense con-
gestion of the organ; and in the fourth, gan-
grenous abscess supervening upon asthemic 
pneumonia. Two instances of undoubted gan-
grene of a portion of the lung which have oc-
curred in my practice were observed in cir-
cumstances altogether similar to the above; 
both were in persons whose constitutions were 
infected by intemperance, and both followed con-
gestive or asthemic pneumonia, which had been 
neglected in its early stages. One of these 
cases recovered by the aid of means about to 
be noticed. Drs. Williams and Hussan have 
also recorded cases of recovery after gangrene 
of a portion of the lungs, in the works referred 
to in the Bibliography.

[According to Rokitansky, who is, perhaps, the 
first living authority on the pathology of the 
lungs, gangrene of these organs occurs under two 
forms, viz., **diffuse** gangrene and **circumscribed** 
or **gangrenous eschar.** "In **diffuse** gangrene we 
find a larger portion of the lungs discoloured, 
greenish, or brownish, and filled with a like-
coloured, moderately frothy, flocculent, turbid 
serosity, which renders the affected parts soft, 
rotten, and easily converted into a pulp, shre-
ddy mass. The whole gives forth the peculiar 
gangrenous odour. Towards the circumference 
of the gangrenous part, the discoloration, in-
filtration, and diminution in the firmness of the 
lung gradually decreases, and imperceptibly 
passes over into tissue which exhibits nothing 
abnormal except simple, colourless edema and 
anemia. It corresponds to diffuse gangrene of 
the bronchi, and is almost always associated 
with it; it is rare, upon the whole, but always 
atains a considerable degree of extension, as 
it commonly inculpates the whole, or, at least, 
the greater part of a lobe. It is most frequently 
found in the upper lobes, under circumstances 
which have led to the formation of emphysema 
and anemia in them, and to passive stasis in 
the lower lobes. It may be regarded as so 
much the less an essentially independent affec-
tion, as it is almost always associated with 
gangrene of the lungs, and may be readily induced by the exhalation of gas or 
ichorous fluid from it upon the bronchial and 
pulmonary mucous membranes; or it may fre-
quently arise from a similar affection of a bron-
chus. The above description of gangrene of 
the superior lobes will answer in all respects 
when any other portion of the lungs is affected. 
It is distinguished in particular by the absence 
of all decamation by means of a surrounding 
reactive inflammation.

"As has already been remarked, it should 
be carefully distinguished from **softening of the 
lungs.**"

**Circumscribed or partial** gangrene of the 
lungs occurs in the form of gangrenous eschar, 
and is, beyond all comparison, far more fre-
quent than the former variety. In any one 
part of the lungs, we may find a larger or 
smaller portion of the parenchyma converted 
into a blackish or brownish-green, harshish, but 
most and tough eschar, which adheres to the 
adjacent tissues, and gives forth the peculiar 
gangrenous odour in a very marked degree; it 
is, as Lenne truly remarks, very similar in 
appearance to the eschar produced by the ac-
tion of lunar caustic upon the skin. It is 
sharply circumscribed, and the surrounding 
tissues may be in various conditions.

"The eschar gradually separates from the 
adjacent parts, and is then found seated in an 
evacuation which corresponds to it in form and 
size; its circumference and edges are soft, 
shreddy, pulpy, and bathed in an icchorous fluid; 
it's centre is a hard, firm, blackish-green plug.
More frequently, however, the whole eschar 
breaks down into a greenish, brownish, ex-
tremely fetid, icchorous fluid, in which are 
termixed many rotten, shreddy remnants of 
parenchyma; no trace of a plug is left, and 
the whole is contained within a cavity, to the walls 
of which a shreddy tissue infiltrated with ichor 
adhers.

"The original size of a gangrenous eschar 
and its cavity varies from that of a bean to 
that of a hen's egg; but usually the latter is 
not larger than a hazel, or English walnut; its 
shape is, upon the whole, irregular, but gener-
ally somewhat roundish; its seat is more fre-
quently in the superficial than in the deeper 
parts of the lungs, and more frequently in the 
lower lobes than in the upper.

"These eschars either occur singly, or else 
several are present simultaneously.

"Gangrenous destruction attacks more and 
larger bronchi, the larger the gangrenous cavern 
originally was; they form the passages through 
which the horribly fetid effluvia and sputa are 
exhaled and ejected. It attacks the pleura the 
more quickly, the nearer the eschar was origi-
nally situated towards the surface of the lung. 
If the eschar should then separate from the 
lungs, it will, provided no adhesions prevent it, 
fall free into the cavity of the pleura; if it have 
already broken down into a thick, icchorous 
fluid, then this will flow into the pleural sac, 
and pleurisy, with icchorous exudation, and 
pleum-thorax will ensue; either the fetid gas 
which is accumulated in the gangrenous cavern 
will alone form the pleum-thorax, or, if the 
cavern communicate with the air passages, 
them both gas and atmospheric air will be ef-
fused into the chest. Such superficial gangre-
nous eschars are recognized at a glance, after 
opening the thorax, for the pleura above 
them is either converted into a blackish-green 
eschar, the internal surface of which is shrunked 
and hardish, or, if the eschar have already 
broken down without perforating the pleura 
then this latter will appear of a blackish-green 
colour, be moist, rotten, and puffed up by the 
gas in the cavern; finally, if the pleura be -
erated in one or several places, or be perforated, or perfectly destroyed by a spontaneous dissolution of its tissues, which may happen in either partially, wholly, or not all concealed and covered by the remnants of the pleura, and either partially or wholly emptied.

"The original gangrenous abscess should be distinguished, if possible, from one which has undergone a consequent enlargement; very large caverns are rarely of primitive formation, but have arisen from the extension of circumscribed gangrene; they, as will subsequently be shown, are not circumscribed in the same manner as the primary abscesses.

"The pulmonary parenchyma surrounding a gangrenous abscess is at times in a normal condition, with the exception of being the seat of a serious or sanguineo-serous inflammation; when melting down of the eschar takes place, diffuse gangrene may ensue in this to various distances. More frequently, however, we find it in a state of reactive inflammation, of various degrees of intensity and character. Very frequently, simple asthenic stasis is formed, and gradually changes into inflammatory congestion, in which it remains for a long time, and then slowly passes over into imperfect hepatization. In consequence of a want of energy in this reactive inflammation, the original gangrenous destruction may extend into it in various directions and distances, so as often to attain to the size of a man's fist or child's head. In such cases, the adjacent tissues become discoloured more or less rapidly, without the successive extensions being marked by any distinct limitation, and break down into a gangrenous abscess, and will finally, if the gangrene may reach the pleura, and there occasion all the consequences which have been alluded to; and if the pulmonary pleura be adherent to the costal, this also may be involved in the destructive process.

"Frequently we find the surrounding tissues forced into a higher degree of inflammation, viz., that of evident hepatization, which is at times so extensive as to include the whole of the lobe in which the gangrene is located. It often happens that the disease proves fatal, mostly in consequence of the severity of this reactive inflammation.

"The most important process, however, takes place in the tissues immediately surrounding the cavern, and must be regarded as a natural curative endeavour. The reaction here appears as an inflammation of the interstitial cellular tissue, which, together with the walls of the cavern, passes over into suppuration, and thus effects the separation and ejection of the splanchnæal parts.

"At the commencement of this process, the gangrene still progresses in single parts, and we find the pus, which is secreted from the walls of the forming purulent abscesses, still mixed with gangrenous shreds of tissue, and with iehor. In the course of time, the suppuration gains the upper hand, and, after the sphecachelated parts are ejected through the bronchi, the cavern is changed into a simple suppurating abscess. The internal parts of the walls are infiltrated with pus; beyond this, for three, four, or six lines, the parenchyma is grayish-red and firm, and in case the inflammation of the interstitial tissue is coupled with crumous exudation into the air cells, we find a scarcely perceptible, very minute granular texture. If the suppurative process in the internal layer of the capsule now abates, a cavity will be left, with whitish, cellulo-fibrous, cellular walls, which sooner or later approximate each other and coalesce in the manner described when treating of tuberculous vomice, so that nothing but a cicatrix will remain. This is the manner in which circumscribed pulmonary gangrene heals in single, rare instances.

"If the softening of the eschar progress very rapidly, and none or only very slight reactive inflammation be developed in the adjacent parts, or if the primitive eschar enlarge itself very quickly, then the gangrenous destruction may involve large blood-vessels, which have not yet become obliterated, and exhausting haemorrhages ensue into the cavern, bronchi, and, when the abscess has opened into the pleural sac, even into this latter.

"Partial gangrene often arises in healthy lungs, under the influence of general depressing causes, especially in weak, decrepit, and dysenteric subjects: it then develops itself out of circumcised passive stasis. Besides, it associates itself, when aided by similar exciting causes, with pneumonia, in all its stages; also to pulmonic abscesses, tubercles, tuberculous vomice, and to bronchitis, especially that which arises in the course of various exanthems. Finally, it appears in the train of typhus fever, as a local expression of a spontaneous degeneration of it into putrescence; or it may be excited by the absorption into the blood of gangrenous iehor from distant abscesses itself; and the gangrene may reach the pleura, and there occasion all the consequences which have been alluded to; and if the pulmonary pleura be adherent to the costal, this also may be involved in the destructive process.

"The symptoms of gangrene of a portion of this organ are chiefly the appearance of a most disgusting odour of the breath and expectoration, rendering the patient loathsome to those around him, and even to himself; with general sinking, or remarkable depression of the powers of life, and collapse of the features, consequent upon a severe attack of asthenic pneumonia. The matter exuded in the generally consists of a fetid, greenish, or of a dark-emitted sanious matter or fluid, sometimes attended by a discharge of blood. Dr. Strokes remarks, that the stench is not constant; for, during the progress of a case, it may disappear more than once. In some cases the expectoration is putrid, while the breath is comparatively free from odour; but the gangrenous stench is generally perceived when the patient is made to cough.

174. b. The treatment of gangrene of the lungs should be based upon the intention of enabling the system to resist the contaminating influence of the septic matter formed in the organ, while means are being used to diminish the septic tendency of the matter,—while bark, the chlorides, and camphor, with opium, are taken internally; and wine in the intervals between the exhibition of these, chlorine gas, or the fumes of creasote and camphor may be inhaled. Dr. Strokes advises the use of the chloride of lime and opium. In the cases to which I have alluded (§ 173), a somewhat similar treatment to the above was prescribed. In the first, which occurred many years ago in dis-
pensary practice, the decocation of bark with the chlorate of potash, and compound tincture of bark was ordered, and chlorine gas was inhaled. Camphor and opium were also taken at intervals; and the terebinthinate embrocation was almost constantly applied on the chest. In the second, which I saw more recently in consultation, very nearly the same means were employed, and the fumes of creasote and camphor were inhaled. In this, the unsuccessful case, the remedies appeared for a time to arrest the disease. LAMNNE recommends for this state the sulphate of quinine, and Dr. WILLIAMS the nitro-muriatic acid, which was used in the case which recovered under his care; but the particular means should be selected with reference to the previous condition and the habits of the patient.

176. VII. Tubercles are the most frequent lesions to which the lungs are liable. They are fully considered, with reference to this organ, in the articles Tubercles and Tubercular Consumption.

177. VIII. Malignant Structures in the Lungs.—The lesions truly malignant which are occasionally met with in the lungs are, scirrus, encephaloid or fungid disease — the medullary sarcoma of some writers—and melanosis. — A. Scirrus or cancer is very rarely observed in a true or unequivocal form in the lungs, and then only in the scirrous state, the subsequent stages of softening, ulceration, &c., of the indurated mass not having supervened. Scirrus of the lungs occurs only consecutively of cancer in some other part, and most frequently of the mamma. It may involve the parietes of the chest, pleura, and a portion of the lungs, there being firm adhesions of the pleura, a shrunk, dense, and glistening state of the lungs, and dilatation of some of the bronchi. In rare cases, a portion of the organ is indurated, glinting when divided, particularly near the large bronchi, and similar to scirrus; and yet the absence of cancerous disease from all other parts renders the malignant nature of this change very doubtful. Dr. CORRIAN has denominated this a form of the disease that has obtained in the organ, cervosis of the lungs. Open or ulcerated cancer of the lung is rarely or never seen. Dr. BAYER has recorded a case in which this change was said to have been observed; but he has not stated whether or not the ulcerated cavity communicated with the bronchial tubes.

178. B. Fungo-hematoid disease, or medullary sarcoma, is sometimes met with in the lungs, much more frequently than scirrus, and occurs either in separate tumours or infiltrated through the organ. — The medullary tumours vary remarkably in this situation. They are, in some cases, soft and brain-like; in others, tough, more dense, or even fibro-cartilaginous, or much softer, and resembling the pancreas in colour and consistence. They are either encysted or irregular and non-encysted. In some they are loose, cellular, and vascular, and contain patches of extravasated blood. In others, the texture of the morbid mass partakes of two or more of the above characters. Indeed, these malignant forms, both sarcoi and medullary — are modifications of nutrition, depending, as I have remarked in the article Cancer (§ 26), upon a weakened and otherwise morbid state of the system generally, this state occasioning specific changes in the organic sensibility, nutrition, and secretions of parts, according to predisposition or concurring causes.

179. b. When the medullary matter is infiltrated through the lungs, it appears as intermediate between tuberculous disease and chronic hepatisation or consolidation, and is apt to be confounded with either of those, if medullary sarcoma has not been detected also in some other organs or parts.

180. While scirrus is, perhaps, never primarily developed in the lungs, medullary sarcoma may occur either primarily or consecutively in them; or it may be coetaneous in this and in other organs or parts. It is obviously a constitutional malady, and depends originally upon a depraved state of the vital powers, in connexion with alteration of the circulating fluids, the albuminous portion of which is deposited in certain parts, in an exubrant and modified form, and subsequently undergoes a low and morbid state of organization and nutrition. (See tuberculous Disease, &c.)

181. C. Melanosis is the third form of malignant disease of the lungs, and is met with in them either in the form of distinct tumours, or as irregular, cellular-like deposits, or as infiltrations of the natural structure, or, indeed, in the several states presented to observation in other parts of the body. It may affect the lungs exclusively, but this is extremely rare. It is most frequently observed in this organ and in other parts of the body in the same case. It is occasionally associated with carcinomatous disease with fungid disease. (See art. Melanosis.)

182. D. Symptoms, &c.—The occurrence of these malignant diseases in the lungs is rare, and ascertained with difficulty during life, unless pectoral symptoms appear during the existence of either of these maladies in some external part. The symptoms occasioned by them depend much upon the extent to which they invade the organ; and the physical signs closely resemble those of solidification from hepatisation of the tubercle. The history of the case, the general symptoms, the absence of the local or constitutional signs of tubercles, and the cachectic state of the system, with or without the appearance of anaemia, will serve to direct the diagnosis. In the early stages of these maladies, however, the symptoms are very equivocal, and consist chiefly of impeded breathing and circulation through the lungs, with emaciation, cachexia, anaemia, dropsical effusion, dyspnoea, a leaden or livid hue, &c. At more advanced periods, the expectation, which was previously scanty or absent, becomes more abundant, and is similar to that of bronchitis or pneumonia, owing to the supervision of either or both in the course of the malady, or, rather, of the destructive process occasioned by the morbid mass on the adjoining tissues. In some instances the sputum is streaked with blood, and, in rare cases of melanosis, with some black matter.

183. When these maladies are developed chiefly in the lungs, they occasion death by compressing or obliterating large vessels and bronchial tubes, and by ulcerating, or destroying by their pressure, or otherwise changing, by invading, the adjoining tissues. Cavities
may be formed in the lungs in consequences of the pressure or development of fungoid or melanoid tumours; but this result is very rarely observed, unless consecutively upon the fungo-hematoid tumour.

184. The treatment of these lesions is altogether hopeless when they implicate the lungs.

185. IX. Spurious Melanosis—Anthracosis, Stratton—occurs in the lungs in a peculiar form, and from a cause affecting only this organ, namely, from the introduction of carbonaceous matter, or from the infiltration or inhibition of carbonaceous molecules. The first observation of this organ was first noticed by Dr. Pearson, and subsequently by Drs. Gregory and Thomson (Edin. Med. and Surg. Journ. No. 109), and by Dr. Carswell (Pathol. Anatomy, article "Melanoma"). This change occurs chiefly in the lungs of old people, or of those who have been long engaged in avocations by the light of smoky lamps, or in mines; and it has been observed in various grades. When fully produced, both lungs present a uniform black or carbonaceous deposit, affecting either fully all their tissues. The bronchial glands partake, also, of the same colour. This change has been shown, by the experiments and observations of Drs. Christison and Gregory, to arise entirely from the smoke, soot, and minute particles of coal-dust inhaled during the respiration of air loaded with these carbonaceous matters. A portion of these seem to be imbibed or absorbed by the bronchial membrane, until a considerable accumulation takes place. This may be greater in certain parts of the pulmonary structure than in others; but when it has advanced far, it seems to act as foreign matter, and to cause or to favour the development of irritation, or even ulceration, or to render the lungs more dense and friable, this organ being even infiltrated by a black serosity, and also broken down in parts into irregular excavations, in the more extreme cases. The physical characters of this alteration—the uniform black colour of both lungs, the absence of any similar discolouration of any other organ, its occurrence in persons habitually exposed to the inhalation of the carbonaceous particles contained in the air of mines or of smoky apartments, and the black matter colouring the organ being shown by experiment to consist essentially of carbon, demonstrate clearly the origin and nature of this change.

186. X. Hemorrhage into the Lungs.—Pulmonary Hemorrhage—Hemorrhage of the Substance of the Lungs—The Pulmonary Apoplexy of Laennec and other French pathologists.—In this article has been considered the pathology and treatment of "Hemorrhage from the respiratory organs," or "Hemoptysis," as the disease has been very generally denominated. In it the haemorrhage most frequently proceeds from the bronchial membrane, although the blood may also proceed from the substance of the organ, and, owing to rupture of the vesicular and cellular tissues of the organ, be poured into the bronchi, and thence be ejected, or be carried along the smaller bronchial ramifications. It is this latter, or pulmonary form of hemorrhage, to which I shall now briefly allude.

187. Hemorrhage from and into the substance of the lungs arises from the same causes as were shown to produce hemoptysis, and presents similar complications and pathological relations as pointed out in that form of hemoptysis (§ 108–120). Pulmonary apoplexy or hemorrhage (1) may be confined to the vesicular structure of a portion of lung, the blood being poured out in the vesicles; (2) or it may be seated in the cellular tissue, or, having ruptured the air cells, have passed into this tissue; (3) or it may have ruptured the pleura, and passed into the pleural cavity. These varieties are usually proceeded by pulmonary congestion of longer or shorter duration.

188. A. When the effused blood is enclosed in the air cells, Dr. Carswell describes it as forming a round, circumscribed, solid mass, surrounded by the natural spongy tissue of the organ. The cut surface of this mass is of a very deep red colour, has a homogeneous aspect (excepting the open mouths of the bronchi and large blood-vessels, which are of a light red), and a granular arrangement, which is partly effused by pressure or decomposition of salt and water over it, the removers the coagulated blood from many of the air cells, a minute honey-comb appearance being thereby produced. The size of the masses varies from half an inch to two inches in diameter.

189. B. When the blood is poured into the cellular tissue, generally owing to laceration of the air cells, it spreads to a great extent, sometimes to the greater part of a lobe, or even of a whole lung. In this case a ragged excavation is formed, filled partly with fluid, partly with coagulated blood, which escapes portions of the engorged and lacerated pulmonary substance. This form of hemorrhage may exist in the same portion of the lung with the preceding. When this is observed, the round form, circumscribed margin, and hardness which accompany the first are well marked, and in the centre of this, when laceration has occurred, there is a quantity of coagulated blood (Carswell).

190. C. The third form is a consequence of the second, the effused blood occasioning laceration, not only of the cellular tissue, but also of the pleura.

191. When blood is effused into the vesicular or cellular structure of the lungs, it may be retained in these situations, or a part of it may pass into the bronchi, and be expectorated. The latter occurrence is much more common than the former, and constitutes a variety of hemoptysis which can rarely be distinguished, during life, from that variety consisting of hemorrhage from the bronchi. The irritability of blood which finds its way into the bronchi is generally in proportion to the extent or laceration of the pulmonary tissue. When it is great, it may not only fill the bronchi of the affected lung, but also those of the opposite one, and thus occasion asphyxia.

[Diagnosis.—The milder form of hemorrhage into the lungs, or pulmonary apoplexy, "resembles the severer variety of congestion of the lungs in its symptoms: according to Laennec, there is great oppression of the chest, with cough, attended by much irritation of the larynx, and sometimes by very acute pain in the chest; expectoration of bright and frothy, or of black and clotted blood, either quite pure, or mixed with saliva or mucus; the pulse is..."
frequent and full, with a peculiar kind of vibration, even when soft and weak, as if it frequently is after a day or two; the heat of the skin is natural, or nearly so; the heart and arteries frequently yield a marked hollows sound. The diagnosis of the disease is obscure, for Lænæe states that, of all the symptoms, the splitting of blood is the most constant, commonly copious, returning by fits, with cough, oppression, anxiety, intense redness, or extreme paleness of face, and coldness of the limbs. But every pathologist knows that circumscribed pulmonary apoplexy is frequently found in the cadaver, though there had been no hemoptysis during life; again, the almost invariable dependance of hemoptysis, if at all considerable, upon tuberculization of the lungs, is an admitted fact. As about two thirds of all cases of pulmonary apoplexy depend upon disease of the heart, generally hyper trophy of the right ventricle, it is evident that if the above train of symptoms set in, and there be no evidences of tubercular disease, but marked signs of disease of the heart, we may at once conclude upon pulmonary apoplexy, the more especially if copious hemoptysis be also present. Lænæe placed great stress upon the presence of dulness of percussion over the seat of the hemoptoic infarctus, with absence of respiratory murmur there, but present of crepitant rattle around the dull part; these signs, however, are only found when the hemoptoic infarctus is seated on the very surface of the lungs, which is not the often case.

"Severe apoplexy of the lungs is a more frequent cause of very sudden death, in aged persons, than even cerebral apoplexy. It may commence with oppression of the chest, difficulty of breathing, great livity of the face, and coldness of the limbs; at other times, the first symptoms are, a sense of extreme weakness and oppression; the patient grows pale, and totters, or, perhaps, falls down, yet he generally recovers, and reason returning, he may even be able to tell the by-standers that his distress is in his chest; the face is blue, as in one strangled, the eyes project from their sockets, froth and blood at times collect before the mouth, and slight gushes of black blood may occasionally follow; the breathing is short and unequal; there is rattling in the trachea and bronchi; the pulse, from being full and strong, rapidly becomes small, weak, and fluttering; the limbs are cold; and, in a quarter or half an hour, a cold, damp sweat breaks upon the skin. It is more dangerous than general apoplexy; life is more speedily extinguished, and remedial measures are altogether less efficacious; the latter generally last twelve or more hours; this frequently kills in a half or one hour. The appearance of the corpse is often sufficient to indicate the disease: there is great lividity over a large surface of the body; the eyes are open and projecting, as in drowned persons; frothy, sanguineous mucous oozes from the mouth in great or less quantity, according as the head is elevated or not; the body retains its heat for a very long time, especially in the epigastrium."—(Lievéville.)—Peters's translation of Rokitansky.

192. D. The terminations of pulmonary apoplexy are, 1st. Recovery. This takes place only in the first variety; and in its progress the granular arrangement disappears, the margin becomes less defined, the deep red passes into a dull purple or leaden hue, or into a lighter tint: the hardness diminishes, and the blood-vessels and bronchi become permeable. At last the natural structure reappears. 2d. Suppurition and gangrene rarely supervene. 3d. Instead of being absorbed, the blood has been said to become converted into a coagulum or gangrenous matter, or become solidified within a cyst. Dr. Carricelli adds, that he has not met with an instance of this. 4th. When the hemorrhage is excessive, it may be fatal either instantly or in a very short time.

193. E. The treatment of pulmonary hemorrhage is fully discussed in the part of the article Hæmorrhage above referred to. (See Hæmorrhage from the Respiratory Organs, § 123, et seq.)
its sub-division: 1st. Lupus with extension of the disease superficially. 2d. Lupus with phagedenic destruction of parts, or with extension in depth; and, 3d. Lupus with thickening or hypertrophy of the affected part.

3. I. Description.—I. Lupus Superficialis.

—Lupus with superficial extension of Lesion.—This species may be divided into two varieties, that without tubercles, and that with them.

4. A. Lupus superficialis non-tuberculous, the superficial lupus without tubercles. This variety attacks continuous surfaces of various extent, and destroys or affects superficial layers of skin. It occurs principally in the cheeks, and is not attended either by tubercles or by incrustations. The skin acquires a yellowish-red tint, and is slightly elevated, particularly at the margins of the affected part. A slight epidermic exfoliation takes place on its surface, which is smooth, red, or yellowish-red, and shining; and the exfoliation proceeds slowly and without interruption. It is unattended by pain, but the part is somewhat tender when touched, the redness disappearing nearly or altogether on pressure. After the disease has continued for a very considerable time, the skin appears to be much reduced in thickness, the parts more recently invaded appearing red and slightly elevated. As the disease subsides the epidermic exfoliation ceases, the redness declines, but the skin remains thin, atrophied, shining as if seared by a hot iron, or resembling a cicatrix after a superficial burn, and allowing the subjacent vessels to appear through it, as if they were imperfectly covered. The above description of this variety is taken from a case at present under my care, which commenced nearly twenty years ago, in a spot about the size of a bean, at which time I first saw it. M. Rayev believes this variety to commence in a solitary tubercle, and to spread by the formation of fresh tubercles around those which already exist. MM. Biert, Scheibe, and Caenave, however, admit the absence of tubercles in this variety.

5. B. Lupus Superficialis Tuberculatus—Superficial Tubercular Lupus.—This variety differs from the former chiefly in the more or less manifest presence of tubercles in its early as well as in its advanced progress. These tubercles are small, soft, dusky, or yellowish-red, and cover a space of various extent. They may remain stationary for a time, varying from a few weeks only to several months, or even years, when they may suddenly become the seat of irritation. Their number then increases, the tubercles apponeumatus, they coalesce by their bases, their summits ulcerate, and they form a continuous ulcerated surface of irregular shape and various extent. The check may thus be attacked, and the disease may slowly extend over the whole face, destroying the ale of the nose, and spreading even to the front of the neck. The tendency of this variety is to destroy the surface of those parts on which it appears. It attacks not only the face, but also, although less frequently, the chest, and the anterior aspects of the thighs and extremities, appearing there in continuous patches. The crusts covering the ulcerated surface are thick, rough, and blackish; and when cicatrized form, they are tender, thin, and livid. Tubercles often reappear in the midst of the cicatrized and ulceration again takes place in them. When ulceration stops, cicatrization assumes the form of irregular white bands, stretching from the part where the disease began, and are similar to the cicatrices after burns.

6. ii. Lupus Phagedenica.—Lupus Excedens.—Noli me tangere.—Lupus with Extension in Depth.—This species generally begins with the appearance of one or more small tubercles on the ale, or tip of the nose. These tubercles are soft, smooth, and dusky, or yellowish-red colored. Their elevation is usually slow. This species occasionally commences as a chronic inflammation of the mucous membrane of the nasal fossa, with swelling and redness of the nose. A thin scab then forms at the opening of the nostrils, and is succeeded by a thicker one; and ulceration is established, and extends to the ale of the nose. In other cases, a livid tint, with slight swelling of the point of the nose, is the first indication of the disease. The discoloration increases, and a superficial sore is formed, which becomes covered by a scab, and the ulcer extends in depth. In some instances the disease begins in a similar manner in one of the ale. As the ulceration proceeds a fetid sero-purulent fluid is poured out beneath the scab, and not only the integuments, but also the cartilage, are slowly and silently destroyed. The nose is sometimes red on the surface only; and occasionally it becomes pointed, sharp, and tapering, the nostrils tending to close. The cartilage at the angle uniting the two lateral halves superiority, seems then to project, and presents a red tint perceptible through the soft parts.

7. The extent of destruction thus produced varies extremely. In one case almost the whole nose is destroyed; while in another the point only is partially injured, as if a portion was removed by a knife. After the ulcers have been arrested and healed, new tubercles occasionally form in or near the cicatrices, the work of destruction recommences, and the whole nose and septum ultimately disappear.

8. The progress of the disease may be slow or rapid; after several years a small portion only of the nose may be lost; and, less frequently, the whole of it may be destroyed within in thirty or forty days—Lupus vorax. Sometimes the least interference aggravates and accelerates the malady; and after appearing to advance towards recovery, it often suddenly assumes a more livid hue, and ulceration either recommences or is extended.

9. A cicatrix of the nose and gum is destroyed before the outer surface of the nose is implicated. When the ulceration commences in the skin of the organ, the mucous membrane of the nasal fossa is generally chronically inflamed, and ultimately ulceration takes place in it also, and spreads along it, being occasionally reflected to the arch of the palate and to the gums, which are then deeply furrowed.

10. The tubercles of lupus excedentia are sometimes formed in the upper lip near the alae nasi, or near the commissures of the lips; and the consequent scabbing and ulceration occasion great pain, with destruction of parts. The consequent cicatrizations also give rise to deformity of the lips and mouth.

11. iii. Lupus with Hypertrophy or Thick-
LUPUS—WITH HYPERTROPHY—DIAGNOSIS.

those and the cancer while the circular ear monulous served obvious time. on slightly other pertrophy, first, if ly yellowish-red enlarged, edges lous of markable quamation «f portion iippcars 12. it 16. their their form in the of the lenticular portion iiippcars.

9. The red colour, the erythematous areola surrounding the indurations left by the pustules of acne rosacea, and these pustules themselves, usually seen in the vicinity of these indurations, sufficiently distinguish rosacea from the indolent tubercles of lupus.—c. The general tawny or lirud hue of the skin, and the form and arrangement of the tubercles, which retain the tint of the surrounding integuments, distinguish them from the real lepra, or elephantiasis of the Greeks, from lupus with hypertrophy. The tubercles of lepsoy appear as small, knotty, unequal tumours, followed by swellings, which deform the face, these tubercles being commonly disseminated in several parts of the surface of the body. The tubercles of lupus with hypertrophy are, moreover, arranged in a circular form, extending at their margins, which are definitely limited and covered with squamae; circumstances which do not occur in lepra.—d. The thick irregular prominences of Impetigo are yellow, rough, and not very adherent; those of lupus are of a dark brown colour, thick, and very adherent.

18. e. The term "Noli me tangere" has been loosely applied by Home, Willan, Bateman, and S. Cooper, both to the tuberculous indolent ulcerations of lupus, especially when affecting the nose, and to the malignant or virulent ulcers which sometimes attack this place, the lower eyelid or the cheeks or lips; these ulcers are now known as ulcers of lupus, and have been described by Travers, Lawrence, Mackenzie, and Muller as cutaneous cancer, or malignant disease of the face. These virulent ulcers of the integuments of the face, which often commence in or near the lower eyelid, or upper part of the cheek, have been confounded with lupus by M. Raver; while they have been distinguished from that disease by Bitt, Jacob, and Byron, and from true cancer by these and his contemporaries, as virulent wounds and ulcers seem to form a connecting link between lupus on the one hand, and cancer on the other, as respects both their local characters and their constitutional relations. They resemble the former in their seat, in their being strictly local during the greater part of their progress, without affecting the adjoining glands, and in their equally slow destructive course; while they nearly approach the latter in the advanced period of life at which they occur, in their consanguinity to a car lupus, or scrotal, in the languid pains felt in them at an advanced stage, and in their constant but slow extension; no spontaneous check or arrest of their course taking place when left to themselves, although, like lupus, they may be completely cured by powerful escharotics and alteratives. Dr. Byron, in a very interesting paper on this kind of ulcer and lupus, has instance of eight cases of the former which occurred at an age much more advanced than that at which lupus is usually observed.

19. f. Lupus generally commences in several, or in a cluster of tubercles; cancer in a single tubercle only. The tubercles of the former are soft and indolent; the tumour of cancer is hard and painful, is surrounded by a firm base,
and is the seat of occasional lancinating pains. Cancerous ulcers are, moreover, eroded and painful; they present a fungous appearance, without the dry, thick scabs characteristic of lupus.

20. g. Syphilis affecting the face is often distinguished from lupus with great difficulty, especially when the disease is confined to tubercles without ulceration. The tubercles of syphilis are generally large and rounded and of a dusky copper colour, have much less tendency to ulcerate than those of lupus, which are flatter, softer, and covered by their squamae, partially detached. In the state of ulceration, syphilitic tubercles differ from those of lupus. The syphilitic ulcer is deep, its edges are swollen, sharply cut, and copper-coloured; the ulcer of lupus is of a dull red, and appears confined to the skin. In this latter, the skin is first attacked, then the cartilages, and afterward, and rarely, the bones; while in the former the disease more frequently begins in the bones, and extends to the skin. The tubercle of syphilis, moreover, is generally attended by pains in the bones, by nodes, ulcers in the throat, palate, &c., and by iritis.

21. III. Prognosis.—Lupus is a most obstinate disease, months, or even many years, elapsing before it yields to treatment. Lupus exædema is seldom subsided until parts have been extensively destroyed. It is, however, less obstinate, and its consequences less severe, if a judicious treatment has been adopted at an early period, especially when its progress is slow. Soft, bluish, or livid cicatrices, surrounded by tubercles of various sizes, indicate a renewal of the disease in its most obstinate form. The establishment of the catamenia, which commonly produces a favourable change in most chronic eruptions in females, has no beneficial influence on this.

22. IV. Causes.—Lupus is a somewhat rare disease. It generally commences between the seventh and twenty-fifth years of age, and very rarely after forty. It attacks women more frequently than men, and is more common in country places than in towns. Although it occurs in all constitutions and diatheses—the robust and the delicate—yet it is most frequently met with in scrofulous and weakly lymphatic habits. Dr. Hoveton states, that in Dublin, where the poor are inured to poverty and want of cleanliness, it is often met with, although some of the worst cases come from country places.

23. V. Treatment.—The treatment of lupus is internal or constitutional, and external or local.

A. Internal or constitutional means should have reference to whatever disorder may manifest itself in the digestive or other organs, and to the form of cachexia which may be present. Generally those medicines which exert an alterations with a restorative effect are the most beneficial; and which are capable of reviving the digestive, the assimilative, and the excreting processes. The more superficial forms of the disease are generally connected with the scrofulous diathesis, and in these especially the treatment advised for Scrofula is particularly appropriate. In these, as well as in the others, the preparations of iodine, especially in the combinations about to be noticed, are of great service.

24. The chloride of barytes was recommended by Bateman for this disease; but its injurious action on the stomach has prevented its general use, and the chloride of lime has been therefore more commonly adopted. One dram of the solution of this substance may be prescribed in a pint of water, and half an ounce may be taken at first twice, and subsequently three or oftener in the day, the dose being also increased gradually. The preparations of iron have also been recommended. The chlorides and the iodide of iron are the most beneficial. The sulphate of iron and chalybeate mineral waters, particularly those which contain carbonic acid gas, are also of service.

25. The animal oil of Dippel has been much employed on the Continent, commencing with doses of five or six drops, and gradually increasing them to twenty or twenty-five drops. The decoction of Feltz has also been advised; but these, as well as most other constitutional remedies, generally fail unless aided by local measures, by light, nutritious diet and pure air. The preparations of arsenic, especially Fowler's solution, and the Auratic Pills (each containing one thirteenth of a grain of the white oxide of arsenic and two thirds of a grain of black pepper) have been found influential in arresting the progress of the disease. The arsenical preparations have likewise been employed in conjunction with alkalies, narcotics, especially coconuts, and tannin. Small drops of the bicarbonate of mercury given until the gums are affected, or the same substance dissolved in the compound tincture of cinchona, have also been recommended by some physicians. More recently the combinations of iodine with mercury, or iodides of mercury, have been resorted to with considerable success; but the most decided benefit has been found by Dr. Byron and others to have been derived from the internal as well as external use of the "purulent emetic" of a Dublin chemist, generally commencing with five drops, given three times a day in distilled water, and increasing the dose to ten, fifteen, or twenty drops: this medicine is being diluted with an equal part of pure water for external application. The great efficacy of this medicine in lupus has been proved by Drs. Gravels, Hickson, Stokes, Byron, and White, and by Mr. Carmichael and other surgeons; and generally in cases which had withstand iodine, arsenic, and mercury, when separately or otherwise employed, than in the form of an iodide of arsenic and mercury.

26. In all cases of this disease, a pure, mild, and dry air; the use of the warm or vapour bath, or of the vapour douche, and strict attention to diet and to the states of the digestive, assimilating, and excreting functions, are requisite. Excess in the use of animal food, or of fermented or distilled liquors, must be avoided during the treatment; and the patient ought to be restricted chiefly to farinaceous and mucilaginous articles of diet; and to the use of whey, or of fresh milk with soda or Seltzer water. During a course of internal medicine, external or local means should be carefully and constantly applied; and where there is much irritability of the digestive mucous surface, and particularly when the internal remedies above mentioned increase or induce disorder of the digestive organs, these external means should
be chiefly confined in, while gastric irritation should be allayed by bland and digestible food, taken in moderate quantity.

27. M. Lisfranc advises the treatment of lupus to be commenced with small or remedial venesections, three or four ounces of blood being taken at as remote a point as possible from the seat of disease; and, when the irritation is great, or the patient plethoric, he recommends a recourse to depleitory bleeding. Dr. Bateman states that, in three or four cases of lupus tubereles in the face, the muriate of barytes, taken internally, proved of some benefit. The development of erythema, or even of erysipelas, by these substances, should not be dreaded, as either rather mitigates than aggravates the future course of the disease. In some instances, the application of the tincture of iodine more or less diluted, or of the indrected solution of the iodide of potassium, may be premised.

29. When the application of these, or friction, with ointments containing either of these iodides, are inefficacious, or when ulceration has commenced, recourse should be had to caustics. Of these, the most commonly recommended are lunar caustic, caustic potass, the butter of antimony, the bis-nitrate of mercury, nitric acid, the animal oil of Dippelet, and the preparations recommended by Frere Combe and Dupuytren. But these appear to be interior in efficacy to the chlorate of zinc, and the liquor hydriodatis arsenici et hydrargyri, introduced by Mr. Donovan, of Dublin.

30. When the disease is extensive, the application of the more energetic caustics should be limited to a portion only of the surface, each portion of it being touched in succession. If the ulcerated surface be moist and clean, the caustic may be applied to it at once; but if it be covered by scabs, these should be previously removed by poultices. In the indolent and hypertrophied variety, blisters may be applied previously to caustics. The animal oil of Dippelet has been much used by Continental physicians as a local irritant, in order to modify the mischief, particularly where the seat of the disease is the face. It should be applied by means of a small brush passed repeatedly over the whole of the surface. Dupuytren's powder (consisting of eight or twelve grains of arsenious acid, and an ounce of calomel) is a safe caustic, and has been found efficacious in the slighter cases of the disease. It should not be applied at once to a too large surface.

31. Frere Combe's arsenical powder or paste (consisting of white oxide of arsenic, ten grains; sulphate of mercury, two scruples; animal charcoal, powdered, ten grains) is a powerful remedy, and is most suited to old and obstinate cases; but it should not be applied at once to a surface of greater extent than that of a shilling. It is followed by an erespilatous inflammation of the surrounding parts. The bis-nitrate of mercury, prepared from common, twice, or three draehms of the proto-nitrate of mercury, and an ounce of nitric acid, is much employed by M. Bierr. It excites erysipelas inflammation. It may be applied over the ulcers, tubercles, and scars, which are soft, or purple, or are on the point of breaking out afresh, by means of a small brush dipped in the acid; but it should not be passed over a surface of greater extent than a crown piece. Some scraped lint may then be placed over the cauterized surface, and moistened with the acid. Mr. Frere states, he has used the nitric acid freely, and produced a healthy sore which readily healed.

32. According to the observations of Dr. Byron and others above referred to, these applications may be superseded by the chlorate or chlorid of zinc,* and the liquor hydriodatis arsenici et hydrargyri. The former may be applied in its solid form, or, rather, the diseased surface should be touched with it, as frequently as the parts will support it. The latter, if reduced, may suggest. The latter remedy may be applied locally, from time to time, while it is being exhibited internally. It may be applied in a wash or lotion, with an equal quantity, or more or less of water.

33. During the treatment of this disease, care should be taken to prevent occlusion of the nostrils by the contraction of the scars. This may be done by the introduction of a piece of sponge, duly prepared, which should be persisted in for a considerable time after the excrescences have formed. Both during the local treatment, and after a cure has been effected, benefit will accrue from vapour or warm baths, and particularly from the vapour douche. In such circumstances, the douches and baths of the Dauphin attached to the Thermes de Maria Therese at Bagneres de Bigorre, or a recourse to the douches and baths at Aix-la-Chapelle, or other places, conjoined with the advantages derivable from changes of air, of climate, of regimen and diet, will generally prove of advantage. It is not improbable that, in these cases, the regimen and diet—the use of pure water and of vegetable and farinaceous food exclusively—so eloquently and argumentatively insisted upon by Dr. Lambe, aided by pure air and regular exercise, may prove of essential service; but as to this I am unable to speak from experience. In all cases, change of air, particularly to the seaside, and the use of the means most suited to promote the general health, and to remove associations of visceral disorder, ought not to be overlooked.

* The chlorid of zinc should be mixed with two or three parts of flour, and moistened with as little water as possible. It is a caustic of great power, and requires delicate management. It should not be applied thicker than one or two lines, nor left on longer than six to ten hours; an application of one or two times, for ten or twelve hours, in some cases, form an eschar of nearly a quarter of an inch in depth. The pain is of a very durable character, compared with that of the acid preparations, the nitric acid; it is undoubtedly one of the best applications, in the doubtful-looking ulcerations met with on different parts of the body. Pure creosote is a useful application in many mild cases of the ulcerating form, when pencilled over the surface with a brush. The chlorid of antimony and the proto-nitrate of mercury have both been used with success by Phillips (Lond. Med. Gazete, March 20, 1840). Donovans solution, with sarecpilla, we have found the best internal remedy.
LYMPHATIC AND LACTEAL SYSTEM.

Absorbtion System. Vasa Lymphatica; Vasa Lymphifera; Systeme Absorbant, Fr. Die Saugethern, Germ.

1. Pathologists have very generally attributed not only several organic changes to the lymphatic system, but also various functional disorders. That this system is capable of an increased activity of its functions is probable; but we have no proofs of the circumstance. We merely infer it from the rapidity with which fluids, or even morbid growths, are removed during certain states of the frame, or from the operation of various substances on the body. But this result may proceed from diminished activity of the vessels concerned in the production of those fluids or growths, or from a retardation or arrest of the normal action which occasioned them, as well as from increased activity of the absorbent system. Without, however, pursuing this subject at this place, I may remark, that it appears extremely probable that the functions of the absorbent system are controlled by the vital energies of the frame in a similar manner to the other vascular systems; that they may be diminished, augmented, or even otherwise changed, by the varying states of these energies; and that as the healthy are opposed to the morbid function of the absorbent system, so the restoration of the latter to the former state will necessarily be followed by a return also to its original condition and form.

2. It was acutely contended by Mr. Hunter, that an increased state of vascular action always coexisted with diminished absorbing function in the parts where the former state prevailed; and that, as vascular action was lowered, the absorbent function became augmented. There are many phenomena which occur during the course of disease, and in the course of various plans of treatment, which seem to favour this opinion. But these may be explained in a different manner; and by simply referring them to the different states of vascular action and conditions of the secreting apparatus merely, of the existence of which states we have positive proofs, without calling to our aid an opposite condition of a different series of vessels, of which condition we have no evidence. In order to illustrate this point, let us suppose that in order to remove an effused fluid or a morbid growth—an ascites or a bronchocoele—and we succeed in our efforts. The question is, whether the means employed have produced the desired effect by changing the state of action of the vessels whence the effusion and morbid formation proceeded, bringing back this action to the healthy condition, the absorbent functions remaining unchanged; or by exciting or rousing the absorbing vessels which had become impaired, particularly in the place affected. It is obvious that the former of those effects merely would be sufficient to account for the change produced, without having recourse to the latter; for we can scarcely suppose that the means which would diminish action in one series of vessels would increase it in another. It is, however, extremely probable that morbid depositions and growths depend not only on a diseased state of the vital actions of a part, manifested chiefly in its capillary, nutritive, and secreting vessels, but also upon certain conditions of the circulating fluids; and that the same means which remove these states will seem to have restored the healthy condition of the absorbing vessels, although the functions of these vessels may have been but little affected by them.

3. The following case will illustrate this view. A professional gentleman, well known to several of my medical friends, called upon me, complaining of rheumatic pains in various parts of the body, and of disorder of the urinary organs. But his chief complaint was a tumour, as large as his head, on the right side. It was firm, doughy, and apparently fatty. I prescribed the iodide of potassium with liquor potassae in full doses. In the course of a few days the rheumatic pains had ceased, and the tumour was very much diminished in size; and after a few weeks not a vestige of the tumour remained. In this case the medical agents evidently operated by passing into the circulation, and thereby affecting the state of vascular action and nutrition in the tumour, and partly also the chemical condition of the fatty deposit in the cells, thereby rendering it more capable of being absorbed.

4. The influence of the lymphatics in producing disease has evidently been greatly overrated by many pathologists, and particularly by Hewson, Cruickshank, Irexland, Johnston, Soemmering, and Alard. That the functions of this system may be disregarded, and that they may, owing to the properties of the fluids and matters which they convey into the circulation, be frequently instrumental in the production of disease, cannot be denied. But that they are often the seat of disease seems disproved by the rarity of their organic lesions. M. Andral states that he has examined the thoracic duct and principal lymphatic vessels in upward of 600 cases, and found but in very few instances any appreciable changes in the parietes of these vessels.

1. DEFLN. — Sharp, burning pain; diffused swelling, tenderness, and heat; red lines manifest in the course of the absorbent vessels, when external parts are affected; symptomatise fever, &c.

2. Inflammation of the absorbents or lymphatics may be readily confounded with inflamm-
tion of the organ in which the inflamed vessels are seated; and there is every reason to suppose that both kinds of inflammation may coexist, or the one supervene upon the other. There is no doubt that lymphangitis sometimes coexists with phlebitis, and that either, especially the former, may give rise to the other; and in some of the cases, particularly the phlebitis, may mask the other, according to the degree in which either is affected.

3. Lymphangitis occurs chiefly in superficial parts, and is most frequently seen in the extremities. It much more rarely is observed in large absorbent trunks, and in deeply seated or internal organs. M. Andral found in upward of 800 dissections the parietes of the thoracic duct inflamed in three cases only. The lymphatics proceeding from the mamma are not infrequently inflamed, particularly in connexion with lactation, or consequentially upon inflammation or organic lesions of the organ. Those of the lower extremities are also often affected, either consequentially upon abrasions, punctures, &c., or during the puerperal state; but the lymphatics of the upper extremities are the most frequently inflamed, owing to the liability of the fingers and hand to be injured or contaminated during the discharge of their numerous offices.

4. Lymphangitis is rarely observed in the internal viscera, probably owing partly to the difficulty of detecting this lesion in these organs, particularly when they are the seat of other changes, or to the readiness with which it may be overlooked. However, I have seen the lacteals inflamed and structurally changed consequentially upon ulceration of the intestines, and in connexion with enlarged mesenteric glands; and those of the uterus inflamed in examination of fatal puerperal cases. Similar facts have been recorded by M. Monod, Tonnelé, Duplay, Lee, Ollier, and others. MM. Gendrin and Tonnelé observed in two cases of metro-peritonitis, complicated with lymphangitis, the inflammation extending to the thoracic duct. M. Andral observed the superficial lymphatics of the lungs inflamed in a patient who died of tubercular consumption. There can be no doubt of the not infrequent occurrence of lymphangitis of internal viscera when they are the seat of ulceration, or when morbid matters are absorbed from them by the lymphatics. In these circumstances, either these vessels, or their glands, or both vessels and glands, and even the veins also are liable to inflammatory action, which may assume either an acute or chronic form, according to the constitution of the patient and the nature of the causes.

5. Causes. — A. The predisposing causes of inflammation of this class of vessels are nearly the same as those which dispose to inflammation in other cases, viz. the delective and irritable constitution and scrofulous diathesis; a weak and delicate constitution; a lowered state of the vital energies of the frame, and the puerperal states, especially the period immediately consequent upon parturition; great loss of blood; previous disease, as scrofula, fevers, syphilis, and a cachectic state of the frame; unwholesome states of the air; confined and ill-ventilated apartments, &c.

6. B. The exciting causes are mechanical or chemical irritants, especially punctured wounds; the inoculation of noxious, morbid, or putrid animal matters, or acrid substances; the absorption of malignant, ichorous, sanguine, or purulent fluids from foul, cancerous, or malignant foci; or the ingestion of vegetable or tuberculous dust from cereals and scrofulous or syphilitic nurses, &c.; the absorption of matter from whitloes, tubercles, anthrax, variolons putstules, and abscesses; the bites and stings of reptiles and insects; abrasions of the cuticle; acrid applications, burns, and scalds; the protracted or incautious inunction of mercurial or other preparations; and the bites of animals. I have seen it caused by the bite of a rat, in a very interesting case attended by Mr. Ryan of Farningham and myself, and by the bites of the dog and cat when taking the hook from their throats, and by the accidental punctures produced by their teeth. In two cases of this kind, which I saw many years ago, the symptoms assumed a very dangerous form. The most common causes are punctured and abraded wounds, and the inoculation of putrid and noxious animal matters. I have seen many instances of it in cooks and poulterers, who had injured their fingers in preparing game for cooking. Punctures or cuts during dissections are also frequent causes.

7. ii. Description. — A. Symptoms of Acute Inflammation of the Lymphatics — Lymphangitis Acuta. — The attack may or not be preceded by chills or rigours; and it may be characterized by signs either of phlogistic action, or of great depression of the vital powers; by local action and fever either of a septic form, or of an asthenic, adynamic, or ataxic kind; the former, however, being generally ushered in by rigours, the latter seldom presenting this symptom. The form of the accompanying fever depends entirely on the nature and combination of the causes and state of the patient's constitution and habit of body; those causes which consist chiefly of mechanical and chemical irritation being generally accompanied by asthenie action, while the inoculation of deleterious or poisonous substances, or the absorption of ichorous or morbid matters, especially when occurring during a lowered state of the vital energies and marked predisposition, are always characterized by asthenie, adynamic, or ataxic symptoms.

8. a. The diagnostic signs of the disease are sensitive, stinging, and burning superficial pain, and tenderness in the course of the lymphatic trunks, accompanied generally with increased heat and appearances of reddened lines beneath the skin, commencing in the seat of injury, or in an ulcerated or suppurated part, and disappearing about the situation of the adjoining glands, which generally become painful, swollen, or inflamed. These reddened lines, or streaks, are extremely sensible to the touch, and seem like thin, knotted chords placed under the skin. The parts from which the inflamed lymphatics originate, or through which they pass, are generally swollen, tense, and moved with pain and difficulty.

9. b. The constitutional symptoms are generally those of irritative fever, with various grades of vital power, according to the nature of the exciting causes, and the circumstances
peculiar to the patient at the time of their operation. They most commonly, however, assume an adynamic form, or are characterized by greatly increased or irregular vascular action, and depressed vital energy. When internal and deep-seated lymphatics are inflamed, or the principal trunks, as the thoracic duct, &c., the case is extremely obscure. The constitutional affection is generally similar to that now noticed; and the phenomena altogether differ but little from those characterizing inflammation of internal veins, or from asthenic inflammation of the internal organs whose lymphatics are affected.

10. Chronic lymphangiitis is rarely met with, excepting in serofulose habits, and during the course of syphilitic and malignant diseases, when it is generally associated with chronic inflammation and obstruction of the lymphatic glands. Unless the superficial lymphatics are affected, the diagnosis of this form of the disease is extremely difficult. Its existence in many cases even of this description is often merely a matter of inference, and the symptoms accompanying it are seldom distinctly marked. When the lymphatic vessels have presented the appearances of dissection, usually resulting from a state of chronic inflammation, the existence of some other organic lesion, particularly of parts whence the diseased vessels proceeded, has generally been ascertained, as of serofulose tubercles and ulcers, syphilitic or cancerous ulcerations, carbuncles, elephantiasis, and malignant diseases.

Sir A. Cooper found the lymphatic vessels of the cord enlarged, their parietes thickened, with an insatiable thirst of their valves, in a patient who died with chronic disease of the testicle. Indications of chronic inflammation were observed in the thoracic duct of another patient by the same surgeon; and M. Andrè has found similar appearances in both the lymphatic and lachetic absorbents.

11. iii. Terminations and Prognosis.—The disease terminates, 1st. In resolution; 2d. In organic changes, chiefly limited to the vessels affected without occasioning death; and, 3d. By chronic inflammation of death. — A. The degree of danger is to be inferred entirely from the nature of the exciting causes, from the condition of the patient's frame anterior to the attack, and from the character of the constitutional symptoms. Unless when extremely slight, and when attended with but little febrile disturbance, it ought always to be viewed as a serious disease; and when the vital energies are evidently depressed, when the disease proceeds from the inoculation or absorption of noxious matters, particularly morbid or poisonous animal secretions, when the pulse becomes very quick, with a dark-brown tongue, or with low delirium, offensive secretions, &c.; when these and other symptoms of adynamic or ataxic fever supervene, the danger should be considered great. An increase or diminution of these unfavourable symptoms will of course indicate a similarly modified degree of danger. On the other hand, when all the more violent local or constitutional symptoms abate, owing to the treatment employed; or when the causes are not of a very noxious description, nor the system of the patient much injured previously, or the vital energies impair-ed, a favourable termination may be anticipated.

12. B. A fatal result is commonly occasioned either by the extension of the inflammation along the vessels to the large trunks, or into the veins, or by the introduction of the noxious cause, whatever it may be, into the circulation, and the general contamination of the fluids and soft solids of the body which it thereby produces, or by the combination of the above effects. These results, although occasionally observed in weakened and irritable states of the frame, occur not so frequently as in phlebitis, but still they occasionally take place; and, therefore, our prognosis should be guarded, and the diagnosis considered as one of much importance. It is generally observed that the disposition of the inflammation to extend to the internal lymphatics and veins, and the liability of the morbid matter to be carried into the system, or to contaminate the frame, are in great proportion to the depression of the powers of life characterizing the progress of the complaint. When these powers are sufficient to the production of coagulable lymph, by which the extension of the inflammation may be prevented, and the injurious effects of the cause of the disease thereby limited, recovery generally takes place, either by resolution, or by a limitation of these effects to the lymphatics and their glands merely.

13. C. Appearances after Death.—These are chiefly increased redness, thickening, an easily lacerated state, the presence of purulent matter in the vessel, and, in rarer instances, ulceration. In most cases, redness of the vessel had given place to the other lesions before death had occurred, and thickening, a dull pearly white state of the coats of the vessel, obliteration of the canal of the vessel, and its conversion into an impermeable fibrous chord, are the chief changes. In more chronic cases, these latter changes, or a dilated, knotted, thickened, and indurated state, with remarkable whiteness, are generally remarked.

14. The appearances consequent on inflammation of the thoracic duct, in two cases recorded by M. Andrè (Archives Gén. de Med., t. vi., p. 542), were loss of the redness of the internal surface of the canal, with thickening of its parietes in both instances. In one of them the duct was filled with purulent matter, one of the kidneys having been converted into a purulent sac, and surrounded by large collections of matter. In the other case no purulent matter was found in the duct, but all the adjoining lymphatic glands were inflamed. A similar instance is described by M. Gendrin. M. Andrè states that he has observed, in other lymphatic vessels, similar lesions to those found in the thoracic duct in the above cases. He instances a patient who had died of phthisis, with ulceration of the internal surface of the small intestines, and in whom the lymphatic vessels proceeding from this part of the alimentary canal were similarly altered.

15. Thickening of the coats of the vessel may proceed so far as to occasion obliteration of the canal. M. Andrè states that the walls of the thoracic duct may be so thickened as to cause a partial, or even total, obliteration of its cavity.

16. Obliteration of considerable lymphatic trunks is occasionally observed as a conse-
fluence of inflammation. In many of these cases the obliterating proceeds from inordinate thickening of the coats of the vessel as now stated, but in others the vessel is simply constricted, or reduced to a fibrous chord. M. ANDRAL has recorded a case in which the thoracic duct was altogether obliterated, and a collateral circulation established by a considerable branch, which came off from the duct a few lines below the point where it was obliterated, and re-entered it a short distance after it again became permeable. (Arch. Gén. de Méd., t. vi., p. 504.)

17. iv. Treatment.—The indications of cure in this disease are: 1st. To diminish local inflammation and irritation; 2d. To prevent their extension along the vessels to the larger trunks and internal parts, and to fortify the powers of life against the introduction of the morbific cause into the system, or of the secretions from the internal surface of the inflamed vessels. The first indication is best fulfilled by local blood-letting when the inflammation is very considerable. General blood-letting is rarely requisite, unless the patient be very phlegmatic or robust. I have, however, treated several cases without even local depletion, and the patients have recovered rapidly. The constant application of cloths, kept wet with cold water or with evaporating lotions, has been tried by VELPEAU and others. I have believed that these have increased the pain, and favoured the extension of the disease. More advantage appeared to accrue from warm, emollient, and anodyne applications and fomentations.

In two or three cases the local affection was almost immediately arrested by means of a strong turpentine embrocation applied to it, and of the internal medicines about to be recommended. M. VELPEAU advises mercurial frictions to the part; but these are not only painful, but of doubtful advantage. A similar remark applies to vesicatory, rubefacients, and compression, also tried by this physician.

18. When suppuration has occurred, or is about to take place, around the inflamed lymphatics or glands, even local depletion may be dispensed with; poultices and emollient applications are then most beneficial; and, as soon as matter forms, a free exit should be given to it, in order to prevent its absorption, and a perpetuation or increase of the mischief.

21. ii. Constitutional treatment, whereby the second indication of cure (§ 17) may be fulfilled, is of much importance. After having evacuated, by chologogue and stomachic purgatives, facial accumulations and disordered secretions, tonics with alteratives will generally arrest the progress of the disease, when judiciously prescribed, and with due regard to the state of the stomach. I have generally given the decoction of bark, with the compound tincture of bark and an alkaline carbonate, or with ammonia or camphor, or capsicum with this inunction, and with the roast benefit; but the remedies have been varied according to circumstances; still, the principle of practice has been adhered to. Indeed, the same means as are fully noticed in respect of the treatment of diffusive inflammation of the cellular tissue and of phlebitis are altogether appropriate to this disease.* (See art. Cellular Tissue, § 34, et seq., and Veins—Inflammation of.)

Classification. iv. Class. ii. Order (Author).

21. Orto and others believe that organic lesions are more frequent in the lymphatic system, more frequently in the youngethein the old. This opinion, however, applies only to certain lesions, as those connected with scrofula, rickets, and syphilis, and not to those consequent upon malignant or cancerous maladies.

22. i. The changes more immediately connected with inflammation have been described above (§ 13); but it is not improbable that several of those about to be noticed proceed more or less remotely from changes produced by acute or chronic inflammatory action.

23. ii. The lesions affecting chiefly the canal or calibre of the lymphatics are analogous to those found in other circulating vessels.

24. a. Varicose Dilatation.—This change of the lymphatics has been noticed by Schreeger, Tilesius, Mascagni, Soemmering, Attenhofer, Bichat, [Carsewell] and Meckel, in persons who have died of pulmonary diseases, hernia, and dropsical effusions. It seems probable that, as in varicose veins, this state of the lymphatics proceeds from pressure on the trunks or branches which are encysted lymphatics, or from obstructions to the course of the lymph through them. M. Amussat mentions a case in which the lymphatics of the pelvis and those coming from the groins were varicose, and filled with pus. This state of the lymphatics extended to the thoracic canal. The patient had encysted abscesses in both groins, and died from pneumonia, complicated with cerebral affection. (Arch. Gén. de Méd., t. xxi., p. 608.)

25. b. Dilatation of lymphatics has been supposed to give rise to rupture of them, and various consecutive changes, by Morton, Van Swieten, Haase, Assalini, Soemmering, Brambilla, and others. That rupture may occur on some rare occasions is probable, but it is certainly not so common, nor the cause of so many diseases, as these authors believe. It has not been demonstrated satisfactorily by any of them, lymphangitis with Mr. Ryan of Farningham, that will illustrate the treatment here recommended. A gentleman, about thirty years of age, was hit by a rat in the second joint of the right fore-finger. Inflammation of the absorbed, extending from the bite up the arm to the axilla, took place. I saw him a few days afterward (the 6th of October); the arm was then swollen and hard, but the course of some of the inflamed lymphatics could still be traced. What appeared the most singular was, that there was a hard, firm, and almost elastic swelling of the arm of the opposite side, much more marked and general over the whole arm than in the arm of the injured finger, with some swelling, stiffness, and pain of the lower limbs and joints. Tongue loaded, the pulse quick and full. The following were prescribed:—

On the 23rd, Mr. Ryan informed me that "he continued to improve after the 6th from the 7th until the 13th, when he got cold, which brought on a return of enlargement of the arms and stiffness in the legs." His tongue was loaded, and brown in the centre and towards the root. A full dose of calomel was composed, and the extract of capsicum was prescribed, and directed to be repeated, if necessary. The doses of sodium of potassium and of liquor potassae in the emulsion draughts were increased, and tincture of capsicum added to them. The stomachic aperient was to be continued. These means produced the desired effect.
although Guiffart says that he had seen it in one instance. I agree, however, with Dr. Buil-
tin, in admitting the possibility of rupture of the thoracic duct.

3. c. Contraction and obliteration of the lymphatics have been believed to occur by Halle
and Ollivier, and may take place, as in other
 circulating canals, as a remote consequence of inflammation, or of pressure, or of obstruction
of their canals, by organic or other changes.

27. The thoracic duct has already been shown to have been occasionally obliterated by thick-
ening or other morbid alteration of its coats.
 Its canal may likewise be obstructed by a variety of
 morbid productions either formed in its interior or conveyed there by absorption. It may also
arise by pressure made on it by tumours external to it. When this duct is obstructed or obliterated, the circulation of
the lymph is generally kept up by a variety of sup-
plementary passages, as by, 1st. The great lymph-
atic trunk of the right side; 2d. By collateral
branches arising from the duct below the ob-
literated part, and entering it above this part;
3d. By a second duct arising from the reccep-
taculum chylii, and ascending to near the sub-
elavian vein, where it unites with the other,
entering the vein either along with it or singly;
4th. By large lymphatic trunks opening directly
into different parts of the venous system, par-
ticularly into the vena azygos, the vena cava,
the common iliac, splenic, mesenteric, and other
veins, and into the vena portae; and, 5th. By lymphatics communicating with veins in the
interior of their glands.

28. iii. Vices of texture, of a spurious and mal-
gnant nature, may occur in the lymphatic sys-
ten. Besides induration, thickening, and conse-
quent obstruction or adhesion of these vessels,
 arising from inflammatory action, and already
alluded to, other changes may implicate the
parietes of the lymphatics.

29. a. Fungal productions have been de-
veloped in these vessels. Sir A. Cooper has re-
corded instances in which these were found in
the thoracic duct.

30. b. Carilaginous and osseous formations
are rarely found in the coats of the lymphatics,
although instances are recorded by Mascagni,
Cruchshank, Walter, Cheston, Portal, At-
treys, and &c., in which these changes were
observed.

31. c. Tubercular degeneration may take place
as a consecutive disease in the parietes of the
lymphatics, and has been described by MM.
Crueviller and Andral as occurring in these
vessels in the course of tuberculous consump-
tion. In these circumstances, the coats of the
lymphatics proceeding from tubercular ulcerati-
ons were opaque, of a whitish yellow, hardened;
and thickened, their canals containing tu-
bercular matter.
 In these instances, however,
the tubercular change was very equivoal; for,
although the contents of the vessels were of
this nature, yet the changes in the parietes of
the vessels were similar to those generally con-
sequent upon prolonged irritation or chronic in-
flammation.

32. d. Cancerous, carcinomatous, fungo-hama-
toid, and melanoid degenerations sometimes im-
licate the lymphatics consecutively, although
it is doubtful whether either of these varieties of malignant disease occurs in these vessels
primarily, or otherwise than as a consequence of its advanced progress in some part of the
body, especially cancer uteri. M. Andral has
detailed an interesting case of this description,
in which the patient had already the thoracic duct in the following manner: this duct was
considerably enlarged, of a dead white colour,
and filled with a whitish puriform fluid. Its
internal surface was studded with a great num-er of round, whitish bodies, about the size of
pease, which were contiguous with the tissue
of the parietes of the vessel, and perfectly anal-
ogous to the cancerous masses developed in the
abdomen and pelvis. In the intervals be-
tween these bodies, the parietes of the duct were
found to be thickened, and presented a dead
white colour, traversed here and there by red-
dish lines, and in other points were reduced to
a soft pulp of a dirty reddish white. The left
sub-Clavian vein in which the duct opened free-
ly, was distended by a number of dense clots
of blood, adhering intimately to the coats of
the vein, the inner surface of which was wrinkled,
and of a dark brown colour.

33. iv. Morbid Contents of the Lymphatics and
Lacteals.—The alterations presented by the
contents of these vessels are various, and arise
either from the vessels themselves, or from disease in a part in which they originate; the matters which they contain
either having been formed in them, or merely
introduced by absorption.—a. Blood has been very
rarely found in the absorbents in a pure state.
Professor Lippi (Journ. des Prog. des Scien.
Med., t. iii., p. 192), however, states that he has fre-
cently observed, in cases of pneumonia and
hepatitis, blood in the lymphatics proceeding
from these viscera; and he conceives that the presence of this fluid in the lymphatics to any
considerable extent is incompatible with the continuance of life. M. Sanson has recorded
the case of fatal erysipelas, in which the great-
er number of lymphatics seated in the pelvis
and in front of the spine, as well as the tho-
racie duct, were distended by blood, which, on
being analyzed by M. Barreul, was found per-
fectly pure (Archives Gen. de Med., t. xxi., p. 628).
Mascalini relates several cases of sanguineous
exudation from the pleura and peritoneum, where the lymphatics ramifying on these membranes
were distended with blood. This is consistent
with the remarks of Professor Lippi.

The lymph contained in the thoracic duct in the
healthy state frequently presents a rose tint,
and M. Magendie states that it presents this
tint in a marked manner after an animal has
been kept long fasting.

34. b. Pus has been found in the lymphatics
by Dupuytren, Vellep, Soemmering, Dumas,
and others. M. Andral has seen the thoracic
duct filled with pus in a woman who had sus-
puration of one of the veins; the coats of the
duct being red and friable. M. Vellep found
pus in the lymphatics of the lower extremities
in a case of phlegmasia dolens; and M. Dupuy-
tren observed it in a case of abscess in the
leg. Soemmering, Gendrin, and Andral have
found pus in the lymphatics, arising from ul-
cers of the intestines; and Mascagni in the
lymphatics of the lungs in phthisical subjects.
Dr. Lauf states that the lymphatics up to the
thoracic duct were filled with a sanguineous
matter, in a case of gangrene of the lower extremi-
LYMPHATIC GLANDS—INFIRMATION OF.

35. c. Tubercular matter of a curdy appearance has been not infrequently found in the lymphatic vessels proceeding from the necrated intestines of phthisical patients. M. ANDRAL, M. CRUVELIER, GENDRON, ORTO, and others have adduced numerous cases of this description. In these cases the lymphatics appeared like so many knotted white cords passing from the intestines towards the mesentery. This matter also has been found in the inguinal, pelvic, and superficial pulmonary lymphatics, and in the thoracic duct. M. ANDRAL refers to a case wherein it existed in all those vessels.

36. d. Bile has been stated to have been detected in the lymphatics of the liver by MASCAGNI and SAUNDERS. M. ANDRAL has not observed this; but he has seen a remarkably yellow tinge in the lymph contained in the thoracic duct of icteric patients. Milk has also been found in the lymphatics by SOEMMERING and ASSALINI, in females who have died in the puerperal states.

37. c. Culverian matter has been found in the lymphatics by PONCY, ASSALINI, CHESTON, SCHERL, ATENHENPFR, SOEMMERING, and LAUTH. The last-named physician states that, in a case of caries of the iliac bones, he found the lymphatics of the pelvis filled with osseous matter.

38. f. The molecules of cancerous, medullary, and melanoid productions have been found in the lymphatics proceeding from the seat of these malignant diseases by most of the authors mentioned above, as well as by others.

39. III. LYMPHATIC GLANDS—DISEASES OF.
—Lymphatic ganglia are composed of 1st. Lymphatic vessels variously convoluted; 2d. Fine cellular tissue uniting these convolutions; 3d. Of a fibro-cellular membrane or capsule enclosing the forgoing; and, 4th. Of blood-vessels supplying the gland, both entering it along with the lymphatics and ramifying in its capsule. The nerves cannot be distinctly traced, and consist chiefly of such as accompany the distribution of the arteries.

The glands vary in size from two to ten lines; they have an average diameter of one third of an inch, of a light pink colour, and situated in such places as abound in cellular tissue, particularly at the bends of the joints. They occur in great numbers at the groins, as well as at the armpit, the side of the neck, the posterior mediastinal cavity, and in the cellular tissue of the pelvis and mesentery. In several of these places they are connected in chains or clusters—a great number are fat, have a peculiar arrangement, and are, I imagine, formed by joining connective tissue, and are not glandular in structure. They are situated at different depths in the skin, and are variously connected with each other. The lymphatic glands are more susceptible of disease than the lymphatic vessels, and hence are more frequently the seat of it. This is owing to their organization and functions, norbad matters which fail of making an impression upon the trunks or ramifications of these vessels not infrequently inducing inflammatory or other changes in their glands. When they are susceptible of disease, I shall first notice inflammation of the lymphatic glands, and afterward the chief organic lesions to which they are liable.

I. INFLAMMATION OF LYMPHATIC GLANDS—SYN. LYMPHADENITIS, HELDENBRAND. ACUTE Lymphatic; ADENITIS LYMPHATICA; OLLIVIER.

CLASSIF.—III. CLASS, I. ORDER (Author in Preface).

41. DEFENSE.—Swelling, hardness, pain, and tenderness in the nodes of the lymphatic gland, frequently attended by chills and followed by heat, by increased pain on motion, by febrile reaction, often by redness of the surface, when superficial glands are affected, and suppuration.

42. The lymphatic glands are often the seat of inflammation, and, although those which are more superficial, or have more or less intimate anatomical relations to superficial parts or to the extremities, are most frequently affected, those which are more deeply seated, or which are altogether internal, are also occasionally infected; but, however, the lymphatics, admitting of recognition in the latter situations during the life of the patient.

43. A. SYMPTOMS.—When a lymphatic gland becomes acutely inflamed—Lymphadenitis acuta—it is swollen, hard, painful, and tender to the touch. Chills, or even rigours, may be felt at the onset, and there is generally symptomatic fever, varying in type or character with the constitutional powers and the cause of the affection. The surface of the seat of the disease is usually warmer than natural; sometimes it is reddened and a tumour is observable, particularly as the inflammation advances and when the gland is not deeply seated. The pain usually increases or becomes sharp, and the inflammatory action extends to the surrounding cellular tissue, rendering the swelling less circumscribed, as well as greatly increasing it. As the skin is more distended, it is more reddened, or even livid. In the course of a few days the tumefied part becomes softer in one or more points, and more or less distinct, superficial or deep-seated, but circumscribed fluctuation may at last be detected, the pain having even become more pulsating. A spontaneous opening at this part, as described in the article Abscess, or puncture of it, gives issue to purulent matter, varying, in quantity and character, with the size and maturity of the abscess, and with the constitutional affectation. After the discharge of matter, the infiltration of the surrounding cellular tissue is removed, the sanguineous exudation is suppressed and inflammatory action in the gland subsides, and the aperture closes.

44. The terminations of acute lymphadenitis are resolution, suppuration, and chronic induration or enlargement.—a. Resolution is not infrequent, and may be expected when the disease remains for a few days stationary, or does not extend to the surrounding cellular tissue, the tumour remaining circumscribed and moveable. When the adjacent cellular tissue is affected, resolution very rarely occurs, and, when the skin covering the part is red and the subjacent cellular tissue much engorged, it is not to be expected.—b. Suppuration follows the circumstances just mentioned, especially when the surrounding cellular tissue is much infiltrated from extension of inflammation to it. If suppuration be limited to the gland, the tumour is circumscribed, moveable, and feels elastic or fungous; and when the integument covering the gland is divided, the tumour formed by it partially protrudes from the opening, and consists of the inflamed, friable, reddened gland infiltrated with purulent matter, which, with the increased injection of its vessels and inflamma-
tion of serum, occasions its enlargement. In many instances, the surrounding cellular tissue is chiefly inflamed, and the suppuration is limited to it—one or more points, particularly externally or around the affected gland, without, however, assuming a very regular or circumscripted form. The gland itself is then not so swollen as in the former case, and presents, upon being cut into, a more regular red, or grayish-red tint, and is firmer and not so friable or soft. In other instances suppuration takes place both in the gland and in the surrounding cellular tissue, at one or more points.

—c. Induration and enlargement are chiefly observed when the acute has passed into the chronic state of the disease. The lymphatic glands, during inflammation and its several consequences, present the same changes and the same post-mortem lesions as have been fully described in the articles Inflammation and ABOUSS.

45. B. CHRONIC INFLAMMATION OF LYMPHATIC GLANDS—LYMPHADENITIS CHRONICA—is as common a disease as the acute. It often follows this latter, and frequently supervenes in the course of chronic diseases, or of irradiation of parts from which lymphatic vessels passing through glands arise, as ulcers, chronic cutaneous eruptions, &c. It is, however, most common in serofibrinous constitutions, wherein it may occur either as a primary affection, or as a symptomatic or consecutive malady of other antecedent changes or lesions. (See art. SCROFULA.)

46. When the chronic follows the acute disease, the acute symptoms subside gradually, either before suppuration has commenced, or after it has taken place to a small extent, or in a limited portion only; and slight pain and heat, with swelling and hardness of the gland, continue until ultimately the latter only remains. When chronic lymphadenitis occurs primarily, the gland swells gradually, becomes hardened, and slightly painful, particularly on pressure and exertion. The skin retains its colour, and the surrounding cellular tissue is either unaffected or slightly affected, the enlarged gland being moveable. Symptomatic fever is rarely present, or, if present, in a very slight degree.

No change may occur, locally, for an indefinite period, unless some local or constitutional influence, or the lymphatics, of the gland.
LYMPHATIC GLANDS—Structural Changes of.

51. E. Treatment.—a. The treatment of acute lymphadenitis should depend very much upon the state of the constitutional powers. When the disease assumes a purely aethenic character, local bloodletting freely prescribed, promoted by the usual means, is always necessary; but, in order to procure the resolution of the disease, it should be resorted to early, and before the integuments have become red, or other indications of suppuration have appeared. M. Velpeau has advised the application of blisters to the surface of the part, in order to procure resolution; and subsequently poultices or mercurial ointment. In strong or plethoric persons these must be followed by equally strong local depilation. If the disease appears in a cachectic state of the system, or with signs of asthenia, local depilations are rarely of service. In these cases particularly, as I have frequently seen them consecutively upon scarlet and other fevers, alternatives in conjunction with tonics have proved most beneficial, tending to limit both the extension of the disease and the consequent amount of suppuration, which, in these circumstances, can rarely be prevented; but even in those the amount of disease and its duration will be greatly lessened by the exhibition of the liquor potassae, or Brandish’s alkaline solution, with or without the iodide of potash, in the decoction of cinechona and tonic tinctures, or the preparations of sarsa. At the same time, the secretions and excretions should be promoted by means of alterative and chologogue aperients, and stomachic purgatives.

b. If suppuration appear inevitable, poultices should be applied, and as soon as any fluctuation can be detected, an opening should be made, and the discharge of matter promoted by a continuance of the poultices; the constitutional means being prescribed with strict reference to the state of general and local action, and to the functions of the abdominal viscera. In these cases, as well as in many others, the principles of treatment fully developed and illustrated in the articles Abscess and Inflammation should be adopted.

c. The treatment of chronic lymphadenitis consists chiefly of the application of hot fomentations in some cases, and the occasional repetition of them, of the exhibition of alteratives and tonics, as liquor potassae, iodide of potassee, the iodide of iron, sarsa, cinchona, &c.; of friction with resolvent or deobstructant ointments and liniments, and of salt-water bathing, &c. In all cases of the chronic disease, particularly in scrofulous persons, and of the acute, after the active symptoms have been subdued, a change of air, alternative mineral waters, a cautious use of the iodides in small doses, and the combination of certain of them with the liquor potasse, sea-bathing, and sea-voyaging, change of climate, the tepid shower bath or douche, a moderate or limited use of animal food, with a sufficient amount of vegetables and farinaceous diet, and a very liberal use of new milk, whey, or fresh buttermilk, as a common beverage, will generally secure recovery and prevent future attacks.

d. The specific states of lymphadenitis require few remarks. When the disease assumes an asthenic or malignant nature in connection with similar constitutional maladies, the powers of the system should be promoted, and energetic general and local means should be employed in order to resist the progress of the local mischief. Powerful tonics, antiseptics, and alteratives should be employed, according to the symptomatic relations of the disease; but it is unnecessary to particularize these remedies at this place, as they are fully noticed in the articles Abscess (§ 62), Inflammation (§ 238, et seq.), Pustelence, Scrofula, and Syphilitic Cachexia.

ii. Structural Changes of Lymphatic Glands.

55. These changes are chiefly seated, 1st, in the cellular tissue uniting the convolutions of the lymphatics themselves; and occur most frequently in infancy and childhood, when these glands are most developed, and their functions most active. Dr. Boeker considers that, in diseases of these glands, the cellular tissue uniting the convolutions of the lymphatics are most frequently affected, and that there is seldom obstruction of their canals, as he has found injections to pass freely through them.

56. A. Simple enlargement of these glands is often observed. It generally arises from causes not originally seated in the glands, but from irritation at the origin of the lymphatics passing through them, or from the irritating nature of the fluids which they contain. Thus we perceive painful swellings of the glands of the groin or armpit follow punctures or lacerations of an extremity, or the inunction of mercury; and a similar effect is produced on the glands under the jaw, on those adjoining the trachea, and on the mesenteric glands, from inflammation of the mouth, inflammation of the bronchial lining, and from irritation of the digestive mucous surface respectively. When the irritating cause is not of a specific or poisonous nature, the effect upon the glands is merely that of irritative enlargement, or of healthy acute inflammation, or the latter following the former change. But when a specific cause of a noxious or poisonous nature has affected the absorbents or been conveyed into the lymphatic circulation, a specific and more noxious effect is the result. On each of these will offer itself.

57. B. Inflammation is frequently met with in these glands, in the acute, the chronic, or intermediate states. (See § 42, et seq.) When thus affected, they are more or less red, tumefied, and readily broken down. In the more chronic state of inflammation they are considerably enlarged, hardened, and either become colourless or acquire a darker tint. Inflammation, in its more active forms, is often followed by the formation of purulent matter, which either infiltrates the tissue of the gland, giving it a dirty grey colour, or is disseminated in small distinct drops, or is collected into an abscess. When this last occurrence takes place, it often occupies the whole of this gland, destroying its parenchymatous structure, its envelope alone remaining and forming the cyst to the abscess (§ 45).

58. C. Scrofulous enlargement and inflammation are generally of a chronic kind; the gland swells and softens, and occasionally becomes redder; and, although the suppuration does not rapidly supervene, yet this termination is fre-
quent, is peculiar in its nature, and takes place, in many cases, without any signs of inflammation of the gland itself, although the surrounding cellular tissue and the skin become subsequently inflamed and softened, followed by perforations, through which the scrofulous secretion from the gland is evacuated. This form of disease is generally unattended by pain or tenderness, and the cellular tissue and skin are affected. As the gland softens, a particular part or parts, generally about its centre, are converted into a sero-albuminous fluid; and this change invades more or less of the gland, extending to the surrounding texture, occasioning perforation, and the discharge of a serous fluid containing curd-like matter. On examination, the gland presents the appearances described in the following paragraph (§ 59); and sometimes merely a more friable state of its structure, with cells or cavities containing a partly serous and partly puriform fluid, and a white, albuminous, or curdled matter (see article Scrofula). In some rare cases, serous glands, when inflamed, become rapidly disorganized; sloughing of the cellular texture surrounding them and of the skin takes place; the gland assumes an unhealthy ash colour, and is at last expelled either in shreds and pieces, or in a spheracelated mass. This change has been noticed by Cruickshank and Clarke to occur in serous glands, generally about the bend of the arm, and is evidently dependant on a debilitated and cachectic state of body.

59. *Tubercular matter* is found very frequently in the lymphatic glands, and generally either infiltrated and disseminated through their tissue, or collected into one or more masses of various sizes. In respect of the production of this matter the question is, whether it is, or is not, the result of inflammation. The development of tubercle subsequently to inflammation is, as remarked by M. Andral, undoubtedly exhibited in lymphatic glands; but though in many cases the tuberculated gland presents unequivocal marks of antecedent congestion or inflammation, it is not the less true that in several instances there exists no evidence whatever of the formation of the tubercular matter having been preceded or accompanied by any vascular injection.

60. Tubercular matter, as found in the lymphatic glands, has generally been viewed as the product of secretion, not necessarily of inflammatory secretion, but rather itself occasioning the inflammatory appearances frequently associated with it. M. Andral observes respecting this point, perhaps it may yet be considered as simply the result of an alteration of the lymph itself, either spontaneous, or caused by a morbid condition of the lymphatic vessels, or perhaps resulting simply from its stagnation, caused by some mechanical obstacle to its circulation through the lymphatic plexus. I am disposed to adopt a part of this explanation, and to infer that the tubercular matter proceeds simply from diminished vital energy of the glands affected, occasioning stagnation of the circulation through the convolutions of the lymphatic vessels; and, consequently, a morbid state of the lymph and all the other phenomena attendant on tubercular formations, as inflammation, scrofulous suppuration, &c., alternately supervene. [In children, tubercular matter is most frequently deposited in the bronchial glands. Dr. Lombard found them thus affected in 87 out of 100 children labouring under lymphatic enlargement. In adults the mesenteric glands are most liable to this deposit.] In 100 phthisical subjects, Louis found their bodies tuberculized in 23, or nearly in the proportion of one to four. When suffering under this disease, the glands exhibit different appearances, according to the progress it may have made. Generally speaking, they are enlarged in size, of a dense grizzly texture, white externally, and of a light rosy tint internally, either uniformly, in streaks, or in patches. The tubercular matter itself is of a singularly yellowish colour, especially if it has existed for some length of time, and often contains particles of curdy pus. (Gross.)

61. E. Pestilential Disease of Lymphatic Glands (§ 47). From the first twelve hours to the seventh or eighth day of plague, the glands in the armpits and groins become enlarged, and give rise to an open sore, accompanied with sloughing, and the discharge of a foul, dirty-coloured fluid. The texture of the gland seems softened, of a dark gray, grayish-brown, or brownish-red colour, becoming rapidly disorganized and wholly destroyed, especially in the fatal cases. This state of the glands is often associated with carbuncles, to the irritation occasioned by which it has been imputed. But this is evidently not the case, as the lesion of the glands often commences as early as the formation of carbuncles, or even precedes it. Both lesions evidently depend upon the same cause, namely, to a certain change of the vital condition of the parts affected, deranging the capillary circulation in the one, and the lymphatic circulation through the glands in the other, and changing the states of the fluids circulating through each system of vessels respectively, and inducing the ulterior changes characterizing both.

62. F. Disease of the glands from the absorption of noxious matters is not infrequent. The effect produced by these matters on the glands varies very considerably, owing, 1st. To the nature of the injurious cause; and, 2d. To the constitution and state of the vital energies of the patient at the time. Phlegreutene bula is one of the most common effects proceeding from this source. It is occasioned by the syphilitic poison, or by repeated or too long continued courses of mercurial injection, especially when acting on an unhealthy state of the body. Hence these noxious matters excite inflammatory action of an asthenic or diffusive kind in the gland, extending to the capsule and surrounding cellular structure; and these parts become painful, hard, somewhat hot, and of a brownish red. The skin passes from this tint to a dirty grayish brown, loses its vitality, and, with the cellular tissue underneath, alternately ulcerates and sloughs. The glands, however, still remain undestroyed, generally enlarged, and of a brownish-red or purple colour, and evincing a very low grade of vitality, until the destruction of the surrounding tissues isolates them more or less completely, when they are thrown off in the state of slough.

63. G. Enlargement and destruction of the glands sometimes follow the inoculation and absorption of putrid or poisonous animal secre-
tions or fluids, as in wounds from dissection, and the bites of poisonous reptiles. [Also in epidemic erysipelas, plague, and low malignant fevers from the same cause.] In cases of this kind, the noxious matters contaminate the lymph circulating through the gland, the vitality and circulation of which become greatly injured, and rapid disorganization is thereby occasioned, extending to the adjoining structures, and in the course of the lymphatics departing from thence. In cases of this description the gland rapidly softens and enlarges, loses its healthy colour, and assumes a dark and foul appearance, and ultimately spherulates either in part or altogether. * 

64. Induration of the lymphatic glands is frequently met with in consequence either of repeated attacks of chronic inflammation alternating with partial resolution, or of the continued irritation in a part whence the lymphatics passing through the gland originate. This disease is not infrequent in strumous habits, and is characterized by a very slight or entire absence of pain in the gland. When examined with the scalpel the gland is enlarged, hardened, so as often to grate when divided, and presenting a whitish tissue, with a very few red vessels, the remains of its natural vascularity.

65. *Scirrrous induration may proceed from the same causes as simple induration, particularly in persons advanced in life; or from scirrrous disease in the part in which the absorptions of the gland originate. When divided, the gland is observed to be very slightly vascular—less so than natural; very much hardened, of a bluish gray, or grayish white colour, somewhat elastic, and consisting of gelatinous and gelatinous matter traversed in every direction by dense cellular or fibro-cellular tissue, of a lighter colour than the matter traversed by it. This lesion is often accompanied with a dull pain, which is sometimes exasperated, in the substance of the gland. (See art. CANCER.)

66. *K. Cancer is met with in the lymphatic glands, but it very rarely occurs primarily; it is commonly consecutive of this malady in adjoining or related structures. It assumes in the gland the form of a simple cancer in other parts. It is characterized by excava-
tions of pain in the enlarged and hardened gland, by the absence of tenderness, the very chronic state of the disease, an unhealthy or cachectic habit of body, and mature or advanced age. The gland, when divided, is vascular, indurated, of a reddish brown hue, and its tissue is converted into a dense fibro-cellular substance, with cells containing a granular amorphous matter traversed in every direction generally or partially from this state to that of softening and ulceration, with an acrid, foul secretion, irregular fungous excrecences springing from the disorganized surfaces, carcinomata of the gland has taken place. (See CANCER.)

67. *L. *Fungus hematodes of the lymphatic glands is rare. Mr. Wardrop observed this change in the mesenteric glands. I met with one case of it in the absorbent glands in the groin, in a boy of about thirteen years of age, who had a number of haematomal tumours in different parts of his body. The structure of these glands was similar to that described under the article Fungo-Haematom Disease.

68. *M. Melanotic deposits sometimes take place in the lymphatic glands. But this lesion should be distinguished from the dark discoloration which is occasionally met with, without any organic change. (See MELANOMA.)

69. N. *Calcareous and osaceous deposits in the lymphatic glands have been described by Crockshank, Ballie, Goodlad, Dupuy, Raynor, and Andral, and are stated to occur most frequently in the bronchial and trachial glands in persons advanced in life. I have, however, met with this change previous to puberty, both in the bronchial and mesenteric glands; and M. Andral mentions a similar case. This pathologist refers to cases which occurred to him and to M. Reynaud, in which the presence of bony and calcareous deposits in the glands was coincident with destruction of some of the bones, leading to the inference that the calcareous phosphate which had been absorbed from the seat of disease in the bones had been deposited in the lymphatic glands. In cases of this description the calcareous deposits are frequently not limited to the glands, but are found also in the lungs.*

iii. Lesions occasioned by Diseased Lymphatic Glands.

70. These glands, when enlarged or otherwise diseased, may derange the functions or structure of adjoining parts, either communicating irritation or occasioning mechanical pressure, or interrupting the circulation of the lymphatics, and causing swelling of the parts whence they arise. The bronchial glands have been found enlarged, so as to impede the passage of air into the lungs, and even to give rise to atrophy of the portion of lungs the functions of which had been obstructed. They may also occasion inflammatory irritation of the part, of the bronches pressed upon, leading to perforation; and, if the enlarged gland contain pus or tubercular matter, these may be evacuated into the bronchial tube and thus obstructed; and even recovery may take place, more rarely, however, if the gland contain tubercular matter, inasmuch as the glands seldom contain this matter unless it exists also in the substance of the lungs.

71. Enlarged lymphatic glands in the vicinity of the pylorus may compress the passage so as to occasion a great proportion of the symptoms attendant on scirrhus of this part; or they may compress the hepatic duct and occasion jaundice, and they may similarly affect the cystic and common ducts. A case occurred to me in 1821, in which the common and pancreatic ducts were so compressed by a cluster of enlarged lymphatic glands as entirely to obliterate their canals; the patient died jaundiced, and the gall-bladder and hepatic ducts were enormously distended by dark-colored *

* [We have met with several instances of deposition of calcareous matter in the mesenteric glands in scrofulous subjects, although they are more frequently met with in the conglobate glands at the roots of the lungs. In a case of a lady who died of epidemic erysipelas, we found most extensive deposits of chalky matter in the glands of the mesentery; no other portion of the lymphatic system exhibited any marks of disease. When young, she had been subject to scrofulous enlargement of the glands of the neck.]
MAMMA—DISEASES OF THE.

MALARIO.—See Endemic Influences.

MAMMA, DISEASES OF THE.—As these diseases come chiefly under the cognizance of the surgeon, a brief notice of them only will be required in this work. Diseases of the breast are either malignant or non-malignant: this distinction is not, however, as in general, one, for tumours which have long existed in an indolent state, occasioning no serious symptoms, may become malignant under the influence of constitutional disease, of the changes accompanying the cessation of the menses, and of depressing passions of the mind. Sir A. Cooper, admitting this limitation, distributes diseases of the breast into three classes: "1st. Those which are the result of common inflammation, acute or chronic; 2d. Those which, though they affect a peculiar or specific action out which are not malignant, and do not contami- nate other structures; 3d. Those which are not only founded on local, malignant, and spec- ific actions, but are connected with a peculiar and unhealthy state of the constitution."

2. M. Velemp divides diseases of the mamma into, 1st. Inflammations and their conse- quences; and, 3d. Tumours of various kinds. Both these divisions are defective; for there are affecting the mamma their peculiar inflammation nor of tumour, but which are functional and nervous. These have hard- ly received sufficient attention from systematic writers; indeed, with a few exceptions, they have not even been noticed, and, when noti- ced, but imperfectly. The circumstance of their being very commonly sympathetic, either
of disorder of the uterine functions, or of pregnancy, should not excuse this neglect, since they do not always depend upon this cause, and even when they are so associated, they are often the most prominent and distressing part of the disorder. I shall, therefore, divide the affections of the mamma into, 1st. Functional and painful disorders; 2d. Inflammations and their immediate consequences; 3d. Tumours and morbid growths not primarily or generally malignant and contaminating; and, 4th. Tumours or formations of a malignant and contaminating nature.

1. Functional and Painful Affections.

—The functions of the mamma may be either imperfectly or not at all performed at the period when they are destined by nature to be discharged, or, after they have commenced at this period, they may suddenly and entirely cease. These functions may likewise be performed in an excessive manner, either absolutely or relatively to the constitutional powers of the nurse. With the exception of deficiency and suppression of the milk, and of painful affection of the mamma, these other functional disorders of this organ are treated of in the article Lactation.

i. Deficiency or Suppression of the Milk.—

SyN. Agalactia, ayagálaktia (from α, priv., and γαλάκτως, milk). Agalactie, Fr. Der Mangel und Milch, Germ.

ClassiFi.—I. Class, II. Order (Author).

4. Defin.—The non-appearance or the suppression of the function of the mamma at the period intended for the performance of it.

5. After parturition the function of the mamma is generally disarranged with more or less activity; but it may not be manifested, or, having been performed for a time, it may prematurely or quickly cease. This non-performance of the office of the organ may be either primary, or consecutive and symptomatic, more frequently the latter.

6. A. Primary agalactia is generally caused by powerful mental emotions; by constitutional delity; by want, misery, and starvation; and, in particular, by cold applied to the body generally, or to the mamma more especially, in connexion with inanition. When it proceeds from mental emotions, the disorder is often only of temporary duration; but when it arises from other causes, it is generally permanent.

7. B. Symptomatic agalactia is often consequent upon fever and inflammations occurring after delivery, or at any period of lactation, more particularly upon aeritiids, hysteritis, and excessive discharges, &c. When these diseases agalacta soon after parturition, the mamma do not become full and enlarged, as usually observed at this period, but are lacel, and secrete little or no milk; the elements of which, thereby accumulating in the circulation, favour the production of effusion in the seat of inflammation. If the disease, of which agalactia is the consequence, is severe, or continue for any considerable time, the function of the mamma is rarely resumed; but if it be slight, or of short duration, the milk returns to the breast with the subsidence of the malady.

8. The diagnosis of agalactia should not be overlooked, and the affection, whether primary or symptomatic, should not be confounded with the retention of the milk caused by inflammation of the mamma, and by obstruction of the lactiferous ducts. In these cases, the mamma is hard, painful, and swollen; and the excretion rather than the secretion of milk is impeded or interrupted.

9. The circumstance of partial or complete agalactia being sometimes concealed by nurses, particularly by those who are hired to suckle, should be kept in recollection; and, where the infant presents any indication of insufficient nutrition, or is peevish, irritable, and dissatisfied when applied to the breast, the state of the mamma should be ascertained.

10. The various affections of agalactia, and the treatment of the affection in its several forms, are fully stated in the article Lactation (see § 18, et seq.).

ClassiFi.—II. Class, I. Order (Author).

11. Defin.—Pain, more or less severe, in one or both mammae, most frequently in one only; generally recurring with intermittent heat, or general fever.

12. Painful affection of the mamma is most frequent during the early months of pregnancy, and in connexion with functional disorder or organic disease of the uterus and ovaria. In its slighter forms, it sometimes accompanies the irregular appearances of the catamenia soon after puberty, and suppression of the discharge, either then or at later epochs. Complete or violent neuralgia of the mamma is rare, but less severe pains are not infrequent in nervous and hysterical females, and in those who are the victims of tight lacing, especially when the uterus or ovaria are the seat of irritation, or in the circumstances just alluded to.

13. a. When the affection is purely nervous, it is characterized by the nervous temperament, and hysterical tendency; by the recurring, and even periodic form; and by the absence of local or general plethora, and of hardness or fullness of the organ. In these cases, the left mamma is more frequently affected than the right. When it depends upon congestion of, and vascular determination to, the mamma, the pain is more continued, although attended by exacerbations; and it is more liable to occur in this form in sanguine and irritable temperaments, in females of a full habit, and in the course of pregnancy and suppression of the catamenia, than in other circumstances. M. Capuron remarks that this affection may be so severe in irritable females as to cause agitation, sleeplessness, and delirium. In those of a full habit, the mamma sometimes become full and somewhat hard, and the pain is more obviously connected with distention of the fibrous envelope of the gland, both mammae being more frequently affected than one only. Females who have experienced pain in the mammae before marriage generally have a return of it afterward when they become pregnant; and it may continue for a considerable time, or recur at intervals. If it be attended by congestion or vascular determination, these are liable to increase as the period of parturition approaches; and in plethoric females it may terminate in inflammation and abscess after delivery.

14. b. Diagnosis.—In all cases of pain in the mamma, the state of the organ should be carefully ascertained, as respects the existence of
inflammation or of tumour. The former will
be indicated by local heat, fulness, tenderness, and
fever; and when these are absent, and no
tumour exists, the state and functions of the uter
require attention. This affection of the
mamma rarely occurs unconnected with some
change in the state of the uterus and its appen
dages, or with pregnancy; and this latter should
be suspected when the pain is associated with
suppression of the catamenia. The pain may,
however, occur before this discharge has made
its appearance, and it may be the first indication
of the accession of this change of female life.

15. c. Treatment.—The indications of cure
should be entirely based upon the associations
of the complaint, particularly with the states
of the uterus. If this organ is the seat of ob-
vious disorder or actual disease, the treatment
should be directed chiefly to the removal of
such disorder. The pain in the mamma is here
merely a symptom of the uterine disease. If
it be consequent upon pregnancy, it is equally
a symptom, and one which requires palliatives
only; but these should not be neglected, as a
per sist en ce of the affection may excite fever,
or produce other disorders of a serious nature. In
this case, anodyne fomentations, cooling aper-
ients, narcotics given so as to procure repose,
gentle friction of the mamma with soothing or
powerfully anodyne liniments, and belladonna
and camphor plasters, are the most appropriate
means. If the patient be plectoric, and the
mamma full and tense, a small or moderate
blood-letting, and diaphoretics, as Dover’s pow-
der, the liquor ammoniæ acetatis with spirits
etheris nitrici, antimonials, &c., are the safest
remedies.

16. If the affection present a nervous charac-
ter, the circumstances tending to increase the
nervous disposition should be avoided. These,
however, the physician often can only suspect;
and certain of them he can hardly mention, al-
though there is no doubt of their having induced
and prolonged the disorder. Local excitement,
mental emotion, a heated imagination, tight
laeving, &c., are all often more or less concern-
ed in the production of the complaint. It ap-
pears in the period of puberty or at later epochs;
and, when this is the case, the treatment fre-
quently fails, if it be not assisted by an aban-
donment of the cause. In this state of the dis-
order, however, the local means above men-
tioned (§ 15) should be aided by such as will
regulate or promote the catamenia, or subdue
uterine irritation, and by those which will re-
store the impaired tone of the nervous systems
and of the organic functions; especially by
cautions of quinine, the sulphate of iron, and anodynes. The preparations of iodine, the iodicale of potassium with liquor potassa,
the iodide of iron, and the various chalybatic
preparations and mineral waters, may be pre-
scribed, particularly when the uterine functions
are disordered, or when the blood is deficient in
quantity or in haematozine.

II. Inflammations of the Mamma.—Syn.
Mastitis (from mers, mamma); Mastitis ; In-
flammation des Mammelles, Mastite, Fr.; Ent-
zündung der Brüste, Germ.

CLASS. III. CLASS. I. ORDER (Author).
DEFIN. Pain, tenderness, and tension of the
mamma, with febrile commotion.

17. 1. Inflammation of the Nipple.—Vari-
ous inflammatory affections are confined or ex-
tend to the nipple, and occasion, when neg-
lected, unpleasant or painful effects. The chief
of these are simple excoriations, eczematous
and other eruptions, cracks, fissures, and ulcer;
Sore or inflammatory states of the nipple are
very frequent, and are often a source of great
distress. They are most common with first
children, but some women suffer from them
after all their confinements. Inflammatory
appearances are seen two or three days after
the application of the infant to the breast, and
continue with farther changes for an uncertain
time.—a. At first the nipple and areola are dry,
rough, red, and harsh, and then excoriated, hu-
mid, and turbulent, often wounded, congealed,
chapped, or fissured, especially at the base of
the nipple, and acutely painful. When the
excoriation is considerable, a serious discharge
is poured out, and extends the excoriation to
the surrounding skin. In more severe cases
the nipple exhibits two or three deep fissures,
and these may become so extensively ulcerated
as to be partly or even altogether destroyed.
In most of these, sucking not only aggravates
the inward affection, but occasioning the sores
or cracks, and occasions extreme torture. When
the sores prevent the sufficient application of
the child to the breast, the consequent accumu-
lalion of milk occasions distention and inflam-
mation of the mamma.

18. b. The causes of sore nipples are chiefly
the too frequent application of the infant to the
breast, thereby occasioning the removal of the
protecting sebaceous secretion of the part, and
favouring inflammatory irritation, vascular in-
jection, and subsequent inflammatory con-
sequences. The constitution, habits, and modes of living of the pa-
tient, particularly the use of irritating and ex-
citing articles of diet, and of heating beverages,
also favour the occurrence of this affection.
The state of the child’s mouth, tongue, and
gums, more especially aphthæ of these, fre-
quently affects the nipple; while, on the other
hand, the discharge from the sores of the nip-
ple often inflames the mouth of the infant.

19. Treatment.—In order to remove this
affection, Dr. Churchill advises the nipples to
be washed with soap and water, and dried, and
afterward bathed with spirit and water, night
and morning, during the last month of pregnan-
cy. Sir A. Cooper suggests washing the nip-
ples some time before lying-in with strong brine,
in order to harden the cuticle, and render it less
proone to crack. Dr. Burns states, that a com-
aggregation of white wax and butter is often use-
ful; and that stimulating ointments, such as
the spirit of turpentine, &c., when coming from
the parts, are sometimes of service; or that the parts may
be touched with burned alum or nitrate of sil-
ver, or dusted with some mild, dry powder.
Some physicians prescribe solutions of alum;
some, solutions of sulphate of zinc; and oth-
ers, the supernatant liquor of a mixture of lime-
water and the chloride of mercury. One of the
best applications is a solution of a draught of
borax in four ounces of water and half an ounce
of spirit of wine, or in equal quantities of wa-
ter and dilute acetic acid. Pure and fresh palm
oil is one of the most efficacious applications
to the nipple, and the safest to the infant; it
need not be washed off previously to applying
the child to the bosom, unless it be made the ve-
thick for other substances. Several writers advise, particularly when chaps, cracks, or fissures exist, a weak solution of the nitrate of silver to be applied after each period of sucking, the nipple being washed before the infant is again held to the breast. Various mechanical means have been employed where fissures, ulcerations, &c., exist. Shields, with prepared cow’s teats, are the best of these. Feeding the infant two or three times a day, or a temporary resourse to a nurse, will facilitate the cure; but the milk should not be allowed to accumulate, lest inflammation of the breast itself supervene.*

20. ii. Acute Inflammation of the Breast.

—A. The symptoms of this disease are nearly those which characterize acute inflammation of other glandular parts, somewhat modified in their progress and results by the peculiar functions and relations of the organ. Sir A. Cooper describes an adherence, a supplicative, and an ulcerative stage, the existence of each of which is readily recognised during the progress of the disease. The severity of the symptoms depends upon the principal seat and extent of the inflammation. When the cellular tissue and skin are alone involved, local pain, soreness, with circumscribed hardness and tension, are felt, with slight inflammatory fever. But when the gland itself, its connecting cellular tissue, and the fascia are implicated, the pain is then very severe, and extends to the axilla; the swelling is then more general, and more considerable, the tension greater, and the fever more intense; the skin being hot, the pulse quick and full, with thirst, headache, sleeplessness, &c. If the gland be generally inflamed, the breast has an irregular or nodulated feel, as if consisting of several tumours. The secretion of milk is suspended, at least for a time; but it generally takes place after the acute stage has subsided. In this, the adhesive stage, lymph is thrown off readily into the surrounding cellular tissues, and a hard and exquisitely sensitive swelling is produced.

21. After a while an inflammatory blush appears on the surface, the pain becomes throbbing and very intense, rigours or chills, succeeded by heat and perspiration, indicate the formation of pus; a particular portion of the tumour, commonly where the surface was first red, becomes smooth and prominent, and fluctuation is sensible to the touch. Detachments of the cutis follows, with ulceration of the cutaneous textures, and discharge of matter. The whole process usually occupies from ten days to three weeks; but its duration depends upon the intensity of the inflammation, the constitution of the patient, and the depth of the abscess.

22. The pointing of abscess of the mamma is generally near the nipple; and when the abscess is superficial, or implicates chiefly the cellular tissue, the matter discharged consists of digested pus, usually contained in only a few cubic centimetres. When the abscess is extensive, invading the gland and fascia, the matter is sometimes contained in several cavities, and

* [Cressor diluted with Jeord makes a very good application in cases of sore or inflamed nipple, as does also the mixture of catechu, or of kino, the acerate of lead, or Gout- tare’s lotion. An artificial nipple, of a very ingenious construction, and invented by Dr. Pratt of this city, is one of the most successful and ingenious contrivances in these cases that we are acquainted with.]
weeks; and when resolution does not take place, it generally arrives at the stage of suppur- 
action in a few days. But a slighter state of infiammation of the organ may exist, and, from 
the state of the local and general symptoms, be confounded with another disease. In this 
case, the little pain which is felt, the absence of heat of the breast or skin, and of febrile 
symptoms, and the want of rigours or chills, often prevent the suspicion of the formation 
of matter, which is generally indistinct and deep-seated; and suggest the existence of a mali-
gnant tumour, requiring an operation for its removal, which has been even actually performed or attempted. 31. b. The Treatment of these cases should consist of means to promote the secretions and excretions, and to improve the state of consti-
tutional power, which is generally more or less 
in fault. The pilula hydrarg. chloridi comp., 
with soap at night, and tonic decoctions or in-
fusions, with alkalies, &c., during the day, are 
usually indicated. If matter have not yet form-
ed, Sir A. Cooper recommends the application 
of discentent plasters and stimulating embrocations, in order to promote the absorption of in-
filt rated fluid.* But when matter is formed, 
the abscess should be opened and poulticed; 
tonic medicines should be exhibited, and a gen-
erous diet allowed. The glands in the axilla 
sometimes become enlarged from irritation, but 
subside when the disease in the breast is re-
moved. 32. iv. Chronic Infiammation of the lac-
tiferous tubes.—Lactal or lactiferous Swelling, 
A. Cooper. This disease sometimes follows 
infiammation of the nipple, and consists of inf-
flamation, generally chronic, of one of the lactiferous tubes near the nipple, by which its 
channel is narrowed, or entirely obstructed, to 
the extent of half an inch or more, while the 
portion which is not thus affected becomes 
readily distended with milk. 33. a. The symptoms are as follows: The tu-
mour is confined to one part of the breast, from 
the nipple to the circumference; and it has not 
been preceded by redness, or any other sym-
ton of infiammation of the part which is dis-
tended so as to form the tumour. The patient 
complains of a severe sense of distention, which 
is increased when the child begins to suck. 
There is distinct fluctuation in the tumour, 
while no other symptom of abscess is present: 
the cutaneous veins are enlarged, but the part 

is not discoloured. If the swelling be opened, 
several ounces of milk are discharged, which, 
being suffered to rest for a few hours, forms a 
cream upon its surface. If a small puncture 
only be made, the milk discharged, and the or-
ifice allowed to close, the fluid re-accumulates, 
and the symptoms are renewed. When the 

* [We believe that this affection may generally be treated 
successfully by pursuing the mode of treatment recom-
}
distention is excessive, ulceration sometimes takes place; the milk is discharged through a small aperture near the nipple, and this discharge often continues during the whole period of lactation.*

34. 6. The treatment should consist in removing the child, which will soon occasion a cessation of the secretion of milk, and then a simple puncture may be made, which will relieve the distended tube. If, however, the child be suffered to continue at the breast, the opening should be made larger, so that the milk may escape while the child is sucking, as happens when a natural relief is effected by lactation.

* It is well to recollect, as Cooper has suggested, that this disease resembles in its nature, to some extent, that occurring in the fluid secreted by the prostate gland.

The one is an obstruction of the sub-maxillary duct and accumulation of saliva; the other is an obstructed lacrimal tube, which is followed by an immense collection of milk, from its escape being prevented at the nipple, owing to the obliteration of the duct at that part. ([Art. and Dis. of the Breast, Am. ed. Philad., 1845.])

III. ORGANIC LESIONS OF THE MAMA GENERALLY OCCURRING INDEPENDENTLY OF INFLAMMATION.

CLASS. IV. CLASS. I. ORDER (Author).

35. This class of diseases of the breast seldom originates in any form of inflammatory action, or, at least, in an unequivocal and manifest state of inflammation; but rather in conditions of the part and of the system very different from it—especially from true or ethereal acute inflammation. This class is mostly referable to low states of vital power and vascular action, in connexion with altered or morbid nutrition and secretion in the organ—to local irritation and lesion allied with constitutional vice or disorder.

This change is generally associated with a considerable degree of mastodynia. It consists of a full and bruised appearance of the organs, accompanied with pain and exquisite sensibility or tenderness.—a. It occurs chiefly in females under twenty-five years of age, and is preceded by severe pain in the breast and arm. The extravasation of blood occasioning the ecchymosis begins a few days before menstruation, and either is limited to a single spot, appearing as if a small blow had been inflicted; or consists of several small spots: generally one large patch and several small and paler patches are observed. It occurs chiefly in females of delicate fibre, who have large bosoms. The part is exquisitely tender, and the pain passes down along the inner side of the arm to the ends of the fingers. This affection sometimes disappears a week after menstruation; but, in the more severe cases, it continues until the next menstrual period. It is evidently a consequence of the excess of menstruation determined to be poured to the organ prior to the catamenial discharge, and indicates great irritability of the system, in connexion with weakness of the capillaries, whereby they are incapable of resisting the determination of blood to them. It is generally attended by irregularity of the catamenia, and constitutional debility and irritability.

37. b. The treatment should be directed to the uterine and constitutional relations of this affection. The preparations of iron, the mineral acids, sulphate of quinine, or sulphate of iron, in the compound infusion of roses, or other appropriate tonics, may be prescribed; and the liquor ammoniae acetatis with spirits of wine, tincture of opium and rose water, may be applied locally.

38. ii. Atrophy of the MAMA.—Absorption of the mammary gland, or, rather, wasting of this part, usually occurs at an advanced age, or subsequently to the disappearance of the catamenia; and it has been said to be produced by the excessive use of the preparations of iodine; but probably, in some of the cases where this effect has been said to have been produced, the adipose substance in which the gland is imbedded is the part chiefly absorbed. Atrophy of this organ does not appear to follow the tumefaction of it sometimes consequent upon cyanhe alporesis. ([Cumin, Edin. Med. and Surg. Journal, vol. xxvii, p. 227.])

39. iii. Hypertrophy of the MAMA.—Enlargement of the organ is observed to a very great extent. In most of the slightest cases, however, particularly when both mamme are enlarged, the hypertrophy is chiefly owing to the great increase of adipose substance around the gland.—a. True hypertrophy of this organ is independent of any morbid change of structure, and of any distinct tumour. It is entirely an unusual, and sometimes an almost monstrous growth of the gland. The increase of size is generally uniform, and it is at the same time more or less pendulous. At the commencement, indications of increased determination of blood to it are sometimes evinced, as heat, uneasiness, augmented sensibility, &c. True hypertrophy of the mamma is called, by
Sir A. Cooper, "the large and pendulous breast." It consists in an increase of the substance of the mammary gland, the lobes of which can be distinctly felt enlarged and hardened; and they are sometimes tender on pressure. This disease generally commences soon after puberty, and is believed to be always connected with defective or disordered menstruation. The breast, in many cases, has attained so enormous a size that the patient is compelled to remove the dress above the waist. It is, however, distinctly ascertainable. In a case mentioned by Mr. Hey, after the removal of the left breast, the menses, which had been entirely suppressed, returned, and the right breast diminished to less than half the size it was before the operation. The amputated breast weighed eleven pounds four ounces.*

40. Sir A. Cooper describes a peculiar form of hypertrophy of the mamma incident to unmarried women of the age of thirty or thirty-five, and which are defective in quantity, and who are the subjects of severe leucorrhoea. The breasts become enlarged, but not pendulous. On careful examination, the lobes of the gland can be distinctly felt enlarged and hardened, and moving freely on one another. Both breasts are affected, but one usually more than the other, and there is occasional pain, especially just before the appearance of the menses, which are scanty, pale, and of short duration. The tumour is due to either the growths which augment the pain, and, in these cases, cold has a great influence in lessening the menstrual secretion. An enlarged absorbent gland is sometimes found in each axilla; but this arises from simple irritation. After a while the breasts begin to waste, and in a few years are nearly absorbed.

41. b. The treatment of this affection is that of amenorrhoea, of which it is generally a consequence. In the first variety it may be cured by a simple, but this is not always necessary. In the second variety Sir A. Cooper recommends the application of the emplastrum ammoniacum cum hydrargyro, and of leeches when there is pain. In both varieties the preparations of iodine are the most appropriate remedies, and when judiciously prescribed, and combined with debauchery and cimenmogens, are often of service. The iodide of potassium alone, or with liquor potassae and comium; the iodide of iron, and the iodides of mercury, should be preferred, as they exert an emmenagogue operation, while they diminish the size of the mamma.

42. iv. Scrofulous Tumours of the Breast.

—i. In women of a strumous diathesis the mamma is subject to various indolent tumours, which in their earlier stages are not easily distinguished from diseases of a much more serious nature. Sometimes a hard lump forms in the organ and remains almost quiescent for months, or even years; or the whole gland may be affected with scrofulous enlargement. The general tendency of the disease, however, is to the slow and imperfect suppuration characteristic of strumous affection, and it produces the curdy appearance which the contents of scrofulous abscesses always present. Ulcera- tions of great depth and extent sometimes result, but the topical disease usually produces no proportionate effects on the constitution. In this disease the part is always enlarged, not contracted, as in one form of carcinoma. The tumour is tender when grasped, but it does not present the stony hardness observed in the latter malady. According to Dr. Cumin, it is never attended by retraction of the nipple. The indications of the strumous diathesis of the patient, together with the characteristics of scrofulous ulceration in the part, will farther determine the nature of the disease.

43. b. The treatment of scrofulous tumours of the breast is the same as that just recommended (§ 41), namely, the exhibition of the preparations of iodine; of Brandeau's alkaline solution, comium, &c.; or the means advised in the treatment of the other gland to which the stroma is directed to the uterine functions; the cata- menia ought to be promoted and the general health improved.

44. v. Adipose Tumours are but rarely found in the breasts, but they reach a very considerable magnitude. In the cases described by Sir A. Cooper, the tumours formed, in one case, between the gland and the surface of the pectoral muscle, and in another, between the different parts of the breast. According to Sir A. Cooper, it is never attended by retraction of the nipple.

45. In the treatment of these tumours, the internal use of the iodide of potassium, with or without the liquor potassae, should not be overlooked, as I have found these remedies succeed in removing adipose tumours in other situations.

46. vi. Chronic Mammary Tumour.—a. This disease generally affects females between the ages of seventeen and thirty-five. It is often independent of very manifest constitutional disorder, and it does not necessarily affect the general health, unless by occasions anxiety in the mind of the patient as to its nature. But it is usually connected with uterine irritation or disorder. It occurs chiefly in single women, or in those who have not had children. The tumour grows from the periphery of the breast, rather than from its interior, and it therefore generally appears to be superficial: occasionally, however, it springs from the posterior surface, and it is then more difficult and not so readily differentiated. It is extremely moveable, and glides easily over the surface of the breast, to which it is attached chiefly by an aponeurosis. It begins and often continues for many years without exciting pain; in some cases, however, it is attended with an aching pain, which extends to the shoulder. It is not generally tender to the touch, but Sir A. Cooper has occasionally found it so just before the menstrual periods. Its growth is very slow and it seldom attains any great magnitude, usually weighing

* [Dr. S. C. Houston has reported (Am. Journ. of Med. Sciences, vol. xxiv.) a remarkable case of hypertrophy of the mamma in a coloured girl, aged 14, who died in the Philadelphia Hospital on the 24th of February, 1834. The breast, which began to enlarge much earlier than the right, weighed twenty pounds, and measured 42 inches around the base, forming an overflow cover, which extended from the lower part of the neck to some distance beneath the umbilicus. The other breast, which was of the same shape as the left, was also enormously enlarged, but it was perfectly round, presenting not the slightest structural lesion. Around both glands the celluloid-adipose tissue was in a state of hypertrophy, and in neither could there be detected any trace of the nipple. The girl had menstruated, and enjoyed good health until a few weeks before her death, which was occasioned by a contusion of the left mamma, terminating in gangrene. (Gross.) Dostien, a German physician, relates a case, where the enlargement was attended with retention of the milk, and the left breast was found to weigh 64 pounds. Here also no decided structural change could be detected in the gland, except the mere hypertrophy of the adjacent cellular texture.]
from one to four ounces. One, however, which was removed by Mr. Bone, of Brighton, weighed a pound and a half, and Sir A. Cooper mentions a case which occurred in Guy's Hospital, and which he believes to have been of this nature, where the tumour weighed several pounds, and had ulcerated at its most prominent part. These tumours are originally quite free from malignancy; they exist for many years almost in a stationary condition, and then gradually diminish and disappear.

47. b. The most distinctive anatomical feature of this tumour is its lobulated structure, which may be felt by careful manipulation before its removal. On dissection, the tumour is found to be composed of large lobes, similar to that which envelops and enters the interstices of the mammary gland; and this envelope becomes denser in proportion to the magnitude of the tumour. When first laid bare, the tumour appears to be composed of large lobes, like those of the breast; but when more completely unravelled, it is found to consist of smaller and smaller lobes, similar in form, and easily separable by maceration in water. Sir A. Cooper observes, 'The impression made upon the mind during the dissection of the tumour is, that Nature has formed an additional portion of breast, composed of similar lobes, but perhaps differing in the absence of lactiferous tubes. When first opened, they appear red in the circumference, but whiter in the interior.'

48. c. The diagnostic marks of this disease are, the youth of the patient, scirrhus rarely appearing before thirty, this disease seldom after it; absence of pain, or of pain similar to that of cancer; the pain sometimes felt being slight, and considerable swelling existing for years without it; the general health being either not at all or slightly affected:* the slow progress of the swelling, and its stationary condition for many months, or even years; its extreme mobility, its superficial position, or its situation upon or in connexion with the gland rather than in it; and, lastly, its lobulated feel, it being distinctly composed of numerous lobes conglomerated into one mass, with a divided surface. The gland of the axilla very rarely enlarges, the enlargement being the result of irritation only.

49. I believe that Sir Astley Cooper is correct in his observation that, although these tumours are not in their commencement malignant, and they continue for many years free from the disposition to become so, yet, if they remain until the period of the cessation of menstruation, they may assume a new or malignant action. I believe, moreover, that the protracted and the depressing emotions generally, may produce the same effect, even before this period occurs.

50. d. The cause of this disease is chiefly vascular determination consequent upon irritation seated principally in the uterine organs and extending to the mamma. Hence it is often associated with signs of uterine excitation or irritation, or with disorder of the catamenia. It is sometimes ascribed to a blow, or to the pressure of stays; but these are rather occurring or additional than the only causes.

51. e. The treatment should be directed chiefly to the state of the uterine organs; for the disease is seldom much influenced by means directly applied to it. The disappearance of the tumour is generally owing to the cessation of the uterine irritation in which it originated, or to the mamma being called upon to exercise its natural function in the secretion of milk. The catamenial discharge ought to be regarded as its period, its quantity, its colour, and its duration. When it is scanty, difficult, attended by pain, pale, or delayed, I have found an occasional purgative of-colonel and compound extract of coleosynth, and the preparations of iron or of iodine, more particularly the iodide of iron, the iodides of mercury with conium, or the iodide of potassium with liquor potassae and tonic infusions, extremely beneficial. The mist. ferri composita with conium, in moderate doses might be attended to the biliary and digestive functions, are also very serviceable. Where these functions are torpid, the pilula hydragr. chloridi composita with soap and conium at bedtime; and the infusion calumbes, vel infus. casearillae, cum infuso rhei et sodae sub-carbon, &c., twice a day, will generally be of service. The emplastum ammoniaci cum hydragryo, and a weak iodine ointment, are the best local applications; but these should not supersede the internal use of some one of the preparations of iodine, in small doses, and for a long period. Pregnancy and lactation are, however, the most certain means of removing this disease. A young lady resident in a country town had this disease, and two or three surgeons were consulted respecting it. She was engaged to be married, and her intended husband was made acquainted with her complaint. Owing to the opinion then given, the marriage was delayed for more than two years, during which time the disorder was stationary. Another surgeon was consulted, who recognised the true nature of the disease, and sent her to London for my opinion. I advised her no longer to delay her marriage. Sir A. Cooper was afterward consulted, and concurred in this opinion. The disease afterward gradually disappeared.

52. vii. Painful Tumour of the Mamma.—Irritable Tumour of the Breast, A. Cooper.—A. The female breast, as already stated, is liable to severe hysterical or neuralgic pain, quite unattended by swelling or distinct tumour, but similar pains to those above noticed (q 11) are sometimes associated with slight tumefaction of one or more of the lobes of the organ; and more rarely they are attendant upon a specific tumour, described by Sir A. Cooper. In the neuralgic affection, without any circumscribed tumour, the swelling appears to be merely an incidentel complication, as in neuralgia of the face and other parts. The pain, though greatest at some particular part, generally pervades the whole breast, and extends to the shoulder, axilla, arm, and fingers of the affected side, sometimes also extending downward even to the hip. The slightest pressure on the

* When the patient perceives the physician to be suspicious of the malignant nature, her anxiety may so disorder the general health as to increase the difficulty of the diagnosis. Such was the case in respect of a lady sent to me a few years ago from the country by her medical attendant for my opinion. I readily recognised the non-malignant nature of the malady, and in this opinion both Sir A. Cooper and Sir D. Moir concurred, who subsequently met me in consultation on it, entirely concurred.
breast occasions intolerable pain, and alternate sensations of heat and cold are felt in the affected part. The intensity of the pain often occasions sickness and vomiting. The symptoms are much augmented just before menstruation, somewhat relieved during its continuance, and diminished after its cessation.

53. Besides this irritable state of the whole or part of the breast, a distinctly circumscribed tumour is sometimes found, often not larger than a pea, and seldom exceeding the size of a marble. It is highly sensitive to the touch, very moveable, and acutely painful at intervals, especially prior to menstruation. Occasionally several such tumours coexist, but there is usually only one. These tumours continue for years. Sir A. Cooper has never known them to disappear. They sometimes spontaneously cease to be painful, or disappear altogether.

54. a. On dissection, they are found to consist of a solid, semi-transparent substance, with fibres irregularly interwoven. They seem to be productions of the cellular membrane rather than of the glandular substance of the part; and similar tumours are met with in the cellular membrane of other parts of the body, which are attended with the like painful sensations. Sir A. Cooper has not been able to trace any large filament of a nerve into them.

55. These painful or neuralgic tumours of the breast are met with generally between the ages of sixteen and thirty; and from this, as well as from other circumstances, cannot be confounded with other diseases. They affect principally females of a nervous temperament; are commonly connected with deficient, difficult, or suppressed menstruation. In some cases, however, Sir A. Cooper has observed them associated with morbidly abundant menstruation. In a case of this affection for which I was lately consulted, and which has been removed by treatment directed chiefly to the uterine disorders, the return of the tumour occurred during the second month after marriage, evidently in connection with early pregnancy. I have observed these affections complicated with leucorrhoea as well as with catamenial disorder.

56. c. The treatment of this affection should be directed, 1st. To the alleviation of the local suffering; 2d. To the subduing the general irritability; and, 3d. To the restoration of the uterine organs to a healthy condition.

57. a. Sir A. Cooper states that the best local remedies are, a plaster consisting of equal parts of soap ocrate and extract of belladonna; poultices of bread with solution of belladonna; and oil silk, or bare skin, or some other fur worn upon the breast. Leccehs may be used when the pain is very severe; but if prescribed for weak or reduced constitutions, or when the disease is connected with anemia, or too frequently resorted to, they aggravate the irritability of the system.

b. To induce the general irritability, the treatment advised for Neuralgic Affections are the most efficacious, with proper attention to the uterine functions. If the biliary organs be sluggish, the chloride of mercury, or Pemex's or blue pill, with soap, opium, and cinium, should be given at night; and a stomachic or an emmenagogue apertum in the morning; the preparations of iron, or of bark with soda or potash, or cauphor being taken during the day. Sir A. Cooper advises the following pill to be taken twice or three times in the day.

c. In order to remove the uterine disorder, the carbonate of iron, the ammoniated iron, the compound myrrh mixture, the compound aloes mixture, and similar means, combined with such others as the peculiarities of the uterine disorder will suggest, ought to be prescribed. These means may be promoted by a recourse to a hip bath of sea water or of artificial salt water, of a temperature of about 100° or 103°. A salt-water shower bath, or the salt-water douche, on the loins and hips, will also be of service when aided by regular exercise in a dry, temperate, and pure air; by attention to diet and regimen; and by due regulation of the mental emotions and desires.

60. viii. Cartilaginous and Osseous Tumours.—According to Sir A. Cooper, these tumours are consequences of chronic and specific inflammation of the breast, during which a gelatin is effused resembling that in which bone is formed in the fetus. But the formation of bone in the fetus is not an inflammatory process. He supposes that blood-vessels and absorbents enter the effused gelatin from the adjoining parts; and as the latter remove portions of the bone matter, thus constituting the ossific matter in the interstices. BAYLE describes ossification as the last stage of what he designates fibrous tumour of the breast. Sir A. Cooper removed a tumour of the kind under consideration from a woman thirty-two years of age. It was of fourteen years' standing, excessively hard, and very painful. The pain was increased before menstruation, and greatly relieved after it. The skin covering it felt very warm in comparison with the surrounding parts, and the tumour was disintegrated by the application of evaporating lotions. On dissection, the greater part of it presented the appearance of the cartilage which supplies the place of bone in the young subject; the rest was osseous. The most remarkable case on record is that of a nun, in whom the mammae were found after death transformed into hemispheres of bone. (Miscel. Nat. Curios., Dec. ii., An. vi.)

61. ix. Cystic and Hydatid Tumours of the Mammary Glands.—Tumours of this description have been described by Sir A. Cooper, M. VELPEAU, Dr. WARREN, and Dr. CUMIN. The first of these writers has described four varieties of hydatid diseases of the organ, three of which he considers not to be malignant; the fourth to be malignant. A more correct division would be into those consisting, 1st. Of serous cysts; and, 2d. True hydatids; and it is not improbable that the former may assume various forms, or be variously transformed, as respects the external coats and number of the cysts, the appearances of their coats, and the nature of their contents, in the progress of their growth, and by peculiarities and changes in the patient's constitution and health. Indeed, any one of them may possibly assume the cancerous or malignant character, owing to these circumstances.

62. A. The cystic tumours vary remarkably, not only as respects the number and size of
the cysts forming the tumour, but as respects the number and appearances of their tunics, and the nature of their contents. Some of these tumours present one large cyst, with various partitions; others consist of several cysts, merely or less distinct; others, again, and formed of or broken connective tissue: some contain a sero-mucous fluid; others, a sero-sanguineous liquid.

63. Sir A. Cooper describes as follows his first species, or tumours consisting of simple scrofulous cysts, or bags; he, however, confounds simple cysts with hydatids (see art. Hydatids). In this form of disease, the breast gradually swells, and is, at first, free from pain and tenderness. It becomes hard, without fluctuation; and grows slowly for months, or even years, sometimes acquiring a very considerable size. At an early stage the swelling feels entirely solid, and greatly resembles a simple chronic enlargement of the breast; but, after a great length of time, fluctuation may be detected at one part of it. The tumour then begins to increase more rapidly, and fluctuation may soon be detected in several parts. There is still, in most cases, little or no pain; some patients, however, feel an unusual heat in the part, and other ill effects arise in the shoulder or arm. The tumour is extremely movable on the pectoral muscle, and is very pendulous. In some cases, the whole of the mammary gland becomes involved; in others, only a small portion of it. Such tumours often attain a very considerable size: Sir A. Cooper states that the largest he ever saw weighed nine pounds; but that, in other cases, although the diseased breast was entirely filled with cysts, it never exceeded twice the size of the healthy one.

At length, one of the fluctuating portions slowly inflames, ulcerates, and discharges a large quantity of a fluid resembling serum, but somewhat more oily. If the sac be entirely emptied, and the external opening closed, it is a long time before the fluid reaccumulates, and occasionally the sac is obliterated by the adhesion of its sides. Sometimes several cysts burst in succession, at distant periods, forming sinuses which are very difficult to heal. Except during the process of ulceration, the greatest part of the tumour is not at all painful. Even when the tumour is large, ulcerated, and discharging profusely, the axillary glands remain unaffected; or, if one be slightly enlarged, it is from simple irritation, and the enlargement subsides when the disease in the breast is removed.*

* [Sir Benjamin Brodie states that the account which Sir Astley Cooper gives of the hydrated breast has been taken chiefly from cases of "Sacro-cystic Tumours of the Breast" (Clinical Lectures on Surgery, Phil., 1846, p. 200). According to Brodie, the first perceptible indication of the disease is a globular tumour imbedded in the glandular structure of the breast, and, to a certain extent, movable underneath the skin. Sometimes there is only one such tumour; at other times there are two or three, or more; but it is only after they have attained considerable magnitude that the disease can be cured. In the majority of cases the disease is confined to one breast, though sometimes both breasts are affected. The pathological history of the disease, according to Mr. B., is as follows: 1st: A greater or less number of membranous cysts are generated in the breast, containing serum. The latter is, at first, of a light yellow colour, and transparent, but afterward becomes turbid and offensive. In a few cases it is bloody, and others believe that these cysts are formed by a dilatation of some of the lactiferous tubes. 2d. Malignant growths or excrescences are generated from the inner surface of one or more of

61. The second species of cystic tumour described by Sir A. Cooper seems hardly entitled to rank as such, since it is formed on a single case, and a doubt is expressed whether even this might not have been of the nature of the true globular hydatid tumour, so as to be undistinguishable from the preceding species except by dissection. In the case examined by Sir A. Cooper the tumour consisted of vast numbers of cystic formations, the largest of which did not exceed the size of a barleycorn. They were oval, and composed of numerous lamella, which could be peeled from each other, and which were very vascular.

65. B. The true globular hydatid tumour, the third species of hydatid tumour of Sir A. Cooper, is similar to the preceding species of cysts, excepting on parts of the body. Sir A. has found the globular hydatid only to exist singly in the breast, although great numbers are found congregated in other parts. When one of these hydatids is developed in the breast, inflammation is excited, and a wall of fibroin surrounds it. The tumour feels hard, and while it is small no fluctuation is perceptible; but as it increases, and the fluid becomes more abundant, a fluctuation may be felt in the centre of the tumour. Sometimes, when the hydatid has attained a considerable size, it occasions suppuration; and the

these cysts projecting into their cavities. These excrescences seem to consist of albumen or fibrin, which, after some time (if not immediately), becomes organized. They are covered by a thin, delicate membrane, which seems to be reflected over them from the inner surface of the cyst; but whether they are originally formed between two layers of the membrane of the cyst, or which, however, may, by depositing about the substance, or by fibroin being formed on their surface, is a matter of scientific conjecture.

3d. There is some reason for believing that a similar growth of fibrous substance may take place from the external surface of the cysts connecting different cysts with each other. 4th. Under certain circumstances, the cysts become completely filled up by the morbid growths, so that their cavities are obliterated, the tumour being thus converted into a solid growth; which, however, as it is composed of the cysts are perceptible; and this is the prelude to a still further change, in which the greater part of the cysts have a wholly different nature, and are a solid mass of a granulated or hydatidated texture occupying their place. 5th. If one of the membranous cysts be artificially opened, or if it burst from over-distention of the fluid, the fluid escapes, and separates its inner surface being no longer restrained by the pressure of the skin, increases in size, and protrudes externally in the form of a fungus, giving to the tumour a new and more formidable character. In this last stage of the disease, we have evident that spreading ulceration, sloughing, and haematoma, the usual results of an ulcer occurring in a diseased structure, must ensue; and that no remedy is likely to be of service to the patient, except the removal of the affected parts by a surgical operation. Mr. Brodie thinks that it is essential to a proper mode of treatment that we should distinguish those cases in which the disease is still in its earliest stage from those in which the growth of a solid fibrous substance has become superimposed to the simple original structure. In the first of these, he recommends to evacuate the fluid contents of the cysts by puncturing it with a grooved needle, and applying the following embrocation to the breast: 5 oz. Spiritus Camphorati, Spiritus turpini, 3 oz. Liquor Fumaturi, 3 oz. Fat embrocato. A piece of Damien is to be soaked in this embrocation and smeared over the swelling, when the application of the same is to be repeated six or eight times in the day and night until the skin becomes inflamed; then to paint the application for two or three days, and then to discontinue it, when the inflammation has subsided. This course will sometimes accomplish a cure in three or four weeks; in other cases, it is to be continued, with occasional intermissions, for several months; or a solution of some small blisters may be applied, keeping the surface discharging for several days with the burnt cæréna, or a solution of 3% of sallic in 5% of alcohol. The embrocation may be applied in the form of a thin ointment of a camel-hair brush. After the growth of solid substance has begun, there is, of course, no remedy but the removal of the breast by an operation.]
cyst being discharged along with the matter, a spontaneous cure is effected.

66. C. Diagnose—Cystic and hydatid tumours of the breast, in their first stage, may be confounded with chronic inflammation, but are distinguishable from it by the absence of tenderness on pressure, and still more decidedly by the uninjured health of the patient. In the second stage, when fluctuation is perceptible, they may be distinguished from abscess by observing that the fluctuation exists at more points than one; and the puncture of a cyst will at once remove all ambiguity. These tumours of the breast are distinguished from seirrus by the absence of lanecinating pain and stony hardness which characterize the latter, by their mobility on the pectoral muscle, by their pendulous state, and by the unimpaired general health of the patient. Sir A. Cooper, however, has seen a case in which true seirrus was combined with hydatids; and Mr. S. Cooper has met with a similar instance. The former of these writers has never seen those tumours seated in both breasts at the same time. They are met with at all ages after puberty, but seem more frequent under than above the age of thirty or thirty-five. Of the cases adduced by Sir A. Cooper, sixty years was the greatest age.

67. Although neither serous cysts, nor true globular hydatids of the breast, are of themselves dangerous, yet I agree with Dr. Cruick in suspecting that they occasionally give rise to, or rather are transformed into, other morbid changes of a very serious nature. The contents of the cysts are at first a straw-coloured serum; but in course of time it requires a greenish colour, and even a fetid odour. Indeed, I believe that not only these tumours, but also the other chronic tumours noticed above, the cystic and hydatid more especially, may assume, particularly in persons above thirty years of age, a scirrous or malignant character; when anxiety of mind, the depressing emotions, and other causes of physical depression and exhaustion, have permanently lowered the vital energies, and weakened vital resistance to the local mischief.

68. The morbid anatomy of cystic and hydatid tumours is so similar in all parts of the body, that we need not here dwell on their particular characteristics as occurring in the breast. The reader will find them minutely detailed, as respects this organ, in Sir A. Cooper's work, and in the article by M. Velpeau, referred to in the Bibliography.

69. D. Neither local applications nor internal medicines are serviceable in this disease, the treatment of which is purely surgical. If there be only one large cyst, the fluid may be evacuated by a simple puncture, and in some cases it will not again accumulate; but where the enlargement of the breast is excessive, and the cysts numerous, and especially where the patient is under great apprehension of some malignant disease, the tumour should be removed, taking care to extirpate every part of the morbid formation, since, if a single cyst be allowed to remain, the disease will be renewed.

70. E. The third or malignant class of diseases of the breast comprise chiefly cancer and fungus hematoedes, or encephaloid disease. But, after what I have stated in other parts of the work, it is unnecessary to advance at this place respecting these maladies when after.

MANKIND.—See Insanity.
but to this there are many exceptions, the severity of the disease, even in them, depending much upon the prevailing epidemic, and upon the climate in which the epidemic occurs.

3. I. History.—Several writers, and among others Sennert, Welsch, Manard, Oder, and Bateman, suppose that measles were known to the ancients. Oder has even contended that the plague of Athens, described by Thucydides, was an epidemic visitation of this disease. Gruner (Antiqu. Morbor., p. 54) and Sprengel, however, as well as many other judicious authors, have shown that the earliest accounts we have of this disease refer it to about the middle of the fifteenth century, and that the period to which smallpox was conveyed from Arabia to Egypt, and thence into Europe.

4. The earliest account which has been furnished of measles is contained in the Pandects of Rhenius, who describes it under the name of Hhasah, not, however, from his own observations only, but also from the information conveyed by Arron, who lived in 662 at Alexandria. Uberlachen (Uber die Grundlosigkeit der ersten Schilderung, &c. Wien, 1803) entertains, however, an opposite opinion as to the description of Rhazes being applicable to measles, but, in my opinion, without sufficient grounds. Avicenna and Mesue have also described measles (Hhasab), and distinguished it from smallpox (Dschadari), and the morbillous form of scarlatina (Hhamish).

5. It has been supposed by Schnurrrer (Chronik der Seuchen, s. 117), that the epidemic which prevailed, A.D. 455, through Phrygia, Cappadocia, and Cilicia, and is described by Severus as being accompanied with inflammation of the whole skin, turgidity of the eyes, and violent cough, was measles in a severe form; but the imperfect description given of that epidemic leaves room only for supposition.

6. The invasion of Spain by the Saracens in the eighth century most likely extended this disease to Europe at the same time with smallpox. Mention is made in the chronicles of the time that an epidemic prevailed in Italy in 876, which was characterized by pain and turgidity of the eyes, severe cough, epigastrium, and which, as Schnurrrer supposes, may possibly have been this disease. About the middle of the twelfth century, Synesius (De Febrifus, edit. Barnardi, Anat., 1749) translated into Greek the work of an Arabian physician, Abn Dschafar, where smallpox (олуентапосνη οιομική) is distinguished from measles (ετερα λεπτη και ποικη λοιμω.).

7. However, measles were very generally confounded with smallpox even as late as 1674. Anon. (Journ. of 1674) who committed this error were Lange and Diemermroch, while the distinction was first clearly made by Forestus (1597), Schenck (1600), Rivierus (1655), and particularly by Sydenham (1676), and F. Hoffmann (1717), who, with Huxham and Lepereck de la Cloture, have recorded the history of several epidemics, and added greatly to our knowledge of the disease. At the same time, it may be noticed that Morton and Watson confounded measles with scarlet fever, and viewed the latter as a severe variety of the former disease; and, as Dr. G. Burrowes has remarked, it was not until the appearance of Dr. Withering's Essay on Scarlet Fever, in 1783, and of Dr. Willan's Treatise on Cutaneous Diseases, that the profession was fully convinced of the distinct nature of the two diseases.

8. II. Description of Measles.—Instead of dividing this disease into different varieties or forms, as the Rubela vulgaris, the Rubela malignant, and the Rubela sine catarrho, &c., I shall first describe the regular form of the disease, and next notice those modifications, complications, and irregularities which it presents, according to the influence of individual constitution, epidemic prevalence, and of climate.

9. I. The Regular Form of Measles.—Rubela vulgaris, Willan, Bateman, &c. Mortali vestigii eccentrici, Sydenham, &c. Rougcole varicellare vulgaris, &c. The progress of the disease, in its regular and common form, is similar to that of all the eruptive fevers, and consists of four well-marked stages, namely, 1st. The period of febrile commotion; 2d. That of eruption; 3d. The stage of fluorescence; and, 4th. That of desquamation.

10. 1st. The period of febrile commotion, or of precursory fever, is that in which the infection of the whole frame has commenced, and that febrile action appears, which produces, after a certain period, the cutaneous eruption. This stage usually commences with chills, harrassments, shudderings, or rigours, alternating with heat of skin, and accompanied by a turgidity, erethism, or catarrhal irritation of the mucous membranes, particularly those of the respiratory apparatus. The patient is affected with frequent sneezing, coraya, stuffing of the nose, sometimes with dryness and redness of the pituitary membrane; with heat, redness, turgidity, and watering of the eyes; sensibility to light, heaviness, or pain in the head; congestion of the mucous membrane in very young children, and in older subjects, wakefulness; frightful dreams; pain or aching in the back and loins; soreness, pain, and tenderness at the epigastrium, and with slight hoarseness and dry cough. Sometimes the eyelids and sub-maxillary glands are slightly swollen. The appetite is diminished or abolished, while the desire for cold drinks is much increased. The tongue is white and loaded, and an unpleasant taste in the mouth is often complained of. There are frequently nausea, vomiting, and a lax or irregular state of the bowels. The febrile commotion rarely amounts to the production of convulsions or delirium; but generally more or less exasperation of fever, preceded by chills and harrassments, and accompanied with a full, hard pulse, oppression at the chest, and difficulty of breathing occurs towards evening, and remits towards morning, when a slight moisture appears in the skin until the eruption appears. Instead of this, however, there may be so slight a grade of the disease as not to render it necessary for the patient to keep his bed; and yet, in some of those cases, the patient may have complained for several days of catarrhal fever. In the more severe cases, hemorrhage sometimes takes place from the nostrils, or a hemorrhagic discharge occurs from the uterus, in this stage with considerable relief.

11. 2d. Stage of Eruption.—During the third febrile exacerbation, generally about the fourth day from the first occurrence of harrassments, an eruption takes place first on the face, particularly the cheeks, around the eyelids, nose, and ears; and next on the neck, breast, arms, hands, and abdomen; and last on the lower
extremities, with more or less turgidity of the countenance, particularly of the eyelids. Sometimes great restlessness, anxiety, convulsive movements, inequality of pulse, pain and sense of fulness in the head, slight delirium, or epistaxis usher in the eruption, which is generally completed in twenty-four hours. At this period the tongue is red at its point and edges, loaded or furred at its base, and the fauces exhibit some obscure patches resembling the cutaneous eruption. The eruption is at first discrete and scarce, but becomes more numerous and the lesions coalesce. The stigmata increase, are of a crimson or reddish colour, slightly elevated above the skin, and rough to the touch, particularly on the face, and early in the eruption. When examined with a glass, they have a rounded, or, rather, an elliptic form, resembling aniseed. When the papule are fully formed they are of a lively red, but contain no fluid; when pressed by the finger they momentarily lose their colour, which returns rapidly upon removing the pressure; and their circumference is not defined, their colour being deepest in the centre, and becoming paler until they insensibly pass into the natural tint of the skin.

Wedekind (Ueber die Masern. Roschlaum's Magazine, iv., No. 6) observed an extremely fine hair, scarcely discernible by the unassisted eye, penetrating each of the morbillous papule. If the eruption is very scanty, it is never equally diffused over the surface, but appears in clusters in different parts, separated from each other by large patches of healthy skin. Although the papule, or stigmata, may approximate nearly to each other, and coalesce into patches, they never completely run into each other, particularly in the early period of the eruption. In the more severe cases, however, especially in adult subjects, they often coalesce much more closely, the cutaneous surface assuming a deep red. The more acute the fever, the more copious is the eruption, which scarcely ever diminishes the fever, but on the contrary is increased by it, until the period of desquamation. During the eruptive stage the transpiration and breath have a peculiar odour, which generally continues till the seventh day, and is at first of a slightly sweetish, and afterward of an acridulous character, and has been likened by Heilm to that given out by a recently killed goose.

12. 3d. The Period of Floridness. — The eruption continues generally in full force for nearly three days, namely, from the fifth, when it is usually fully out, till the seventh, when it subsides; but this stage presents no distinct marks from the foregoing, for the eruption on the face and neck generally declines on the sixth, while it is fully out on the body and limbs, or even only breaking out on the lower extremities. The stigmata coalesce more closely, the skin becomes more uniformly red, tenac, or turgid, extremely hot and itching, and the turgidity of the face and eyelids, particularly on the fourth and fifth day, is very marked. The tongue and fauces now evince an evident participation in the eruption. The fever and catarhal symptoms show scarcely any remission, but are even sometimes increased. Intolerance of light, dryness of the nostrils, hoarseness and dyspnoea, and a hoarse clanging or barking cough, at first dry, and afterward frequently followed by the expectation of a thin mucus, containing dense, rounded, albuminous particles, continue during this period. Towards evening, the fever, restlessness, and heat of skin increase. Sometimes a slight diarrhoea occurs, from which the patient experiences some relief. The urine is generally of a deep colour, and scanty.

13. 4th. Period of Desquamation. — On the seventh and eighth days from the commencement of the first stage, the eruption declines on all the upper parts; but the subsidence and desquamation of it have generally begun a day or two earlier on the face and neck, the turgidity of which is now much diminished. On the eighth and ninth days, and in the same order as the eruption appeared, it subsides, with desquamation of the cuticle; and on the tenth and eleventh days it has entirely disappeared, leaving in its place a furfuraceous desquamation, passing off generally with an increased and troublesome itching, and a slight moisture on the face. The more prominent and copious the eruption, the more marked the desquamation becomes. Generally, when the eruption is very slight, the skin continues unchanged. In the course of this stage, critical perspiration, a copious sediment in the urine, and free evacuation, frequently supervene and contribute to its felicitous termination. But the pectoral symptoms usually continue longer, and occasionally with increased severity, particularly the cough, hoarseness, and the expectation already described. With the subsidence of these, the system returns to the healthy state.

14. ii. Modifications, Complications, and Irregularities of Measles. — There are various circumstances which contribute to modify the progress and character of measles. Of these, the most important are the prevailing nature of the epidemic, the season of the year, the state of the atmosphere in respect of temperature and moisture, the shape of the room, the ventilation of the place and apartments, the previous health of the patient, and his temperament and habit of body. But I believe that there are few causes proper to the individual that has greater influence on the character of the disease than the vital powers of the system, and the disposition which the patient may possess to affections of some vital or important organ.

15. A. Measles with predominance of Inflammatory Character — a. This form of the disease is generally ushered in with marked febrile symptoms of the inflammatory type; full, strong, or oppressed and frequent pulse; great heat of skin; a phlogistic appearance of the blood drawn from a vein; severe catarhal symptoms, with acute coryza; marked injection and turgidity of the conjunctiva; watery discharge from the eyes; constant cough; with oppression at the chest, great difficulty of respiration, bloody sputa, and other symptoms of inflammation of the mucous membrane of the air passages and lungs, and occasionally with acute pain and other signs of pneumonia or pleuro-pneumonia. The eruption appears rapidly and copiously, with convulsions in young children, and delirium in older patients, or, at least, with most severe pains in the head, after which a slight amelioration is sometimes ob-
served. The eruption is more intensely red, more prominent, and more closely coalescent, so as to occasion a nearly cryspelatous redness and tumefaction of the face and other parts, than in the common form of the disease. Desquamation also often takes place earlier, and is not infrequently complicated with, or followed by, marked inflammation of the lungs and bronchial membrane. It occurs sporadically in those who are exposed soon after infection to cold in any form, particularly to a cold, dry air after the body has been heated; and in children who are teething, and who have been highly or grossly fed, and kept in warm apartments, and are of an inflammatory and plethoric habit.

16. This state of the disease is most frequent during the epidemics which occur in winter and spring; in persons of a robust, sunburned, and irritable habit, and especially liable to kindredague diseases towards its decline, or to dispose to them during convalescence, that strict attention should be directed to the circumstance.

17. This form of measles is so very frequently complicated with serious inflammation of the air passages and lungs, and so liable to kindredague diseases towards its decline, or to dispose to them during convalescence, that strict attention should be directed to the circumstance.

18. a. When extensive or severe bronchitis occurs during the course of this type of measles, the patient is often suddenly attacked with great difficulty of breathing; the face is pale, if it precede the eruption, but generally somewhat livid, or of a deep crimson, if it occur during the eruption. Sometimes the eruption either appears only partially, or recedes prematurely; the lips are also livid; the chest and diaphragm, as evinced by the motions of the abdomen, labour much during respiration, and a sonorous, sibilous, and, lastly, a mucous rhonchus, is heard on auscultation. The countenance becomes anxious; the expectoration is more or less abundant, and attended with severe paroxysms of cough; the pulse is quick, small, or oppressed; and the skin either cool or warm in parts only. This state of disease is not merely a severe form of bronchitis, but an association of it with congestion of the lungs, to which a similar state of the brain is sometimes superadded. The pulmonary affection, in this severe form, may soon terminate the life of the patient, chiefly in consequence of the effusion which takes place in the air passages, together with the loaded state of the vessels of the encephalon.

19. In the less severe forms of the complication of bronchitis with measles, or when the bronchitis is not accompanied by effusion of the organ, the symptoms are less marked; there is less urgent oppression at the chest, and the lividity of the countenance is generally absent. But these less severe states of bronchitis not infrequently superinduce inflammation of the substance of part of the lungs or of a whole lobe. In this case the sputum becomes more purulent, more rounded, and sometimes streaked with blood; respiration is puerile in the vicinity of the affected part, in which the respiratory murmurs is either feebly heard, or is attended by crepitating rattle, or the sound is no longer detected in it, while the chest is dull. In this situation, upon percussion. At the same time, the respiratory motions are quick, laboured, unequal, and imperfect.

20. b. Pleuritis may occur during the course of this type of measles, and the inflammatory action may either originate in, or may extend to the pleura from the affected part of the lungs. But in either case we seldom find in measles that the pleura becomes inflamed without a portion of the lungs participating in the diseased action. The presence of acute pain generally indicates this complication, with immobility of the ribs, quick inspiration, and slower expiration, and pain on percussion, which gives no further information, unless effusion has taken place, when the sound will be muffled, and the exogonous sound heard on auscultation.

This form of complication not infrequently terminates in hydrothorax, particularly after the disappearance of the eruption.

21. y. Another severe and dangerous complication, viz., croup, sometimes occurs in this form of measles. It generally appears during the stages of eruption and florescence, and more rarely subsequently. It is chiefly characterized by hoarseness and ringing, croupy cough, followed by difficult and obstructed inspiration, hoarseness and tumefaction about the larynx and trachea; and by the expectoration, after the paroxysms of strangling cough, of a ropy, clear fluid, sometimes with membranous threads. It very seldom happens that the inflammation of the larynx and trachea, constituting the croupy complication, occurs without some degree of inflammatory action being extended to the bronchi, or even to a portion of that substance of the lungs. When a fatal termination occurs in this state of disease, the air passages present more or less of the usual marks of inflammatory action, and are loaded with a thick, tenacious mucus, or contain false membranes, or both.

22. a. Measles with Predominance of Gastric and Bilious Disorder. — a. This form was first described with accuracy, and the importance of attending to its character pointed out by Sprott. It is chiefly marked by accumulations of sordes in the stomach and bowels; by loaded tongue; pain and tenderness at the epigastrium, hypochondria, and bowels; by marked, bitter, and offensive alvine evacuations; by the great severity of the cough; by depression of the energies of the frame; the slower and less abundant eruption on the skin; by weakness and frequency of pulse; and by severe pains in the loins, limbs, and forehead. It sometimes characterizes summer and autumnal epidemics, particularly during or soon after warm and moist seasons; and it occurs sporadically in weak children during the periods of the first and second season after infection; in the imperfectly nourished, and in those who have had their bowels long neglected.

23. b. This form of measles is frequently complicated with irritation of the mucous surface of the stomach, or with disorder of the liver. But when this latter organ is principally attacked, it is more generally congested than otherwise affected. The complication of this modification of measles with gastric irritation is very frequent in children during the periods of denatation, and is generally indicated by nausea and vomiting, tenderness of pain, or heat at the epigastrium; an imperfect, impeded, or irregular state of the eruption, and its premature disappearance. Congestion of the liver is much more sel-
dom met with, and chiefly occurs in older subjects. It is generally attended by pain and fulness in the right hypochondrium, sallowness of the countenance, an irregular and morbid state of the alimentary evacuations, and a dark, muddy state of the urine.

21. C. Durh hae is not an infrequent complication in this form of meases. It may appear early in the disease. When this is the case the eruption is often delayed, or it is scanty, imperfect, or irregular. It may also take place during the period of desquamation, assuming the character at first of a salutary crisis; but, in consequence of error in diet, or exposure to cold, putting on a more serious appearance, or even taking into the stage approximating to the typhoidal evacuation. When this occurs, the appearance of the evacuations, and the state of the cutaneous surface, require the attentive examination of the practitioner, as being the chief guides to this state of the disease, and to successful treatment. Dr. Abercrombie, of Cape Town, described to me an epidemic prevalence of meases in the colony which presented much of this character; the complication with durh hae, or ceno or dysentery, or the supervision of these during the decline of the meases, or even some time after recovery from that disease, being very frequent and uncommonly fatal.

25. C. Meases with Predominance of the Nervous Character.—In this form of the disease the patient is, from the commencement, much depressed in mind; is severely affected with chills and rigours, which pass into a burning heat, with inquietude, general pain and lassitude, particularly about the loins and limbs, with delirium or somnolency, lepithymia, harsh heat and dryness of the skin, and dry, loaded tongue. The eruption sometimes appears as early as the second or third day, frequently with convulsions, and rapidly extends to all parts of the body. The patches of the eruption are scarcely at all, or only slightly prominent; are paler than the regular disease, and more readily disappear. The febrile and nervous symptoms are never diminished, but, on the contrary, increased by the eruption, particularly if it disappear prematurely, or is expelled by any cause. Sometimes, still more severe and frequently fatal symptoms accompany this form of the disease, such as dyspnoea, dry cough, anxiety, oppression at the chest and precordia, cardialgia, dryness and trembling of the tongue, dryness and redness of the fauces, loss of voice, vomiting, loss of recollection, with stupor, starting of the tendons, tumefied abdomen, very quick, weak, soft, and open pulse, and a crude, scanty urine. The character of the disease so nearly approaches to the typhoidal type of fever, that it has been termed by several authors typhoid mease.

Critical evacuations sometimes occur towards its close, or abortive efforts at evacuation, occasioning fatal determination to some weakened organ, or subsequent visceral disease, which can be removed with great difficulty only. The cuticle is frequently not thrown off in this form of meases.

26. Meases with the nervous character occurs generally at the same season and in the same class of subjects as the foregoing variety (§ 12). It characterizes certain epidemics, particularly those which occur at the same period as epidemic continued fever; and it evidently evinces a more marked determination of the febrile action towards the large nervous centres, particularly the substance and membranes of the brain. This determination is often remarkably increased about the eruptive and subsequent stages, or upon the imperfect appearance of the eruption, or its repression.

27. D. Meases presenting a Malignant or Septic Character.—Rubella maligna; R. Putrida; R. Septica. Auct. var. To many of the symptoms which I have detailed, as marking the nervous form of meases (§ 25), are generally superadded, most commonly during the stages of eruption and florescence, or occasionally somewhat later, the eruption of petechiae, lividity and soreness of the skin, the fever, general dysentery, delirium, or more copious flux of dark decomposed blood from the nostrils, mouth, or vagina: a profuse and exhausting diarrhoea; dark, offensive motions; dysenteric symptoms, and viscid perspirations. The measly eruption becomes, either previously to or contemporaneously with the above symptoms, discoloured, of a deeper and darker red, or livid; and the cuticle is readily rubbed off upon the decline or detumescence of the papule. This form of meases presents a similar state to that of purpura haemorrhagica, or of land scurry, complicated with the exanthematous fever.

28. Malignant meases occurs chiefly in hot, warm, moist, and miasmatic climates, in close or crowded localities; and during hot and moist seasons, in cæ cachetic habits, in the ill-fed, or in those in whom the energy of the digestive and assimilatory functions is greatly impaired, and who have been subjected to those agents which act most injuriously on the powers of life and the integrity of the moving fibres, contaminating the circulating fluids, and occasioning the liquecence of the soft solids of the body. I have seen it prevalent in the natives of warm climates, and in those who inhabit marmal, moist, and miasmatic districts, both in temperate and warm seasons. I have likewise observed it in natives of some of the northern countries of Europe who have been imperfectly fed, and whose only animal food consisted of fish, frequently stale, and eaten with little salt, or vice versa. The symptoms which accompany this form of meases are not less of an alarming character, the fever being paroxysmal, the chills being acute in their nature, and the sweat being copious and offensive; the yellow, oily, and offensive sweat being frequently emitted in great quantities. The face is usually of a livid, livid, and livid complexion, with the eyes sunken in the sockets, conjunctivitis, and discoloured or darkened, the cheeks often presenting a livid or livid aspect, the skin generally being dry, at the same time being difficult to wet by the tongue, which is dry, discoloured, and often dry. The tongue is not infrequently covered with a fur, which is frequently offensive, and sometimes sloughing off. The gums are generally inflamed, and the teeth are often loose, or even often lost. The throat is often inflamed, and the pharynx is generally covered with a membrane, which is frequently offensive. The eyes are frequently inflamed, and the conjunctiva is frequently inflamed, and the conjunctiva is generally covered with a membrane, which is frequently offensive. The gums are generally inflamed, and the teeth are often loose, or even lost. The throat is often inflamed, and the pharynx is generally covered with a membrane, which is frequently offensive. The eyes are frequently inflamed, and the conjunctiva is generally covered with a membrane, which is frequently offensive. The gums are generally inflamed, and the teeth are often loose, or even lost. The throat is often inflamed, and the pharynx is generally covered with a membrane, which is frequently offensive. The eyes are frequently inflamed, and the conjunctiva is generally covered with a membrane, which is frequently offensive. The gums are generally inflamed, and the teeth are often loose, or even lost. The throat is often inflamed, and the pharynx is generally covered with a membrane, which is frequently offensive.
riod of its disappearance, this may be prema-
ture, and the desquamation subsequently be ei-
ther imperfect or altogether wanting.

30. a. Measles without the catarrhal symptoms —Morbillis sine catarrhv annectorum—not infre-
tently occur during the epidemic appearance of the disease; or an eruption presenting all the characters of measles sometimes is met with, but without the usual catarrhal symp-
toms, and without, or with slight febrile con-
motion. This variety was first described by
Willan, and as it does not protect the consti-
tution from the regular form of measles, it is
considered by Frank, Hildbrand, and Wil-
liams as spurious, and as an eruption only re-
sembling measles, and symptomatic of gastric
disorder. Dr. G. Burrows, however, thinks
that this objection cannot be admitted; for, be-
sides the opinion of Willan, Bateman, and
others, that it is a distinct variety, the recur-
rence of measles in the same person has been
seen by these and other writers. In the most
of the cases of this eruption that I have ob-
served, the stages of the disease wanted the
regular order of events, the eruption being
not so marked or complete as in them.

In many, also, of the impotent instances of
a second attack of measles, some doubt may be
entertained as to one or other having been the
regular disease. I believe, however, that I
have seen instances of an undoubted second
attack.*

31. b. Measles without the Eruption—Morbi-
llous Fever without the Exanthemate.—Febris mor-
billosa sine Exanthemate. Hildbrand and se-
veral others have contended that, during the
epidemic prevalence of measles, some children
may have all the catarrhal and febrile symp-
toms of measles, and yet no eruption will ap-
ppear, such children notwithstanding being pro-
tected against a subsequent attack. I have met
with two or three instances, when measles was
prevalent in a family, of one of the children
having all the catarrhal and constitutional symp-
toms without any eruption appearing, and
have attributed this to impaired vital force,
to an anomalous state of the blood, of the
system, and to impaired vascular action, proba-
bley also associated with predominant disorder
of some internal vises. I have seen other in-
stances where the disease has advanced far, the
febrile symptoms having continued for sev-
eral days, when a scanty, imperfect, or evan-
escence eruption has at length appeared after
the exhibition of stimulants or tonics.

32. c. The connexion of hooping-cough with
measles has frequently been remarked upon.
Indeed, there is a very intimate association be-
tween some of the fevers, and the sometimes
prolonged, a very intimate association with per-
tussis, the epidemic appearance of the one be-
ing frequently followed by the other, and the
attack of the one being often followed closely

* (This form of measles occasionally prevails in this coun-
try, and sometimes goes under the name of French measles.
Besides lacking the catarrhal symptoms, the eruption ap-
pears at an earlier period, and is diffused over the surface
in spots instead of a succession of well-defined crescents;
it also is more transient, usually subsiding in 24 hours. It
may exist at the same time with common measles, or sep-
ately; in some cases it has been succeeded by the former
in a few days, showing that it affords no protection against
an attack of the regular variety. Professor Burrows sup-
poses that it is an efflorescence of another nature, depend-
ant on some very different cause; or that, if it is of a mor-
billoso character, it is illegitimate, and therefore truly called
rubella spurt.)

by the other in the same subject. Some phy-
sicians, as De Haen and Macbride, conceive
that they have seen measles associated with
smaltipex in the same person. But I agree with
Reil and Hildbrand in considering this opin-
ion to have originated in mistake.

33. III. The Terminations of Measles.—i. Re-
solution or restoration to the healthy state
usually takes place from the resistance which
the vital energy opposes to the morbid changes
characterizing the disease, and to the influ-
ence of this energy on those organs which are
the emunctories of the disease. When the trait
of phrenomena is not interfered with, the disease
frequently, about the seventh or ninth day,
presents some critical evacuation, which tends
greatly to the restoration of the healthy func-
tions, especially a copious and general perspi-
ration; a paler and more abundant secretion of
urine, which deposits a copious sediment; di-
arrhoea continuing for two or three days, but
readily becoming hurtful if it be not judiciously
managed; a copious discharge of mucus, which
often remains for some time; the subcutaneous
surface of the body becomes smooth and spon-
taneous; and the furfuraceous discharge and
transpiration which takes place from the cutane-
ous surface after the exfoliation of the cuticle.

34. ii. The Sequelae of Measles.—A. Some-
times not only the irregular and complicated
states of measles, but even the more benign
and regular form, leave after them, without any
evident cause, various diseases which place the
lives of patients in great hazard. The chief
of these are pulmonary consumption, the result
of either of a chronic state of the bronchitis which
had accompanied the measles, or of organic
lesion of the substance of the lungs, the con-
sequence of the complication of the disease with
pneumonia, or with broncho-pneumonia, readily
passing into chronic pneumonia, or of tuberculosis
which had been developed during its progress
decline, or which had previously existed.

It is by no means rare to observe both pneu-
monia and pleuritis, or both conjoined, super-
vene during the period of desquamation. The
accesion of pneumonia is often extremly furtive and latent. I have fre-
ently seen patients brought to the Infirmary for
Children with the most severe attacks of pneumo-
ia, in an advanced stage, with all the symp-
toms fully developed, following an apparently
mild form of measles; and other cases, which
had manifestly been advancing for several days
in a concealed manner, and gone on to serious
organic change before the parents had been
alarmed. These latter are very frequent sub-
sequent to a severe or constitutional disease, and shortly after
the inflammatory form of the disease, although they are not peculiar to this variety, but equal-
ly consequent upon the regular, and some-
times on the gastric states of the malady.

In cases of this description the practitioner has
often no opportunity of watching the accession of the local mischief, which may occur so early
in the disease as to be a complication of it, or
during the stage of desquamation. I have,
however, observed it still more frequently—I
may say in many hundred instances presented
before me in the institution already referred to—at
an indefinite, but no very remote period from
the last stage, occurring generally during re-
cov ery, either from an inceasous exposure to

MEASLES—Terminations of. 913
the air, or to cold, early in convalescence, or from an injudicious management of this period, which, in all exanthematic diseases, requires the particular care of the physician in order to prevent their dangerous sequelae. They are, in fact, often more dangerous than even the original diseases themselves.

Improper diet, premature exposures to cold, and even atmospheric vicissitudes, which cannot be sufficiently guarded against, will also frequently occasion the unfavourable consequences now pointed out.

35. B. The symptoms indicating the supervention of disease of the lungs are often extremely particular, particularly if the local mischief commences early in the disease, and if viewed superficially, or without the aid of percussion and auscultation. They chiefly consist of the persistence of cough, expectoration, frequency of pulse, and febrile exacerbations, after the disappearance of the eruption. Or, the different stages of the measles having been completed, febrile action is rekindled and accompanied with oppression, weight or uneasiness in the chest, with a dry, spasmodic cough and difficulty of breathing, commencing after a time with purulent expectoration, occasionally streaked with blood, evening exacerbation of fever, nightly perspirations, loss of flesh, &c. In those cases which are characterized by a gradual or insensible concentration of diseased action in the lungs, particularly in the mucous surface of the bronchi and air-cells, the expectoration which supervenens in the latter stages gradually changes from a clear, whitish thin fluid, containing numerous white albuminous specks or droplets to a thick, mucous, tenacious, and mucous-purulent matter, till it at last becomes more decidedly purulent, the spitting being each distinct and rounded, less tenacious, not running into each other, and forming a viscid, stringy substance, adhering closely to the sides of the vessel, but a yellowish, rounded mass, which inspirits a whitish, turbid appearance to the water in which it is thrown, from mixing partly with this fluid. But these and other symptoms, although most certainly indicating serious disease of the lungs, give us no precise information as to its extent and nature of the existing lesion. This is only to be acquired from an attentive and repeated examination of the chest by means of percussion and auscultation, and from weighing the evidence thus furnished us in connexion with the rational symptoms in the manner pointed out under the articles where these subjects more appropriately fall. The above remarks are equally applicable to the occurrence of pleurisy, either as a complication or as a sequela of measles. When pleurisy, or pleuropneumonia, does occur in either of these ways, it is extremely prone to terminate in effusion of a serous fluid into the pleura, as adhesions are less readily formed in pleurisy when thus complicated than when occurring in an idiopathic form.

36. But effusion into the chest, and even into the pericardium, may be consequent upon mea-
lus without any previous signs of inflamma-
tory action. When thus results supervene, the disordered state of the respiratory and other functions, and particularly the information conveyed by percussion and auscultation of the chest, will generally point out the nature and extent of mischief. Other dropisical effusions, particularly anasarca, hydrocephalus, and ascites, occasionally are observed as sequela of measles, and may be imputed either to increased determination of the circulation to, with diminished tone of the extreme capillaries terminating in serous surfaces, or to congestion of the vessels, particularly those conveying the blood from the adjoining viscera and parts. As in anasarca, so also in the other forms of dropsy, the obstruction opposed to transpiration by the state of the cutaneous surface may determine an increased exhalation or secretion of serum into the cellular tissue underneath and into the subcutaneous tissues. The occurrence of anasarca after measles from granular disease of the kidneys is seldom observed.

37. C. Enteritis, in some one or other of its forms, more commonly appearing as mucous enteritis, or commencing in the mucous surface of the intestines, is a not infrequent sequela of measles, either upon the disappearance of the eruption or during convalescence, particularly in some epidemics. In the remarkable epidemic which appeared at the Cape of Good Hope about 1829, where the disease had not existed for thirty years, and which few under thirty years of age escaped, this sequela was much more fatal than the measles itself, although of a very severe form. (See art. Intestines, Inflammation of.) Diarrhoea, acute or chronic, the former being often inflammatory and passing into enteritis as just noticed, or lapsing into the chronic state, not infrequently with ulceration of the intestines, is often observed after mea-
sles.

38. D. Ophthalmia of a chronic and obstinate character frequently follows the malady, particularly in the fair and serousulous diathesis. In addition to these, serofulous sores and affections of various kinds; enlargements and inflammations of the lymphatic and mesenteric glands; aphthae and ulcerations of the cheeks and gums; furunculi and abscesses of the cellular tissue, and flor albus, should also be ranged among the sequelae of measles.

39. E. When the disease occurs in females who have reached the period of puberty, it may be followed by various irregular forms or manifestations of hysteria, sometimes connected with disorder of the catamenia. Of these, hysterical or nervous cough, occasionally with aphony, is one of the most common, and always requires a treatment suited to its hysterical character.

40. F. A more particular consideration of the above sequela of measles is not consistent with my limits. The mere reference to the subject serves to illustrate the nature of the disease, while it warns the practitioner as to what may occur, and hence points out to him what should be guarded against. These sequelae, moreover, show that the inflammatory character of measles is variously modified in respect of the degree of vital energy and nervous power with which the vascular system and the tissues generally are endowed; that all the vital manifestations, and even the cohesion of the textures, are seriously modified in its progress, particularly in certain of its types; and that while morbid action of an acute and febrile kind may exist, even in an extreme grade, it
may be at the same time conjoined with great diminution of the nervous functions and vital energy.

41. iii. Not only may measles terminate in a *return to health*, and in other diseases tending generally to disorganization, but they may terminate in a more immediate manner, in death. This seldom occurs sooner than the stages of efflorescence and desquamation; but cases have occurred in which a fatal issue has taken place about the period of eruption, congestion of either the lungs or brain, or even both, occurring either alone or in conjunction with effusion of serum, &c., into the air cells and small bronchial tubes of the former, and in the ventricles and between the membranes of the latter, and quickly arresting the functions of these vital organs. In the later stages of measles death generally occurs in a more gradual manner, and may be imputed: 1st. To inflammatory disorganization, commencing and rapidly advancing in some vital organ, either as a complication or as a consequence of the general febrile commotion and constitutional affection constituting the disease. In these cases the eruption may be extremely abundant, premature in its appearance and decline; but it is much more commonly either late, extremely scanty, irregular in its course, or even scarcely appearing. 2d. A fatal result may be occasioned by the extreme degree of general adynamia, or depressed state of the vital energies, owing to which reaction cannot take place sufficient to restore the different functions of the economy to their natural state; or the vital manifestations of the different organs are increased in form, or raised, and the removal of the morbid impression made upon the nervous energies, and through them upon the different emunctories, secretions, and circulating fluids, by the exciting cause of the disease, aided by the different concurrent influences of individual predisposition and pre-existing disorder. 3d. A fatal result may occur in any of the advanced stages of the disease from the combination of these two principal pathological states, either of them existing in a more marked degree than the other, in different cases, in different epidemics, and in different seasons.

42. iv. **Appearances observed in Fatal Cases of Measles.**—These vary according to the nature of the prevailing epidemic, the season of the year, the severity of the attack, and the individual predisposition and state of health at the period of seizure. The lesions detected after death have generally a strict reference to the particular type of the disease, and to the complications which had existed in its development. The regular and unaccompanied measles never terminates fatally unless serious or dangerous visceral disease occurs on its decline, and ends unfavourably. It is different, however, with the other types or states of the disease.—a. In fatal instances of inflammatory measles, the lungs always present more or less change. The mucous surface of the air passages is vascular, of a reddish or dark-red colour, generally in patches of a small size, somewhat softened and turgid, and covered with either a mucous, miliary, or coagulable exudate, in cases which have presented signs of the croupy or bronchitic complication, the above appearances are very marked about the larynx, epiglottis, and trachea, and are sometimes accompanied either with infiltration and injection of the sub-mucous tissue, or with a thick, whitish, albuminous exudation, approaching in parts to an imperfectly formed membrane; but this latter is, as far as my observations have gone, extremely rare. The above changes are more commonly observed in the large and small bronchi, where the accumulation of viscid mucous, containing whiter and denser specks of an albuminous appearance, is sometimes very great. Accompanying these states of the air passages are those in the sub-mucous layer of the bronchial tubes, such as dark, frequently fluid, or semi-fluid blood, a similar congestion likewise existing in the veins and sinuses of the eperchalon. After the more decidedly pneumonic complication, sorous, or sero-sanguineous infiltration of the air cells and connecting cellular tissue, hepatization or condensation of portions of the lungs, purulent infiltration of parts of this organ, or the formation of small purulent collections with disorganization of the immediately surrounding structure, and, lastly, inflammation of the pleura, are the changes which generally present themselves. When pleuritic symptoms occur during the last stages of the disease and terminate fatally, effusion of a turbid serum to a greater or less extent, injection and softening of parts of the pleura, and more or less lesion of the subjacent lung, are usually observed.

43. b. In the nervous type of the disease, the brain is generally much more vascular than natural, and occasionally somewhat softer; the veins and sinuses are congested, and serum, in an inflammatory state, is frequently found in the ventricles and between the membranes. The pia mater is also generally more than usually vascular, and the arachnoid more or less opaque. These lesions vary greatly in degree. Sometimes they are most remarkable on the surface of the hemispheres; but I have observed them most frequently about the base of the brain. The extent of morbid change has frequently no relation to the severity of the nervous type during the progress of the disease. In some cases the lungs are often congested with serum, yet the character of the disease has been marked and severe. In other cases the lesions have been considerable, yet the nervous symptoms have not been proportionately great. It seems as if the manner in which the energies of life are influenced has an intimate relation to the intensity of disease and the manifestations of the nervous functions in its progress.

44. c. In the gastric and bilious type of the disease, the morbid appearances are generally most marked in the mucous surface of the stomach, intestines, and esophagus, and consist chiefly of inflammatory injection, in patches or small grouped specks, and of softening or loss of cohesion of the mucous membrane, sometimes with injection and slight infiltration of serum in the sub-mucous cellular tissue. The liver does not often present much appearance of disease—seldom more than slight injection or congestion of the portal and hepatic veins—the biliary derangement, when it accompanies the disease, being more functional than inflammatory.
three in this country where this character was marked. The most remarkable features in these inspections were the softness of the tissue and the presence with it of bright red or orange characters in which even the heart itself participated. The serous cavities sometimes contained a small quantity of serous fluid of either a turbid or sanguineous appearance. I have observed this kind of effusion in the pericardium, but more frequently in the pleura. The lungs were generally congested, and the mucous surface of the bronchi, as well as some parts of that of the digestive canal, were of a darker colour, even without any very marked injection of the vessels farther than engorgement at the smallest vessels, than in other cases of the disease. The bronchial mucous surface presented, in parts, small livid or purple ecchymoses, similar marks also sometimes appearing in the fauces, stomach, and ceceum.

46. The veins and sinuses of the brain were generally engorged with a dark, semi-fluid blood. The aurricles and large veins contained blood in a similar state. The surface of the body was livid in parts, mottled, and dotted with petechiae of a dark colour, approaching to the characters of purpuramorbus.

[Blood in Measles.—Andral and Gavarret found that in the measles the fibrin never exceeded, nor did it ever fall much below Lecanu’s average (3 parts in 1000); ranging in adults from 2 to 3]. This mean is found at the commencement of the disease; but after the eruption appears, and in the adynamic form of the disease, there is a tendency to a diminution of this principle. The proportion of blood corpuscles, however, is augmented in measles from 1250 in 1400, the natural ratio, to 137, 140, and 148. It will be observed that in the phlegmatic, the quantity of fibrin is materially increased from 3 up to 10 parts in 1000, while the proportion of globules is not increased. Measles, therefore, should be ranked with the pyrexiae, so far, at least, as the state of the blood is concerned. (See Pathologie Hæmatologique, Paris, 1843, or Am. Trans., 1844; also Simon’s Animal Chemistry, Am. ed., p. 255.)

47. V. Tissues most uniformly affected in Measles.—The structures specifically affected by this disease are the tete vasculorum of the skin and mucous membranes, particularly those lining the air passages, and, in a lesser degree, those of the fauces and stomach. The redness observed in the mouth and throat during the stages of eruption and florescence is seldom so intense as in scarlatina. The other lesions of structure observed after measles may partly be attributed to the interruption of those functions performed by the cutaneous and mucous surfaces, and to the consequences thereby produced on other organs associated with them in action, together with the influence of the efficient cause of the disease on the nervous and vascular system, on the circulating fluids, and, indeed, on all the vital manifestations, and even on the organization of the frame. These latter, or more extreme changes, however, are chiefly manifested in the more severe or malignant cases, and are not dissimilar from those which take place in the advanced course of low or adynamic fevers, whether exanthematic or simply continued.

48. IV. Diagnosis.—An exact knowledge of the symptoms and course of the disease in each of its stages, and in all the states and forms it may assume, having, at the same time, regard to its close resemblance to the character of the reigning epidemic, will generally enable us to distinguish it from all other maladies of a similar kind.—a. Miliary fever will seldom be confounded with measles, as its ptyalneider, containing a serous or whithish fluid, scarcely ever appear on the face, and are always accompanied by perspirations of an acid and strong odour. —b. Urticaaria is distinguished from this disease by the itching attending it, by the larger and more elevated papula appearing and disappearing without any order, and by its more fugacious character. It is also distinguished frequently accompanying true or contagious typhus, particularly as described in the article Fever (5 500-503), has a close resemblance to the declining eruption of measles. It is, however, readily distinguished by the history of both diseases, unless when the measles assume the nervous character. In this case the difficulty of diagnosis is much increased. But the more protracted stages of typhus, the profound typhonomia, and the persistence of the eruption long beyond the period of its disappearance in measles, with various other subordinate features, will generally point out its nature to the attentive observer.—d. The early stages of smallpox may also be mistaken for measles; but the marked catarrhal symptoms ushering in the latter, the troublesome cough, the small size of the stigmata, their superficial, slight, and less circumscribed character, and the absence of hardness, will readily distinguish them from the incipient eruption of smallpox.—e. The diffused, comparatively smooth, light, scarlet redness, the severe affection of the fauces, the early appearance at once over all parts of the body, and its occasional sudden subsidence and return, the burning heat and dryness of the eyes, and the tendency to affection of the digestive mucous surface, mark scarlet fever, with which, however, measles have many points of resemblance, fully pointed out under that disease. It has been remarked by Ziegler and my own experience confirms the justice of the observation, that while measles evince a disposition to affect the respiratory apparatus, scarlet fever has a manifest tendency to conquer the cellular tissue. I may add to this, that this latter disease is more intimately associated with a disordered state of the digestive mucous surface, and that this surface is more liable to be diseased in the severe forms of the malady, or after the sudden subsidence of the eruption, than is usually observed to occur in measles.—f. As to rubola, or that intermediate disease between measles and scarlet fever, I will not here point out its distinguishing characters from either one or the other, as this subject is more fully considered in the article Rubola.—g. Roseola is often distinguished with some difficulty from measles; but it may generally be recognised from the circumstance of its being generally symptomatic of delirium, dyspepsia, and a disordered state of the digestive organs. It is very seldom preceded by any very marked fever, or depression of the voluntary powers and vital actions, and is not accompanied by the catarrhal symptoms characterizing measles. It does not superinduce the
morbil affections so frequently observed after this disease.

49. V. Prognosis.—The prognosis in measles is, in many respects, dependent on the type and complication of the disease. Measles is generally less dangerous than the smallpox and scarlet fever. The benign or common form is scarcely attended with any danger, unless as respects its sequelae, or when officiously interfered with. The gastric form of the disease is more serious, but this seldom presents much danger if it be judiciously managed. The inflammatory state should lead us to give a cautious opinion of the result, particularly if it be complicated with croup, bronchitis, pneumonia, pleurisy, or haemoptysis. Of these, croup, pneumonia, and haemoptysis, especially the last, are very dangerous complications. I have met with several cases of haemoptysis in the different stages of measles, but the larger proportion of them have terminated fatally sooner or later, under treatment varied according to the features of the case. The serious and dangerous or malignant forms of the disease are seldom devoid of danger, particularly the latter.

50. Much, also, depends upon the character of the reigning epidemic, which usually, indeed, assumes some one of the varieties into which I have divided the disease. Some epidemics are so mild as scarcely to cause any apprehension as to the result. Others are so severe as to lead us to dread either the immediate or more remote consequences. Partial states that 91 died out of 2807 cases, in 1843, at the London Foundling Hospital, 1 death in 10 cases, and in another year, 1 in 3. In 1793, 6 cases died out of 69; and in 1794, none died of 28 cases in this institution. In 1800, out of 66, 4 died. These results confirm the calculation of Home, who estimated the deaths at 1 in 12. The seasons have also some influence, but chiefly in sporadic cases; for, during the epidemic prevalence of the disease, their tendency is lost in the more predominating character it then assumes. Winter, however, is a less frequent season for the disease than summer and autumn.

51. A premature or retarded eruption generally indicates a severe disease, and one disposed to an irregular form and complicated state. An obstinate, severe, and hoarse cough, accompanied with difficulty of breathing, and much febrile action, prolonged beyond the period of desquamation, evinces a serious affection of the lungs, and danger. Tumefaction of countenance; a pale, yellowish eruption, internunciated with petechiae; copious perspirations without relief of the symptoms, but indicating relaxation of the tissues and of the tone of the extreme vessels; profuse diarrhoea; hemorrhages, particularly those from the air passages and fauces; livid petechiae; a dark or hvid state of the eruption; gangrenous spots or escars; very great debility or exhaustion; a very frequent, very soft, open, or compressible pulse, or an irregular or intermittent pulse; and the presence of nervous symptoms in a marked degree, particularly spasms, or convulsions, are severally most unfavourable symptoms.

The disease is generally more severe in children during dentition, and in young persons near the period of puberty; also in infants during the first or second or third month. Convolusions preceding the eruption, especially during dentition, are unfavourable signs. Adults who have a tendency to pulmonary diseases, or who have previously been affected with them; those of a phthisical or scrofulous diathesis; persons of addicted habits, with debilitated constitutions, and with blurring liquors, and females in the pregnant or puerperal states, generally experience the disease in a severe form. However, the measles are far less dangerous to pregnant women than either smallpox or scarlet fever.

52. The sudden disappearance of the eruption, followed by symptoms of internal disease, or by aggravation of pre-existing visceral disorder, is generally followed by an unfavourable termination. The danger is also great in proportion to the extent and confluence of the eruption, and the violence of the attendant fever. The later the eruption is in supervening upon the fever, the better; the earlier, the worse. Very great lassitude, torpor, and rheumatic pains of the limbs, if experienced long before the eruption, indicate a disease of great severity. Difficult dentition, and hooping-cough, concurring with measles, place the patient in danger. A fatal issue, within the course of the disease, occurs most frequently on the ninth and tenth days. It has been supposed by some writers of the passage of the measles has been severe since the introduction of vaccine inoculation; but I agree with Hildbrand in considering this to be devoid of foundation.

53. b. The favourable indications which occur during the disease are, a moderate eruption with a mitigation of the fever; a disposition to an equable moisture on the skin; a moderate or slight cough, with a mucous and easy expectoration; a free and unembarrassed respiration; a free state of the bowels, and moderate relaxation of them towards the close of the disease: hypostatic urticaria; a slow and slow succession of the changes of the eruption; and no appearance of any irregularity or complication with visceral affection, the existence of which, as I have already shown, often occasions a fatal result at a more or less remote period, owing to the tendency to disorderization being greater in the local affections occurring than when taking place primarily.

54. VI. Causes.—The infectious nature of measles is sufficiently demonstrated, and requires no further comment. The distance to which the emanations from the body of an infected person may infect a sound one has not been shown, nor, indeed, is it capable of satisfactory demonstration; for it must depend
upon the stage and virulence of the disease, and the susceptibility of those exposed to the emaciation. It is probable that the infectious effluvium commences to emanate from the subject of the disease from the first appearance of the eruptive fever, and that it increases in activity until the period of desquamation, after which it declines; but it has not been shown satisfactorily when all power of infection ceases. That the infectious effluvium is formed as early as during the primary fever, and before as well as after the appearance of the eruption, has been proved by several occurrences by which exposure to infection has been limited to certain periods of the malady.

55. b. As in other infectious maladies, so in the morbid effluvium and the disease perpetuated, even after periods of its apparent cessation or disappearance, by fomites, or by the inimibility and retention, for a considerable period, of the morbillous microbe expelled by the infected. Dr. Williams adduces an instance of this, and similar instances on a smaller scale, as respects the results, must have occurred to every physician. A boy from the Foundling Hospital visited at a house where a child was ill of measles. The boy returned in the evening, and mixed with his fellows as usual; but in the course of fourteen days he and all in his family were infected with the morbillous of the disease. The experiments of Howe, Speranza, and others have furnished numerous other proofs of the propagation of the disease by fomites.

56. c. Although the chief modes in which the malady is disseminated are emaciations proceeding directly from the sick, and emanations absorbed and retained for a time by woollen or porous bodies, and afterward given off, still it may be spread by contagion and inoculation. Home, Vogel, Wachsel, Brown, Monro, and Tisser have proved the contagious nature of measles by inoculation, either with the blood, or with the serum taken from the vesicles which are occasionally intermixed with the eruption. It was supposed by some of the physicians just mentioned that a mild form of the disease was produced by inoculation; but the experiments made by Cullen, Rosenstein, Girtanner, and Vaidy have not confirmed this opinion; and the inoculation of measles has never been even partially adopted. The latest trials seem to have been made by Speranza in 1822, who inoculated seven persons, who had the disease regularly and mildly.

57. d. The latent period, or the time which elapses from the impression of the morbid effluvium on the sound constitution until the appearance of the eruption, varies from six to twenty-one days. In the cases of the inoculated disease, the eruption appeared on the sixth and seventh days. (See art. Infection, § 31.)

58. e. The morbid seminum or poison of measles may coexist with some other morbid poisons, as observed by various pathologists. Macbride states that he occasionally saw measles and smallpox in the same patient at the same time, and that the combination was generally fatal. The coexistence of these maladies, either taking the precedence, has been noticed also by De Haen, Vogel, Horn, Pinkel, Bateman, and Williams. The coexistence of cowpox and measles, and of hooping cough and measles, is not infrequent.

59. f. The morbillous miasm, having produced its specific effects, leaves the frame exempt from a second attack. But this exemption is not universal. It is so general, however, as to induce such experienced observers as Williams and Cunningham to believe in its universality; while the exceptions to this law are so rare as to be observed only by few, and, probably, in certain epidemics only. Second attacks have been recorded by Burserus, Rohden, Home, Baillie, Webster, and observed also by the author. It has been fully ascertained that the spurious disease, which has been termed "Moebii sine catarrho," does not protect the system from true measles; but it has not been shown that those cases of morbillous and morbid poisons; and eruptions (§ 31), admit of a subsequent attack.

60. That the morbillous miasm contaminates the circulating fluids, and even the solid solids, and so infects them as to enable them to propagate the disease, is shown not only by the experiments alluded to above (§ 56), wherein the fluids communicated the malady, but also by the fact of infants having been born with the morbillous eruption when their mothers have been the subjects of the disease at the period of parturition.

61. As the measles have been said to have appeared at the same time, and in the same country, they have been presumed to have had a similar local origin. But the measles, Dr. Williams observes, now prevail all over the world, occur at all seasons, and frequently without our being able to trace them to any contagious source; so that we may infer that the morbillous poison is generally diffused through the atmosphere, and at all times of the year. But such can hardly be the case; for, as measles are an infectious as well as a contagious disease (see art. Infection, § 4), and are diffused chiefly by fomites, as the fomites retain the morbillous poison for a long period in temperate or cold climates, and as the susceptibility to infection by it is extremely great, in the young more particularly, while the period which elapses between the first impression of the cause and the development of the disease is long, so it seems the more probable that the extension of the poison will be rapid, wide, and traced with so little difficulty, or not traceable at all, without the general diffusion of it in the atmosphere supposed by Dr. Williams.

62. A few years ago, the measles were introduced into the Cape of Good Hope, where they had not appeared for about thirty years, by a vessel from Europe, in which several cases occurred during the voyage. The disease spread, and with its diffusion the difficulty of tracing the sources of infection in individual cases increased; all being susceptible of infection under thirty or thirty-one years of age. The heat and dryness of the climate during several months of the year being unfavourable to infection, the malady soon disappeared after those susceptible of it had become infected, few remaining liable to it but infants born after its introduction into the colony.

[Prof. Caldwell states that the measles prevailed epidemically in the city and county of Philadelphia, beginning in 1772, every sixth year for a period of 50 years. Prof. Chapman, however, remarks, that for the last 30 years,
there has been no interval of exemption from the disease for any length of time; that, although it may have been suspended for a year or more, it was generally met with annually, either sporadically or epidemically. It seems to have prevailed occasionally, in an epidemic form, from the earliest settlement of this country, and would seem to spread with greater rapidity than almost any other epidemic malady. In 1801, for example, it overran nearly the whole of the United States in a few months; and in 1823 it was scarcely less pervading, affecting even the brute creation, domestic animals having been observed to suffer severely with scarlatina.

The probability of its origin in a mass of proceeding from numbers of persons breathing a confined air with their cattle has been hinted at by Hildendrand. "In diversis ac dissitis villis, præsertim in vaccarum stabilis, in quibus pluræ sepe familias unam prolitis unite totam ferine transfigurant brunam, morbillosum emicere vidimus contagium consque vigens, donec plurimos individus infectis, talique pacto hominum dispositione extincta, exhusto igitur quasi solo, in quo radices figure possit, in leoque bis incidentem occasionem deprehendens, nostris quoque sub zona huncse fomites contagiosum in morbis catarallibus gravioribus, opulente constitutione annua, vel specifica plurium hominum et animalium habitatibus mphfe, primatus oriri posse, conjectura quidem foret, nobis omnino non improbabili, quam tamen ob defectuum observationum defendere nondum auderemus." (Instit. Pract. Med., i. iv., p. 339.)

61 b. The predisposing causes of measles are chiefly the epoch at childbirth, or any period antecedent to puberty. But a susceptibility of, or predisposition to the disease, exists in all persons who have not been infected by it; probably, however, decreasing with the progress of age after the period of puberty. The influence of season is not strikingly manifested, as the disease may be epidemic in any season in temperate climates. According to the Report of the registrar-general, the deaths from measles in the metropolis were 173 in the first, 96 in the second, 94 in the third, and 351 in the fourth three months of 1836; 251 in the first, 623 in the second, 782 in the third, and 380 in the fourth three months of 1839; 194 in the first, 275 in the second, 308 in the third, and 355 in the fourth three months of 1840; 158 in the first, and 147 in the second three months of 1841.

65. Although the prevalence of measles appears to be but little dependant on season, still some influence may be imputed to it—an influence much insisted upon by Sydenham and others, who considered that the disease was usually most prevalent during the first half of the year. More influence is evidently owing to certain epidemic constitutions of the air, which are manifested chiefly by their effects, than to either season or weather; for, at all seasons, and in all kinds of weather, merely occasional cases of the disease may present themselves; and these only may appear for a long period; when suddenly the disease may assume an epidemic form, without any circumstance in the weather or season being observed that can account for the change. Generally, however, incases are epidemic when catarrhal affections are also prevalent; and a frequent connexion has been remarked between epidemic hooping-cough and this disease.

66. VI. AETIOLOGY.—The scope and object of the treatment of measles are, 1st, to moderate and preserve the vital actions; 2d, to subdue or soothe the more troublesome symptoms; 3d, to aid and direct critical efforts, and prevent unfavourable determinations or metastases of morbid action; and, 4th, to prevent or remove the sequelæ or morbid effects of the disease. These intentions nearly agree with those mentioned by Hildendrand. The more general indications, however, to alleviate unfavourable symptoms as they arise, comprises the whole of the foregoing.

67. a. During the eruptive stage, it is chiefly necessary, as Dr. G. Burrows well observes, to pay attention to the regular action of the bowels, to confine the patient to bed, in a moderate temperature, and to a light, farinaceous diet, with cooling and demulcent drinks. The heat of skin preceding the appearance of the eruption is best treated by moderate doses of the liquor ammoniac, and spiritus aetheris, or mixture of the in the external application of cold at this period is not unattended by risk, especially of increasing the bronchial and pulmonary symptoms.

68. In mild cases no farther means than the above are requisite throughout their course. Willan, however, prescribed an emetic on the second or third evening, conceiving that it alleviated the violence of the catarrhal symptoms, and tended to prevent the diarrhoea which usually succeeds the disease; and Dr. Poucher still administered repeatedly antimonial emetics. This latter plan, however, requires caution, and is suited only to cases in which the tracheal or the bronchial and pulmonary affection is considerable, and the accumulation of mucous and mucus-albaminous matters in the bronchi is great and expectorated with difficulty. Dr. Willan remarks, that he has not observed any considerable effect from antimonials, or other diaphoretics, during the eruption: that bathing the feet every evening seems more beneficial; and that emulsions and mucilages after the febrile or no relief to the cough and difficulty of breathing.

69. b. In the inflammatory state of the disease, in which the bronchial membrane, and even the substance of the lungs, the conjunctiva, &c., are the seat of congestive inflammatory action, blood-letting, general or local, or even both, is requisite; but, unless symptoms of inflammatory action present themselves, this measure should be reserved. Sydenham directs blood-letting when the fever is violent, with difficulty of breathing, and other pulmonary symptoms. Cullen remarks, that as the symptoms of pneumonic inflammation seldom come on during the eruptive fever, and as this fever is sometimes
violent immediately before the eruption, though a sufficiently mild disease be to follow, so bleeding is seldom necessary during the eruptive fever, and may often be reserved for periods of greater danger. WILLAN and BATTEN are adverse to bleeding early in the disease, because oppression of breathing, with labouring pulse on the first or second days of the eruption, usually disappear in the course of twenty-four hours. But when the eruption has disappeared, and the cough, pain of the chest, and difficulty of breathing become severe, bleeding and cupping become necessary. WILLAN, however, the symptoms are decidedly inflammatory early in the disease, bleeding ought not to be deferred, for it may be too late if it be put off until the eruption has disappeared. As to the quantity of blood which may be taken, no directions ought to be given. It always should be regulated by the character of the epidemic, and the states of vital power and reaction. Patients in large cities and manufacturing towns cannot bear losses of blood equally with the well-fed, and those breathing a pure or country air; nor is even the inflammatory state of this disease equally tolerant of vascular depletion with primary or pure pneumonia or bronchitis. As in all diseases which are produced by an infectious or contagious miasm, so in this, although in a somewhat less degree than in some, blood-letting should be practised with caution; and even the inflammatory complications they may present or induce are less under the control of, and are less benefited by this treatment, than inflammations which are not thus produced, and not so allied.

70. The opinions of writers as to the propriety of blood-letting in measles have been influenced chiefly by the character of the epidemics which came under their observation; for, while most writers of reputation admit the propriety of this measure in the inflammatory state, they equally condemn it when no such condition exists. HAMILTON, MURRAY, and others did not have recourse to it, probably in consequence of the non-inflammatory nature of the epidemics they had to attend. MORTON, HERBENDEN, HORN, FERGUSON, ARMSTRONG, and others considered that bleeding should form a part of the treatment of the disease, manifestly owing to the inflammatory form of the epidemics which they observed. HERBENDEN advised it whenever the breathing is oppressed. MEAD states, that "about forty years ago the measles raged with great violence in the city, and were more fatal than even the smallpox," and that he always opened a vein in the beginning of the distemper, or as soon as he could "because the disease always brings with it a peripneumony." MORTON deferred blood-letting until after the eruption is completed, the malady being, in his opinion, most inflammatory at that time.

71. Every observing physician must be convinced that in London especially, and in most very large towns, bleeding ought not to be generally adopted in the treatment of measles, although it may be practised with greater impunity in them than in other infectious maladies; and that it should not be neglected in the pulmonary and other inflammatory states of the disease noticed above (§ 42). DR. WILLIAMS justly observes, that we should be content with modifying the symptoms by it; for as the disease has a specific course to run, a sudden cure ought not to be expected. The bleeding, also, should be more moderate during the eruption than after its subsidence; for a mitigation of the symptoms may be expected when it disappears. The presence of menstruation should not deter from blood-letting when clearly required, although it may indicate a more moderate recourse to it.*

72. In aid of vascular depletion, when clearly indicated, and even independently of this agent, when the recoverers of life are too low to admit of it, calomel and opium with ammon, if the sthenic condition prevail, or with camphor or ammon, if the asthenic state is prominent, should be prescribed; and the pulmonic complication otherwise treated conformably with the principles developed in the article on inflammations of the Bronchi and Lungs (see these articles).

73. In all cases, particularly when the eruption has disappeared, of vesicular affection, or if the propagation of the eruption of the organ, the application of rulefacient embroations, blisters, &c., in aid of such other means as the characters of individual cases suggest, will prove of service. When the eruption is repelled by exposure to cold, the treatment should depend upon the frequency and strength of the pulse, and the organ chiefly affected; but in these cases, a strenuous recourse to warm diaphoretics, to the warm bath, to which salt and mustard may be added, and to active rubefacients, blisters, and other external derivatives, is more likely to be indicated.

74. c. In the gastric form of measles, and particularly if associated with hooping-cough, an ippecacuanha emetic early in the disease, or even repeated in the course of it, is often of service. In these calomel and the milder forms of mercury, aided by aperients, are generally required to evacuate accumulated biliary and intestinal secretions. If, in this state of the dis- temper, the eruption be imperfectly evolved, or if it retrocede prematurely or suddenly, the use of warm baths, and applications of rubefacients (§ 73), &c., should be prescribed.

75. d. In the nervous state of the disease, particularly when associated with convulsive or spasmodic symptoms, with singultus, stupor, startings of the tendons, &c., cupping on the nape, or leeches applied behind the ears, when the patient is plethoric, or signs of cerebral pletthora are present, free evacuations of the bowels, and camphor, with small doses of opium, or with hirnhan, are generally of great benefit. The remedy will be called for, according to the state of the case.

* (We believe, with Dr. CHAPMAN, that more circumspection is necessary in the treatment of measles than it usually receives, and that its sequelae are, for the most part, the results of imperfect care, which might be obviated by better practice. General bleeding is certainly one of the most important means of preventing, as well as obviating, those serious complications which so often endanger life in the course of this disease, and it is a remedy which should not be postponed, where symptoms of pulmonic affection supervene, as they frequently do. External revulsives, at the same time, should also be employed, and every means used to relieve congestion of internal organs. We, however, meet sometimes with a typhoid form of measles, which will not yield to bleeding: here we employ the warm bath and other revulsives, warm wine whey, snake-root, ammon, camphor, quinine, and, in some cases, cups or leeches. In all cases the temperature of the room is to be carefully regulated, and the diet and drinks suited to the exigencies of the case.)
or imperfectly evolved in this variety, ammonia, capsicum, ether, various aromatic spirits, and other diffusive stimulants may be exercised; and upon the use of terebinthinate embrocations, and blisters applied only for a few hours. In young children, however, opium and blisters ought to be employed with great caution.

76. e. The septic, putrid, or malignant form of measles requires the exhibition of camphor, ammonia, cinchona, or quinine, the alkaline carbonates, capsicum, the chloride of potash, the chlorides, creosote, and other medicines of the same kind, variously combined, according to the features of the case. In a free use of water and bland diuretics of the opiate, rhubarb, of repeated and conjoined with aromatics, stimulants, &c., are generally used. It has been supposed that local bleedings may be of service early in this form of the disease; but, however early they may be employed, they are of doubtful efficacy. In most respects, the treatment should be directed as recommended for dy

77. f. When diarrhoea follows the disappearance of the eruption, diaphoretics with gentian anodynes, as with sirup of poppies, or the par
garcin elixir; the warm bath, rubefacient embrocations on the abdomen, and mucilaginous or farinaceous articles of diet, are most appropriate. If the diarrhoea be slight, and the evacuations feculent, small doses of hydrargyrum i.e., creta, of pepecuanha, rhubarb and magnesia, are most beneficial, and should be occasionally given, even when it is found requisite to re

MEASLES—TREATMENT—BIBLIOGRAPHY.

rence not frequently observed, the diagnosis is extremely difficult. The Arabian physician Avienzar is the first who attempted a history of this disease. According to Friend, he had been afflicted with it. After him, Salius Diversus (De Pneum. Pec. et Curat. part. Mort. vii. p. 247) has taken particular notice of it, and recorded several cases in which he observed it.

3. i. Symptoms.—Obtuse and deep-seated pain behind the sternum, and extending to the upper part of the back, between the shoulders, and declining towards the epiasternal cartilage. A sense of constriction and internal heat in the same situation; great inquietude and anxiety, thirst, dry cough, or with scanty coloured expectoration, and inflammatory fever. In addition to these, Salius Diversus enumerates short and frequent inspiration, not materially increasing the pain as in pleurisy, unless on a forced respiration; hard, frequent pulse, and decubitus on the back.

4. When the disease is complicated with pleurisy, which is often the case, or with pneumonia, the disease may not be recognised even after attentive examination. If the inflammation extend, or be coetaneous with pericarditis or carditis, as post-mortem examinations sometimes show (Portail, Annot. Méd., t. v., p. 28), palpitations of the heart, syncope, or leiothymia, quick, tumultuous, irregular pulse, in addition to the foregoing symptoms, will frequently indicate the nature of the complication. Mediastinitis occasionally supervenes in the progress of fevers, and even goes on to suppuration without being detected, until upon post-mortem inspection.

5. ii. The causes of mediastinitis are chiefly internal injuries; fracture of the sternum; wounds; the suppression of discharges; the repulsion of chronic eruptions; and the usual causes of pleurisy or pneumonia. (See Arts. Lungs, § 80, et seq., and Pleura.)

6. iii. The prognosis in mediastinitis should be very guarded. The disease seems more disposed than pneumonia to terminate in abscess; and, even when its violence seems subdued, an unfavourable issue may take place. Vanden Wiel (Obs. 19, cent. ii.) records a case which suddenly terminated fatally on the eighth day, the symptoms having been apparently diminished for a short time before.

7. iv. The terminations of mediastinitis are, 1st. In resolution; 2d. In abscess; 3d. In thickening and induration; and, 4th. In death. (a) Resolution of the inflammation takes place with similar phenomena to those I have stated in pleuritis and pneumonia.—b. Death is generally occasioned by the extension of the disease to the adjoining viscera, and the effects thereby produced upon the functions and organs of circulation and respiration. It may also result from the formation of abscess, or from the consequences of chronic inflammatory action continuing after the more acute symptoms have disappeared. Of these I proceed to take some notice.

8. c. Abscess in the mediastinum has received the notice of physicians since the time of Galen, who mentions a case of it from a wound. J. P. Petit records an instance of it from a blow on the sternum. Van Swieten details another consequent upon primary inflammation of this part; and numerous other cases are furnished by Balck, Columbus, Langlet, Vicq d'Azyn, David, Blanchard, De Précis, Forwell, &c.

The abscess is generally seated in the cellular tissue, connecting the laminae of pleura forming this partition, and is the consequence of inflammation arising either spontaneously or from injuries, and, according to the observations of the above authors, is often connected with the scrofulous diathesis and the venereal taint. It may also form in the course of idiopathic fevers.

9. d. The symptoms indicating abscess in the anterior mediastinum are, after the way I have mentioned (§ 3) as characterizing inflammation, the sensation of cold in the course of the spine, with chills or rigours, followed by flushes of heat or perspirations; deep-seated, heavy, and pulsating pain behind the sternum, and extending between the shoulders; oppression, palpitations, syncope, or leiothymia; slow or hectic fever, with irregular chills or rigours; dry, short cough, difficult, wheezing respiration, inability to lie down, &c., and all the phenomena characterizing the presence of purulent formations. If the powers of the constitution continue sufficiently long, the purulent collection endeavours to find its way externally. In some cases it becomes diffused into the abdomen, through the anterior triangular space over the centre of the diaphragm. Occasionally it partially detaches the pleura from the sternum and the costal cartilages, and appears externally at one side of the sternum, forming a round, soft, fluctuating tumour. In the case of a boy aged about six years, who was attended by the late Mr. Earle and myself, the abscess made its way externally at the right side of the lower end of the sternum, and recovery took place. In other cases, the matter, after being long pent up beneath the sternum, destroys and perforates a portion of this bone. In some cases of abscess in this situation the preceding inflammation commences in the sternum itself, or its internal surface, and the caries of it proceed pari passu with the formation of matter beneath it. In cases of this description, the extent to which the destruction of bone takes place and the external wound are much greater, so much so in some instances that the pericardium has been exposed, the heart appearing through it. The immortal Harvey showed a case of this description to Charles II.; and a similar case was observed by Galen.

10. Abscess in the mediastinum is always a most dangerous disease, owing both to its proximity to vital organs, whose functions it impedes, and to the difficulty of ascertaining its existence previously to the appearance of the most serious symptoms. The prognostic should therefore be given accordingly. The cause in which it originated, the state of the vital energies of the frame, and the existence of scrofulous or venereal taint, will also influence the diagnosis.

11. v. Treatment.—Mediastinitis, before it has gone on to suppuration, or to any other unfavourable termination, should be treated as fully stated in respect of pneumonia and pleuritis. (See Art. Lungs, § 91, et seq., and Pleura.)
12. When we have reason to suspect the formation of abscess, the occasional application of a few leeches, and persistence in the antiphlogistic treatment and regimen, particularly in aperients and diuretics, will be serviceable as long as the inflammatory symptoms continue, and the pulse retains much force or none. In an antiphlogistic system, when the pulse is very weak, small, quick, and compressible, and the energies of the system seem insufficient to resist the extension of local mischief and contamination of the frame, then vegetable tonics and bitters, and the mineral acids, alone or combined with tonics, are indicated. When the abscess points externally it should be opened with a lancet, its contents partially removed, the aperture carefully closed so as to exclude the air, and the operation repeated according to circumstances; employing, at the same time, the medical treatment just indicated, viz. small depletions, &c., when action is increased; and when the vital energies require support, digestive nourishment, and the tonic means now stated, and the various remedies advised in the article Abscess (§ 62, et seq.).

13. When the purulent matter is confined below the sternum, producing slow destruction of the surrounding parts, with caries of this bone, the majority of authors quoted above recommend the sternum to be trephined, and an external outlet to be thus given to the matter. Juncker and Platner consider it less dangerous than a similar operation performed on the cranium. Dionis adds a case in which death followed the performance of this operation, but this result was probably not caused by it, or even might have been averted by an earlier recourse to it. Petit, Colon, and Lamartine consider it the only resource in cases of this description, and one which will occasionally be successful. Lasseas states, in his work on surgical pathology, that he treated a physician who had an abscessuto opening about the styphous cartilage, from an abscess in the anterior mediastinum, for fifteen months; its enlargement had been recommended by some surgeons. This was prevented, and the patient recovered perfectly in a few months afterward.

14. Abscess may also form in the posterior mediastinum, though less frequently than in the anterior. In this situation it may be the result of inflammation of the vertebral, or intervertebral substance, or of caries of the former, or it may originally take place in the connecting cellular tissue, and produce caries of the vertebrae from pressure, constant dysphagia, and disorder of the heart. When occurring in the posterior mediastinum, it may have been caused by violent exertion, rheumatism affecting the fibrous structure of the vertebrae, syphilis, scrofula, &c. The symptoms produced are generally more severe, and the result more uniformly fatal, than when abscess forms behind the sternum. Death often takes place suddenly, and then, and frequently not until then, is the cause made known.

15. vi. Thickening and induration of the lamina of the mediastinum are generally the result of chronic inflammatory action. Sometimes these changes are so considerable as to approach to the state of cartilage, in which state M. Portal found them in a case of hydrothorax consequent upon bronchitis.

16 vii. Other organic changes in the mediastinum are occasionally met with, especially serous or tuberculous depositions, enlargement of the thymus gland, lardaceous and abuminous collections of fat and fatty tumours; effusions of blood and serous inflammations. Instances of these are to be found in the writings of Bonet, Morgagni, Lieutard, Riviere, Corvisart, &c. I saw an instance in which serous or tubercular depositions in, and enlargement of, the lymphatic glands lodged in the mediastium occasioned fatal pressure on the trachea and large blood-vessels. Portal records a case in which death was occasioned by a stenatomous tumour formed in the posterior mediastium, and pressing on the large vessels and nerves.

1. Defin.—Discharges from the bowels, or from the stomach, or both by stood and by the mouth of a black, or nearly black matter, consequent upon mucosal or constitutional disease.

2. By Hippocrates and the ancients generally the term melena was applied to the vomiting of black fluids; but, since the appearance of the writings of Hoffmann and Sauvages, it has been extended, and chiefly confined to the discharge of a black matter from the bowels. In the above definition I have extended its acception, so as to embrace the meaning attached to it by both the ancients and moderns.

3. The black colour of the discharges has been variously explained by writers. By the ancients it was imputed very generally to the altered colour of the bile, and by the moderns as generally to the admixture of blood with the secretions and fecal matters in the bowels. Hence, Dr. M. Good divided melena into M. Cholæa and M. Cruenta. When treating of the latter state of this consecutive malady, in the article Hæmorrhage, Intestinal (§ 190, et seq.), I pointed out a third source of variety, namely, in morbid secretion from the mucous follicles. Dr. Graves has illustrated and confirmed this view in his demonstration of the stomachic division of the stomach, the remarks, that a large man, accustomed to eat and drink largely, passed by stool and vomited enormous quantities of black fluid, and experienced crautations of sulphured hydrogen. His tongue was as black as ink. Dr. Graves states, that he ascertained, by numerous experiments, this black fluid to be a secretion from the mucous membrane of the bowels.
4. I. Forms.—From what has just now been stated, it will appear obvious that melena, in all its forms, 1st, as resulting from the exudation of blood from the digestive mucous surface, or the admixture of it in any way with the contents of the digestive canal; 2d, as proceeding from a thick, viscid, and black state of the bile; or, 3d, as owing to a morbid secretion from the digestive mucous surface and glandular apparatus, is entirely a symptom, or consecutive malady; that it altogether is a constant phenomenon upon visceral and constitutional disorder, or structural disease.

5. i. The first, or sanguineous variety of melena, I have treated of at length in that part of the article Hemorrhage already referred to. It is not, therefore, necessary to discuss this part of the subject farther at this place. I may, however, add, that this is the most common form of melena, and that a black matter is not infrequently discharged by vomiting and stool in malignant diseases—both those of a local character and those of a general nature—cases of a febrile and pestilential nature, as yellow fever (see articles Pestilence and Stomach). But although this matter is principally owing to an exudation of blood, either partially altered previously to its extravasation, or chiefly or entirely changed subsequently to its escape from the vessels, by admixture with other matters in the digestive canal; still there is reason to believe that the states of the bile and other secretions in those malignant and constitutional maladies contributes somewhat to the black or very dark hue of these discharges. In some of the many cases of malignant purperal fever I have seen, the fluids discharged by vomiting and by stool have presented the blackish hue of melena; and, after the best attention I could bestow upon the subject, I have considered this hue to be owing to the state of the secretions chiefly; in some instances, however, partly to the admixture of a bloody exudation.

6. ii. The second source of melena, or altered bile, has been also attended to in the articles Gastro-enteritis and Diarrhoea from the Intestines (§ 193, 194), and the means of distinguishing between melena from this and other sources have been there pointed out. In this variety the stools, and sometimes also the matters vomited, present a greenish-black hue, the former being of the consistence and colour of tar or treacle. Two females, the one about, the other above middle age, complained of attacks similar to spasmodic asthma associated with chronic disorder of the liver, and occasioned by vomiting the passing of gall-stones or spasm of the gall-ducts, the countenance being sallow and the bowels confined. I prescribed the strenuous exhibition of cholagogue purgatives, which brought away pithy evacuations that assumed a greenish hue when diluted with water, and entirely removed the attacks.

7. iii. The third source, or the secretion of a blackish substance from the internal surface of the intestines, is probably of much less frequent occurrence than the foregoing. It may arise in a similar state of the system to that which disposes to the production of melanos; the vital powers, and the state of the circulation and of the blood in the capillaries of the digestive mucous surface and glands, not admitting of the due combination of the carbon of the blood with oxygen, so as to form carbonic acid to be discharged by the lungs; but allowing the carbon to accumulate, so as to exude from the surfaces of secreting and yielding membranes.

8. II. Diagnosis.—As Hoffmann has observed, melena is to be especially distinguished by the turmis, spasms, and pain preceding and accompanying the black evacuations, and by the danger in which the patient is placed—a danger frequently becoming the treatment with the continuance of this appearance of the discharges. When, however, it depends upon the excretion of long-pent-up and altered bile, a rapid recovery often follows the evacuation, as in the cases just noticed, and in others that I have seen. In one of these, the patient, who is still alive, and to whom I was first called about twelve years ago, has had frequent attacks of great severity, the copious, black, treacle-like stools being always followed by recovery. The colour of the stools was greenish, and afterward a yellowish-green hue, when diluted with water. If the black discharge be blood altered by the secretions, c.e., it usually presents a reddish hue when diluted with water, or with water containing a little carbonic acid of soda; and when this kind of discharge is put in a small linen bag, and plunged in warm water, the linen is stained of a reddish colour; but when the black fluid, which is excreted from the third source mentioned above (§ 7), is thus treated, the colour is not materially altered. It should, however, be recollected, that various articles taken into the stomach occasion a black appearance of the evacuations, as black puddings, the preparations of iron, and the acetate of lead when it meets with sulphuretted hydrogen gas, &c.; that others give them a red colour, as logwood, bilberries; and some a blackish green hue, as spinach.

9. III. Prognosis.—Melena is generally a dangerous symptom, unless when it proceeds from the passage of blood in small quantity, or in aundetermined state into the intestinal canal, in some one of the less important cases of hemorrhage. It may attend apophasis and haematemesis from suppressed menstruation, and then it cannot be considered a dangerous phenomenon; but, in most other cases, and even when it proceeds from biliary accumulations and morbid secretions, it may be viewed as a highly unfavourable occurrence. The prognosis, however, should depend upon the particular source of this change, and upon the various pathologic conditions of the heart, the vital power, existing in connexion with it.

When it occurs in the course of low, adynamic, or putrid fevers, or of malignant diseases, it indicates a fatal result.

10. IV. Treatment.—a. When the black state of the discharges proceeds from hemor-
MELANOSIS—TRUE—Its Seat.

rhage, then the treatment recommended for hemorrhages from the stomach and intestines (§ 148, 194, et seq.) is the most appropriate, more particularly the exhibition of spirits of turpentine, as then advised. In addition, however, to the usual remedies employed to restrain the exudation of blood, means are required to support the powers of life; and frequently such restoratives should be of the most energetic kind, as brandy, port wine, the hot spices, &c.

11. b. When the black matter seems to consist chiefly of altered bile, or of morbid intestinal secretions, chologogue purgatives, with stimulants, antispasmodics, restoratives, &c., are of general application; but a general consumption of these must necessarily much depend upon the previous history of the case, and the existing pathological states. Melena from these sources is a comparatively rare contingency upon prolonged disorders or complicated diseases, and should be treated according to the several forms which these assume. (See more especially on this subject the article Hemorrhage from the Intestines, § 200, et seq.)

MELANCHOLIA.—See Insanity (§ 106, et seq.)

CLASSIF.—IV. CLASS. H. ORDER (Author).

1. Degeneration, produced in a black, or blackish-brown colour, dissimilar from any other formation or structure, whether healthy or diseased, occurring in various forms in different parts of the body.

2. This was described first by M. Laennec (Bulletin de la Soc. de l'Ecole de Med., 1808), Duguyten, and Bayle, as a distinct disease. It seems, however, to have been previously noticed by Mr. Wardrop, but considered by him as a species of fungus haematodes. The division of the several forms of melanosis suggested by laennec has been very generally adopted; but the results of more recent researches have suggested arrangements, or, at least, modifications, of these arrangements. Melanotic formations, Dr. Carswell remarks, may take place in various and different parts of the body; may present much variety of form, and may owe their production to different agents. But, while I admit the first and second of these propositions, I dispute the third; inasmuch as it is not applicable to true melanosis, and applies only to that comprehensive classification which comprises, as forms of melanosis, those alterations in the colour and texture of parts produced by the introduction of carbonaceous matter into the system, by the action of chemical agents, and by the stagnation of the blood. These latter alterations have been denominated spurious melanoses, and will be briefly noticed in the sequel.

3. I. TRUE Melanosis.—I. Its Seat.—a. The cellular and adipose tissues are the most frequent seat of this disease, and in them it occurs in the largest masses and most circumscribed forms. Owing to the distribution or extension of these tissues, it spreads or extends itself, as in the course of blood-vessels, &c.—b. When melanosis is found in the skin, it is most commonly an extension only of that existing in the subjacent cellular or adipose tissues, and is very rarely a primary alteration of the skin.

c. Dr. Carswell believes that this change very rarely occurs in mucous membranes, those cases in which it seems to exist in these being really instances of it only in the subjacent cellular tissue.

d. Arterial, venous, and muscular tissues; serous and synovial membranes; aponeuroses, tenons, and cartilage, do not contain melanotic matter as a primary alteration, although they present the dark brown or black colour, arising from contiguity with, or from the inhibition, infiltration, or exudation of this matter when in a state of fluidity, or from other causes about to be noticed.

e. The spongy bones, as the sternum, are more frequently affected than the other bones. —f. The liver is, of all the compound structures, the most frequently the seat of melanosis, ranking, in this respect, next to the cellular and adipose tissues. —g. Melanosis occurs much less frequently in the lungs than in the liver, nor does it acquire the same bulk or extent as in that organ. —h. It has been very rarely seen in the spleen and brain. Instances, however, have been met with by Lobstein and Hooper, of its occurrence in the latter.

i. Melanosis has been occasionally observed in the eye, in the pancreas, and lymphatic glands, in the thyroid and parotid glands, in the kidneys, in the testes, in the ovaries, uterus, and mamma. In all these it may exist either alone, or associated with other morbid products. —k. The malignant form of melanosis has been detected in the blood. Dr. Carswell states, that it has chiefly been in the minute veins of the liver and eyes melanosis has been found; the vessels containing this matter appearing like black lines, or striæ, or dots, and sometimes in a pencilled form. —l. Melanotic fluid or matter is very rarely found on the surfaces of cavities, natural or accidental, unless as an exudation from parts underneath, or from the perforation of melanotic tumours.

4. Melanosis is sometimes found associated with other morbid productions. Breschet, Andral, and Lobstein have met with it in the false membranes formed on serous surfaces; and the last-named pathologist has seen it accompanying ossific deposits in the coats of arteries. It is occasionally found associated with scirrhus, carcinoma, and fungo-haematoid formations, not only in the same organ, but even in the same diseased mass. This combination of these morbid productions has induced some writers to consider melanosis as a species of cancer; but the incorrectness of this opinion will appear in the sequel.

5. n. The Forms of TRUE Melanosis.—These are altogether four: 1. The punctiform; 2. The tuberiform; 3. The stratiform; and, 4.
MELANOSIS—ANATOMICAL RELATIONS OF.

The liquid form.—1. The punctiform melanosis is that in which the black colouring matter appears in minute dots or points, grouped together, or scattered over a considerable extent of surface. This form agrees with that which Lenz denominated the infiltrated. Dr. Carswell states that this is most frequently met with in the liver, the cut surface of which appears as if dusted with soot or charcoal. Under a lens the black points appear stellated or pencilled, and in some instances are distinctly seen to originate in the真皮 layer. It is the diffusion of a minute vein filled with black matter. In other instances, the black substance appears to be deposited in the molecular structure of the organ. This form is not met with in the brain, nor in the cellular, adipose, serous, and fibrous tissues.

6. **Tuberiform melanosis** is by far the most common form of the disease. It varies in size from that of a pin’s head to that of an orange in man, or to that of a melon in the horse. The great size which these tumours sometimes assume is owing to the agglomeration on the surface of smaller tumours, the size varying with the number and size of the constituents. The form of these tumours is spheroidal or ovoid when single, and generally lobulated when aggregated. The single tumour occurs most frequently in compound tissues and organs; the aggregated in the cellular and adipose tissues. Both the single and aggregated melanotic tumour may be either encapsulated or non-encapsulated. In the latter, the black matter is in immediate contact with the tissue of the part. In the former, the cyst is formed of condensed cellular tissue, stretched out around the contained matter, and forming a thin, transparent envelope to it. Encysted melanotic tumours do not occur in a very perfect or distinct state in any of the compound tissues or organs, but chiefly in cellular and adipose tissues, owing to the nature of these tissues. The melanoid tumours found occasionally on the surface of the peritoneum and pleura, and there even assuming a pedunculated or polypous appearance, seem to be developed, in most instances, under the serous membrane, carrying the membrane before and around them; it thus constituting a thin cyst or envelope; yet, in rare instances, the black matter has been found external to, or upon the free serous surface, enclosed in a loose, spongy tissue, or serous covering of considerable tenacity, but of great tenuity.

7. **Stratiform melanosis** occurs only in serous membranes. The black matter either may occur upon the serous surface, or it may form a almost distinct layer on the serous surface. In the latter case, the consistence of the black matter is of very firm jelly, or somewhat greater. It seems to be deposited in a very fine, transparent, soft, spongy tissue, like that enclosing the melanoid matter in the serous melanotic tumours just described. This form of melanosis is not often met with in man, but to a much greater extent in the horse.

8. **Lobular melanosis** is chiefly formed in natural or morbid cavities. It is occasionally secreted or exuded in these situations, or effused during the softening process of melanotic tumours. It is very rarely met with in man. It has been observed in the serous cysts formed in the ovaries, and the capsules of the ova which have escaped from these organs.

9. To these four forms of melanosis, which has been minutely described by Dr. Carswell, a fifth has been added by Dr. Noak, which he denominates melanosis aprica, vel ulcerosa; and Dr. Savenko has proposed another, which he describes as carciromatos. The former is more frequently met with in the horse than in man, and is merely a consequence of certain changes produced in the tissues by the matter deposited, that will be hereafter noticed; the latter is only the association of cancer with melanosis.

10. E. One or more of these forms may coexist, and either may exist singly. The tuberiform deposite is the most common and conspicuous of all the forms melanosis assumes. The disease is never confined to one tissue or organ only; but is found to pervade a greater or less number of these either simultaneously or successively. It may be almost equally extensive in all parts which it invades, or it may be abundant in one situation and scanty in another. It may be even so extensive as to render the natural structure of the part imperceptible.

11. **iii. The Anatomical Relations of Melanosis.**—The texture and form of the part in which the melanotic matter is deposited determine in a great measure the consistence which this deposit assumes. There is every reason to infer that the black matter is deposited in a more or less fluid state, particularly in cellular and adipose tissues; and that it acquires additional consistency by the absorption or imbibition of its more liquid parts. Thus deposited in a fluid state in the areole of the tissue, it will necessarily assume various forms according to the nature of the tissue or compound structure, to the rapidity with which the deposit takes place, and to the abundance of the matter deposited. Viewing it in this light, as well as by the aid of microscopic observation, it may be inferred that the melanotic matter is unorganized—is merely an extravasated deposit or exudation into the areole either of natural structures, or of morbid formations, or of both. In many cases it may even be washed away, leaving the cellular filaments or areole which contained it porous, spongy, and reticulated. Whatever vessels, therefore, which may be traced into melanotic tumours, belong to the structure of the part, and not to the melanoid matter itself; and when the melanoid matter is associated with morbid or new productions, the vascularity is that of these productions, and not of the matter deposited in or colouring them, no blood-vessels being traced into the black matter itself.

(The minute texture of melanosis has been carefully investigated by Millcr, who finds it to consist of a fibrous net-work, and of numerous meshes, occupied by free, unadherent pigment cells, the largest of which are more than 0.00108 of an English inch in diameter; while the smaller vary from 0.00105 to 0.00039, or even less. They are of a pale yellow colour, dark, or dark brown, and of a rounded, oval, or irregular figure; some are elongated, and a few are actually caudate, terminating at one or both extremities in a point, or in a fibril. The pigment cells are not present in all specimens, and the smaller ones are supposed to be young cells set free by the rupture of the old. They are filled with yellowish or blackish granules,
and a few of the larger ones occasionally contain, independently of these bodies, a nucleus which is essentially developed. In some of his examinations, Müller found the granules free, and dispersed through the meshes of the fibrous network. It is probable that in these instances the germinal cells were dissolved, or broken down so as to allow their contents to escape. —[Gross.]

12. iv. Physical and Chemical Constitution. — The black matter itself is without any marked odour or taste. It is opaque, malleable with water or alcohol. It putrefies slowly when exposed to the air or kept in water. The stain it leaves upon the bands and in the lungs, in which it has been washed out. It has been analyzed by Lassagne, Barruel, Hecht, and Heney; and the results of all the analyses are, that melanosis is essentially composed of the colouring matter of the blood and fatty substance. M. Fov considers that it is the colouring matter of the blood highly carbonized, and this is very probably the truth.

13. v. Progress. — The progress of the disease evinces certain changes: 1st, in the melanoïd deposit; and, 2d, in the structures in which it is lodged. —a. The inspissation of the matter may be slow or imperfect, as when the matter is still contained in the capillary vessels; or it may be more rapid and complete, as when it is exuded into, or combines with, the molecular structure of a dense organ. When formed in an adventitious cellular or serous tissue, or other morbid production, the changes in it, especially its inspissation, depend upon the density of the production which it infiltrates, its density resisting the diffusion of the exuded matter.

14. b. After solidification has been carried as far as the circumstances of the parts permit, softening takes place. This change is manifestly brought about by the size, situation, and anatomical relations of the morbid deposit. These occasions, 1st, an irritation in the part, and the effusion of serum in and around it; 2d, the extinction of the vital cohesion of the tissues in which the black matter is deposited.

15. B. The changes in the structures in which melanotic matter is contained are readily inferred from what has been just stated. The irritation of the deposited matter acting upon the living tissues as a foreign and dead body, induces further changes. When the deposited matter forms a tumour, compression of the surrounding tissues is then added to irritation; the latter state, by increasing effusion, sometimes augmenting the former, until ulceration and destruction of parts take place. The irritation produces serous effusion, softening of the containing and surrounding tissues, disorganization with or without suppuration, and ultimately open ulceration. The melanotic ulcer thus formed is either regular or irregular; its edges are thin, soft, pale, or slightly red, or tinged with black, bevelled from within outward, and it exudes a black fluid. If the margins of the ulcer are the seat of chronic inflammation, they become thickened, infiltrated, or projecting and hardened; sometimes they are everted, and the internal surface presents a number of excrevices. When cut through, they are of a pale gray colour, and closely resemble scabs. Melanotic ulceration is comparatively rare, and as yet imperfectly observed.

16. vi. Symptoms and Diagnosis. — The symptoms of melanosis are seldom well marked at the commencement, unless the morbid deposition occurs in parts which come directly before our senses, and it is generally not until after death that we are at all enabled to ascertain its existence. As far as the symptoms have been recorded, and as far as I have observed them, even when brought before me in the human subject, melanosis is clearly characterized during the life of the patient by a gradual sinking of the vital energies, a cachetic habit of body, a dusky or ash-coloured countenance, and a marked change of the nutritive functions, giving rise to great emaciation, dropsey, a partial edema of the cellular tissue, sometimes to effusion into the serious cavities, to a weak, quick, and small pulse, with night perspirations towards the termination of the disease; and occasionally, when the lungs are affected, to a blackened mucous expectoration.

17. It is generally observed, that however important or necessary to the continuance of life the organ affected by this malady may be, febrile excitement never manifests itself in an active or marked form: a circumstance serving, in the opinion of Lassagne and Lobsien, to distinguish during life the consumption depending upon melanosis from that proceeding from tuberculosis in the lungs. But this is an insufficient source of diagnosis, for phthisis may exist without any febrile symptom beyond rapidity of pulse and perspirations. These symptoms also characterize the last stages of melanosis, but they are unattended by purulent expectoration and the stethoscopic signs of ulcerated cavities in the lungs, which are generally present in the last stage of phthisis. Melanosis does not appear to give rise to much pain. The presence of black matters in the discharges from the stomach or bowels is no evidence of the existence of melanosis, as such matters generally proceed from very different sources from this, as shown in the article Melena.

18. vii. Remote Causes. — Melanosis has been met with in all periods of life, but most frequently in old age. It is not confined to the human species, but has been observed in the horse, the dog, the cat, rabbit, &c., but most frequently in the horse, and particularly those which are gray or white. As to its exciting causes, the infrequency of the disease prevents me from stating anything with certainty. It seems, however, probable that it is occasioned by whatever lowers the vital energies, and impedes the functions of the respiratory and biliary organs, or the decarboxying actions of the frame.

19. viii. Of the origin and nature of this substance different opinions have been entertained. The most plausible of these refer it to an altered state of the colouring part of the blood, arising from the presence of an extraordinary quantity of carbon; and infer, that the melanotic matter is in its composition nearly allied to adipose substance, particularly as re-
gards the quantity of carbon composing it. This seems to be the opinion of HEUSINGER and GOMER, who refer, in support of it, to the large proportion of the phosphate of iron and carbonaceous matter found in this substance upon calcination. LARNEC considered it as a distinct species of cancer. He was evidently led to the adoption of this opinion by the circumstance of both diseases occurring in nearly similar states of the vital energies of the frame, and in analogous conditions of the soft solids—an evident cachexia, or contamination of the frame, apparently existing in both. Besides, the frequent association of this disease with scirr us and carcinoma seemed to favour this notion. But this can only be viewed as an occasional complication, as melanosis is also found associated with tubercles and other morbid productions. Moreover, the parts affected by this disease often present no signs of change beyond the infiltration of black matter; and cancerous disease is seldom so generally diffused through the various tissues and organs as melanosis is.

Chemical analysis has confirmed the opinions of GOMER and HEUSINGER, and shown that this matter offers some analogy to the colouring matter and fibrin of the blood. MM. Breschet, Cruveilhier, Carswell, and Laun have, moreover, found it in the blood-vessels which have remained undestroyed in softened melanotic tumours. M. Treviranus, in experiments made by him on frogs, observed that, when the blood-vessels were deprived of the nervous influence, a black matter resembling the pigment of the choroid was formed in the capillaries and in certain other vessels. From this it may be inferred, that the black matter thus formed proceeded from the deposition of the carbonaceous particles, which, not having combined with oxygen, had not been eliminated from the blood in the form of carbonic acid, owing to deficient vital and nervous power, and to the efeebled and retarded circulation in the capillary vessels.

21. I am therefore of opinion that the melanotic matter is produced or secreted from the blood, owing to an efeebled state of the vital influence of the system generally, and the capillary vessels in particular; that this state of the vital influence is insufficient for the accomplishment of the healthy changes induced in the capillaries of a part, or of the body generally; and that free carbon accumulates in these vessels, which, under the defective vital energy of the system, and diminished tone of the extreme vessels, is deposited with other constituents of the blood: 1st. In tissues not previously healthy. 2d. In the capillaries; the parts the texture of which have been variously changed; and, 3d. In new formations, as false membranes, carcinomatosous growths, and other malignant productions.

22. IX. Treatment.—The great difficulty of ascertaining the existence of the disease previous to death has prevented the employment of those means which might have been tried if its presence had been evinced. Upon this subject, therefore, medical literature is perfectly barren. In the uncertainty under which the physician is compelled to act in all cases of this description, the general conditions of the frame, and external manifestations of depressed vital energies, will be the chief circumstances on which he can found his indications of cure. His attention will therefore be chiefly directed to those means which are found most energetic in rousing the powers of life, imparting tone to the minute capillaries, and promoting the functions of the various assimilating and secreting viscera and emunctories of the frame. With this view, I can only suggest the employment of quinine with the mineral acids, or with camphor, and alternated with purgatives or aperients; the iodide of potassium and the liquor potasse with compound decoction of sarsaparilla; the muriatic or chloric, or nitro-hydrochloric acids; the carbonate of potash, the chlorides, &c. In order to excite the decarbonizing functions of the liver, while restoratives are being administered, the patient should also be given occasionally. The patient should live in a pure, dry atmosphere, and take due exercise in the open air.

23. II. Spurious Melanosis.—Those states of parts, or of disease, that resemble true melanosis, have been fully described by Dr. Carswell. This spurious disease is caused: 1st. By the introduction of carbonaceous matter. 2d. By the action of chemical agents, and by the stagnation of the blood in the capillaries. A. Spurious melanosis from the introduction of carbonaceous matter in the capillaries. The carbonaceous matter proceeding from common combustion was first supposed by Pearson to discolor the pulmonary tissue. LarneC afterward entertained the same opinion; but the fact was not fully demonstrated until Dr. S. C. Gregory published a remarkable case which came under his care. This form of spurious melanosis occurs only in the Lungs, and is described in the article on the pathology of these organs (§ 183). The action of chemical agents on the blood gives rise to a form of spurious melanosis. In cases of chemical dissolution or digestion of the parietes of the stomach after death by the acid contained in the gastric juices, and in cases of poisoning by acids, the blood contained in the capillary vessels of the digestive tube, as well as that which is extravasated, frequently presents a blackish tint, so as to simulate melanosis of the part. The action of sulphuretted hydrogen gas may also give the same effect. In cases of digestion in the lungs, and that effused in the same situation, a black colour. It is chiefly, however, in a forensic point of view that this subject becomes important.

24. C. The stagnation of the blood in the capillaries from loss of vital power, and independently of the action of acids, or of other chemical agents, sometimes imparts a melanotic appearance to certain tissues. This occurs chiefly in the digestive mucous surface, and in the lungs. In the former situation it is not infrequently observed after death from pestilential cholera; in the latter organ it occurs both in that malady and in the more sudden forms of congestion sometimes supervening upon or-
MENSTRUATION—PHENOMENA OF

Menstrual function. Dr. Branchard has comprehended all the phenomena of menstruation. He has not overlooked menstruation repeated too frequently, nor that which occurs not often enough, or only at prolonged periods. He has arranged the subject into the precocious and tardy development of the menses, excessive and scanty discharge, suppression of the painful, menstrual and abdominal. He has demonstrated the subject in a more practical and advantageous manner than any, and the reasoning of the author is so clear, so connected, so clear, and so arranged, that the subject is most comprehensively and curiously presented.

1. The consideration of the deranged menstruation is a subject for the medical profession, and not for the public. The influence of the menses upon the patient is a matter of daily occurrence. The deviations from the normal period are of frequent occurrence. The effect of these deviations is to bring the uterus into a state of diseased condition.

2. The deviations of menstruation have been very variously classified and considered by systemic writers, as well as by those authors who have confined their researches to the diseases of the uteus. The latter, from the variety and complexity of the subject, are not always easily comprehended. The classification of the last, to which we are especially entitled to look for a full and comprehensive detail of these derangements, the principal only of them are discussed; and others, which are often of great importance in their local and constitutional relations, are altogether overlooked.

3. The deviations of menstruation have been variously classified by systemic writers, as well as by those authors who have confined their researches to the diseases of the uterine. emotion and passion, and the imagination be-
comes more lively. The mammine and pelvic viscera are rapidly developed; the hips and
thighs enlarge; the ovaria become red and
swollen; the Fallopian tubes, with their fim-
itures, as Dr. Farrarson remarks, are elongated,
erect, and irritable. The uterine has acquired
bulk, and a new languor; the organs of the
thorax participate in the effects of that ac-
tion, which is increasing the mammine, so that
the lungs, the larynx, and even the arms ac-
quire the contours of a maturer development.
The intensity of vitality, and the resistance of
the frame to hurtful agents, are such at this
period, that the mortality is less at this than at
any other epoch.

6. If, on the other hand, the uterine organs
continue to increase and the menstrual dis-
charge does not appear, the growth of the body
is impaired, and the general character and ap-
pearance of it unhealthy, languid, blighted, and
imperfectly formed. The mind is dull, weak,
or depressed. The emotions and passions are
imperfect, or altogether absent. The vegeta-
tive functions are less vigorous; and fat and
cellular substance are formed instead of mus-
cular tissue; the mammine and lungs are insuf-
iciently developed; and not only is life less
intense, but it is of much shorter duration, early
maturity terminating a state of sickly and im-
perfect existence.

7. Much discussion has recently taken place
respecting the period at which the menses first
make their appearance; and considerable misap-
prehension has existed on the subject; inas-
much as this flux, when occurring very early, is
ever, nor yet so generally attended as has been
supposed, with other signs of develop-
own or even of advancing puberty. I have
seen in public and private practice numerous
cases of very early menstruation, the flux oc-
curring regularly for months. In one case
brought to the infirmary for children, it was as
early as the sixth year. I have seen several
in whom the catamenia appeared as early as
the tenth and eleventh years in this climate,
and many in warm countries; but in most of
these this flux was the chief indication of com-
encing puberty. The accession of menstrua-
tion has been supposed to be much earlier in
warm than in temperate and cold climates;
but this opinion has been disputed by Mr. Rob-
ERTSON and others. Having paid some atten-
tion to this subject many years ago, I had come
to the conclusion, from inquiries made when
travelling both in hot and in cold countries,
that a considerable difference as to the age
actually exists, although that difference is not
so great as most physiological and other writ-
ers have stated it to be; and I am convinced
that it is partly owing to the difference in the
constitution of the several dark and white races
of the species—that it is as much owing to
organ’s cause as to climate.

8. Besides climate, there are manifestly oth-
er circumstances which, in certain constitu-
tions, cause an early or premature appearance
of the catamenia; and which, perhaps, in other
or opposite constitutions and temperaments,
tend to delay or to suppress altogether this
discharge, by weakening or exhausting the un-
developed sexual organs. A number of female
children sleeping in the same apartment; the
intercourse of the sexes at an early age, as in
manufacturing towns and cities; the tempera-
ture and circumstances in which young females
are placed in cotton and numerous other fac-
tories; the excitements to which the mind is
exposed in these, and in schools, &c., are, in
temperate climates, the chief causes of the pre-
mature or early occurrence of menstruation,
and of the subsequent irregularities of this func-
tion. The influences which are in operation in
large manufacturing localities often place young
females in similar physical and moral condi-
tions to those of the dark races in warm cli-
mates, and hence the difference of the period
at which menstruation commences in both is
often not very great.

9. The following table will show the years
in which 1604 females experienced the access-
cion of the catamenia:

</table>

10. From the foregoing table it will be seen
that menstruation generally commences be-
tween the ages of twelve and nineteen, and
more frequently at the age of fifteen than at
any other. Although it is not always, at its
commencement, correlative with other signs of
puberty still, it must be viewed as generally
connected with and depending upon the chan-
ges taking place in the ovaria and uterus at this
period, and as being determined by the in-
creased development and activity of the nervous
system of organic life endowing the uterine
system. That the ovaries exert an influence in
determining the occurrence of menstruation,
was supposed by FRIED and many more re-
cent writers, and is not improbable. The well-
known case published by Mr. Port, and cases
of disease of the ovaria which have occurred
to Dr. Montgomery and in my own practice (see
the case about to be alluded to), almost dem-
strate this influence. Dr. Power attributed
menstruation to the action of the ovaries. He
conceived that gestation is the natural condi-
tion of the female organs; that a female men-
struation in these she does not conceive; that
certain changes take place in the ovarian ves-
icles preparatory to the transmission of the
ovum, and that parallel changes are taking
place in the uterus, which may issue in the
formation of the decidua; but that, if the stim-
ulus of impregnation be denied, the increased
action of the uterus is not sufficient to produce
that effect, although it is sufficient to cause the
effusion of a fluid, which is the menstrual fluid.
However this may be, there can be no doubt that the accession of the catamenia is the consequence of a periodical excitement, or irritation of the nerves of the uterine organs acting upon the vascular system of these organs, and determining an increased afflux of blood to them; and hence, that it is somewhat analogous to the condition in the lower animals usually denominated that of "heat." An opportunity was afforded to Dr. Hooper of examining the organs of a female who was instantaneously killed by accident during the menstrual period. The uterus was swollen and vascular; its structure less dense than usual, and its internal membrane injected, foamy, and bedewed with menstrual fluid. The ovaries and Fallopian tubes were also swollen and very vascular. Other facts and considerations might be adduced to prove that menstruation is the result of increased nervous and vascular activity of the uterine organs; and this view is that which has been referred to the phenomena which this function evinces during disease.

"It is now generally acknowledged that menstruation, as well as conception, is dependent on the existence and influence of the ovaries. The ovarian vesicle was first discovered by D e Graaf, from whom it received its name; but no important inference was derived from this discovery, until Purkynje, in 1825, found this vesicle in the impregnated yolk. Since then we have been favoured with the observations of MM. Castor, Wagner, Schwann, Wharton Jones, Bichat, Bischoff, Gendrin, Raciborski, Lee, Negrier, Boismont, Girdwood, and others, and which have established, beyond all reasonable doubt, that menstruation is the consequence of the periodical maturation and rupture of a Graafian vesicle, with the escape of an ovum from the ovary into the Fallopian tube, which is washed away by the menstrual blood. It is based on the physiological law of the sex, that an embryonic germ is developed and brought to perfection at several junctures corresponding nearly with the evolution of the lunar period of twenty-eight days each, one ovum being ripened every month.

"The substance of the ovary," says Dr. Meigs (Am. ed. of Colombat, p. 460), "or its stroma, is found to contain a vast multitude of small points, disseminated within its structure. Each of these points, discoverable only by the aid of a microscope, is supposed to be a rudimental germ, ready to commence its work of development whenever the proper time may arrive, according with the period it proceeds in that work by such degrees, that at least one such will be brought to complete maturity, as before said, once a month, as long as the menstrual age lasts, and while the woman enjoys good health. Now, as the microscopic ovum is contained within a double capsule, called the Graafian vesicle, it happens that the containing vesicle expands, and grows with great rapidity during the latter part of the process; it continues to rise from the central or internal parts of the ovary toward the surface, distends the stroma, puts the tunica albuginea on the stretch, and, finally, bursts outward, discharging its fluid, and the ovum in that fluid, with its accompanying retinacular or granular matter, into the cavity of the belly, or, in case of impregnation, into the fimbria of the Fallopian tube, by which it is conducted to and lodged in the womb, to constitute the ovum of a gravid uterus. Now it clearly appears, from the showing of Robert Lee, of London, M. Negrier, of Argus, M. Gendrin, of Paris, and M. Raciborski, of the same city, and many others, that if a woman die in menstruating, or so soon afterward, there is found on the surface of the ovary a bloody and ragged opening, leading into a small pit or crypt, in which is frequently found a small clot of blood, and which crypt once contained the fluid, the granules, and the ovum of the now broken Graafian vesicle. It also appears, where the rupture has recently taken place, the entire ovary is found reddened and turgid, from the hyperaemia induced in it by the development of the vesicle, just as the gum of a young child, over a large jaw tooth, is found to be reddened and engorged from a hyperemic irritation arising from the pressure of the still uncut tooth."

"Differently observed are the phenomena to which they have found the ovary of the same side, the Fallopian tube, and the uterus of a bright red colour in patients dying suddenly during their menstruation; and they declare it to be an invariable rule to find the evidence of a recent rupture in all such persons, while the numerous pits, depressions, and cicatrizes to be noticed upon the surface of every ovary of females between fifteen and forty-five years of age are regarded as the vestiges of these periodical discharges. Stated developments and bursting of the Graafian vesicle may be confidently looked for on one or other of the two ovaries. So firmly does M. Raciborski seem to regard this doctrine as established, that he calls it a regular point, or laying process, whose appearances and laws, as far as ascertained, he has published in his recent work, De la Puberté, &c."—(Loc cit.) For an able résumé of what is known on this subject, the reader is referred to an article by Dr. Purple, of New-York, in the sixth volume of the New-York Journal of the Medical and the Collateral Sciences, p. 229, entitled, "Menstruation, its true Nature and Office, with a Review of the Evidence of its Vascular Origin, with illustrative Cases." See also, the Brit. and For. Med. Rev.ise, vol. xvii., 1844; R. Lee's "Midwifery;" Raciborski, in Gaz. des Hopitaux, vol. iv, 1842; Lond. Med. Gaz., 1844 (cases by Ritchie); and New-York Med. Gaz. (case by Dr. Post.)"

11. The symptoms indicating the first accession of the catamenia are always present or constant; but generally, for some time previous to the accession of the discharge, headache, heaviness, languor, pains in the back, loins, and down the thighs, are complained of, with indisposition to exertion. There is a peculiar dark tint of the countenance, particularly under the eyes; and occasionally uneasiness or a sense of constriction in the throat, or about the thyroid gland. The cutaneous perspiration has often a faint or sickly odour, and the smell of the breath is peculiar. The mammae are enlarged and painful, or tender. The appetite is fastidious and capricious, and digestion impaired. These symptoms continue one, two, or three days, and subside as the menses appear. At the commencement of this function, the second, third, or even the fourth period may not be attended by any discharge; it sometimes
thus recurring irregularly at first, even in healthy females. The period continues from three to six days, and returns every twenty-eight days, excepting during gestation and lactation.

12. In order that this function should be duly established and sustained, the following conditions are requisite: 1st. A healthy development of the female organs of generation; 2d. A certain degree of vigour or organic energy of these organs; 3d. The absence of such lesions as impair the influence of the ovaries, or interrupt the functions of the uterus; 4th. A certain degree of constitutional power. Upon these the healthy or regular state of the menstrual discharge chiefly depends. In healthy females, the discharge may cease between thirty-nine and forty-five years; but in temperate climates it disappears more frequently after than before the forty-fifth year—at least in England. Mr. Robertson states, that of seventy-seven females, ten ceased to menstruate at forty-eight years; seven at forty-nine; twenty-six at fifty; two at fifty-one; and seven at fifty-two; the catamenia thus disappearing in the forty-eighth year of seventy-seven, from the years forty-eight to fifty-two inclusive.

14. II. MANAGEMENT OF THE MENSTRUAL PERIOD. —i. During the presence of the catamenia, the female frame betrays increased susceptibility and excitability; and this period is usually viewed by females themselves as one of greater delicacy and liability to be affected by injurious agents and mental emotions. It is of much importance to obtain satisfactory information as to the regularity and states of this evacuation in all cases in which the health and disorders of females are considered; and therefore the inquiries of the physician respecting it should be careful and precise. —a. When the female enjoys good health, and the discharge is regular and natural in every respect, all that is required, during its continuance, is the avoidance of all influences, physical and moral, which may powerfully affect the body and mind. These may either suppress, interrupt, or increase the discharge, and either contemporaneously or consecutively produce other very serious or even dangerous results. Sudden frights, fits of anger, and all powerful mental emotions may have an injurious effect upon this discharge. Blood-letting, emetics, purgatives, emmenagogues, active diuretics, the more powerful diuretics, and astringents ought not to be resorted to at this period, as they may morbidly increase the discharge, or even altogether arrest it. Cold or warm bathing, hip and foot baths should also be discontinued during this period, especially when it is healthy or natural. Care ought also to be taken not to expose the feet to wet or cold; and to avoid sitting upon stone, cold, or damp seats, or upon the ground. Excessive exertion of every kind; long walks, long rides on horseback, or on rough roads, and prolonged dancing or standing ought also to be avoided, as tending to produce not merely an increased discharge, but even prolapbus uteri, particularly in married females. Females subject to leucorrhoea ought not to have recourse to vaginal injections during or shortly before this period. Dr. Locock remarks, that either "by accident or by criminal impatience, sexual intercourse has sometimes been permitted during this period; and, although not constantly, yet such conduct has been frequently followed by the most serious effects—generally by profuse hemorrhage; at other times by a sudden suppression of the discharge; which to have succeeded fever, delirium, obstinate hysteria, confirmed mania, and even catalepsy."

15. ii. On the first appearance of the menstrual period there is generally little farther required, as respects the healthy young female, than great care in avoiding the injurious physical and moral influences now mentioned; and even when the second, third, or fourth periods for the recurrence of the discharge are passed over, but little may be necessary if no further disorder be manifest. If, however, the female be delicate, or is much confined in-doors, or if the bowels be habitually costive, the preparations of iron or of iodine, with emmenagogue purgatives, as aloes with myrrh, &c., may be administered, and regular exercise in the open air enjoined. A smart walk should be taken daily before breakfast, and be repeated twice in the course of the day. Confinement to close or crowded apartments, and in close or crowded streets; and, still more, numbers sleeping in small, low, damp, crowded, or ill-ventilated rooms; and deprivation of air and exercise— of the free use of the limbs in an open and healthy atmosphere, are the chief causes of the disorders of menstruation in cities and large or manufacturing towns. To these causes may be added want of sufficient sleep, prolonged mental attention and exertion, and whatever tends to impede the functions of respiration, digestion, assimilation, and muscular action. Hence the effects of injurious agents ought to be especially avoided at the epochs of female puberty.

16. iii. The period of the final cessation of the menses is variable; and even in healthy females the change may be attended by phenomena requiring discrimination on the part of the physician. This period is also one which often excites the fears of females. In a few cases, the uterine functions acquire an increased activity shortly before their final cessation, so that females who have not had children for years, or who have been barren hitherto, have unexpectedly become pregnant. More frequently, however, females mistake the symptoms often attending the cessation of the menses for those of pregnancy. The passing over of the menstrual period, swelling and pain of the breasts, the sickness and disorder of the stomach, and capricious state of the appetite, the increase in size, and the movements occasioned by flatulence of the bowels often accompanying this epoch, sometimes induce a belief in the mind of even an experienced female that she is pregnant; and her exact state can be determined
opposition or obstruction are the chief pathological conditions at this period of life; and although local bleedings are necessary to remove impending mischief, still, diet and regimen are the means on which we should chiefly depend for the permanent removal of the evil. A regular state of the bowels; the occasional exhibition of a mercurial to promote the biliary secretion; a light, farinaceous, and vegetable diet, or a very moderate use of animal food; and regular exercise in the open air, are means which are applicable to all cases characterized by vascular fwllations or congestions. When distress of some internal organ is actually present, and when the more acute or active state has been subdued by vascular depletions and other appropriate means, perpetual blisters, setons, and issues will prove of service in removing the remaining irritation, and in preventing a recurrence of vascular determination to, or congestion of, the affected organ.

20. In all cases, the treatment should mainly depend upon the states of the vascular system, in connexion with those of the chief viscera; nevertheless, the nervous manifestations require attention. If the nervous system be morbidly susceptible or sensitive, the vascular system being neither too full nor oppressed, means should be used to impart energy to it, and thereby, as well as by other agents, to remove this condition. If it be connected, as is sometimes the case, with a deficiency of blood, or of hematozine, the ferruginous tonics should be prescribed; and if painful or convulsive disorders be associated with this state of the vascular system, narcotics, antinocyes, and antispasmodics may be conjoined with these. In most cases of sudden seizure attended by convulsions—whether epileptic or hysterical—although following the cessation of the menesc, antispasmodics and antinocyes constitute a principal part of the treatment; and even local depletions should be cautiously and sparingly employed, unless the signs of general or local fulness be quite conclusive, and then they ought to be resorted to in conjunction with the remedies just mentioned.

Classif.—IV. Class. V. Order (Cullen), V. Class, I. Order (Good). I. Class. II. Order (Author).

21. Defin. — Absence of the menstrual discharge at the period of life when it is usually regularly established, or the suspension or suppression of it after it had occurred regularly for some time.

22. This subject may be considered under three distinct heads: 1st. Absence and retention of the menses; 2d. Suppression of the menses; and, 3d. The complication or association of either of these with some other disorder or malady.
i. Absent and Retained Menstrues.—Synon.
Fractions menstruum; retenio menstruum; delayed menstruation; retained menses; obstructed menstruation.

23. Delay.—A delay in the first appearance of the menses, owing to functional disorder or to organic change.

24. The menstrual discharge may be delayed or absent, owing to functional inactivity or disorder; or it may be obstructed or retained by organic change. Hence, amenorrhoea presents two forms, the distinction between which should be preserved; the one being simple and functional, the other structural and obstructive.

—Emansio Menstruum; Delayed Menstruation.—

The differences in the age at which menstruation commences have already been noticed. In some of these instances in which it has not appeared until three or four or more years after the usual period, in which it has been delayed merely, the amenorrhoea being simple, or uncomplicated with organic change or mechanical obstruction, it will be found that the retardation has occurred in one or other of the following states: a. The development and action of the uterine system are not correlative with the growth and health of the body. —b. The development of both the uterine organs and the whole frame is apparently natural. —c. The uterine functions are insufficient to produce a coloured discharge, uterine leucorrhœa being substituted. —

27. The diagnosis of simple amenorrhœa has reference chiefly to its simple or uncomplicated state. 1st. To the absence of malformation and mechanical obstruction. 2d. To the existence of some other disorder or malady, which may have produced or caused some change in the condition, or which may be complicated with it. If there be periodical exacerbations (which do not always attend simple amenorrhœa, but generally that caused by mechanical obstruction), an examination will readily detect the existence of an obstructive cause. When these exacerbations are evinced, and no local impediment exists, the form of the disorder now being discussed may be inferred to exist; and this inference will be confirmed if they be attended by a colourless discharge, or leucorrhœa.

28. The prognosis of this form of amenorrhœa should be stated with caution or reservation in respect of the ultimate result, particularly where it is unattended by periodic efforts (§ 25), or leucorrhœa discharge during these efforts. The more immediate consequences are those complications presented by the disorder as it becomes prolonged; as chlorosis and disorder of the general health; continued leucorrhœa; sterility, at least during this state of the uterine organs; tubercular consumption, various nervous affections, anaemia, serous discharges of the glands or joints, organic lesions of the heart, epilepsy, hysteria, &c. The more acute, but rarer consequences, of simple amenorrhœa, are inflammations of, or effusions on, the brain and its membranes; hemorrhagic attacks; inflammations or congestions of the lungs, &c., as noticed above (§ 25).

29. The causes of amenorrhœa have been generally considered to be indolence and sedentary lives; gross diet, luxurious habits, hot rooms, soft beds, and too much sleep; causes which may have some influence in producing the influence even of their less energetic exciting causes. Nature met with two instances of fatal disease of the brain in this state of menstrual obstruction. I have seen a similar instance, attended by epileptic convulsions, and terminating in fatal coma; also cases of pneumonia, and of congestion of the lungs, in similar circumstances; but most frequently, particularly in the more delicate class of cases, this form of amenorrhœa assumes the complicated state about to be noticed, and the patient passes into chlorosis or into tubercular consumption; or becomes first chlorotic, and subsequently consumptive. In a few cases, however, the slight leucorrhœa may have some discharge occurring and protects for a time the patient from the more dangerous consequences of the obstruction; or some evacuation takes place, from time to time, which proves vicarious of the menses, as will be noticed in the sequel.

26. Dr. Churchill states that he has repeatedly examined the uterus of patients labouring under amenorrhœa; the cervix uteri has generally been small, and more pointed than usual during the interval; but in all these cases a small-sized bougie could be introduced into the cavity without pain or difficulty. During the abortive efforts at menstrual discharge an enlargement of the cervix takes place, particularly in those cases which are attended at this period with some leucorrhœal discharge.
the complaint in some constitutions, but which are often less influential than others that have been entirely overlooked, more especially sleeping in close and crowded rooms; want of exercise in open air; celebration of sexual exci-
tion and occupation at the period of approaching puberty, to the neglect of the physical aids of bodily development; early masturbation, and all over-excitIng and debilitating and exhausting influences; the vicious system of modern and fashionable education; the occupations of the poorer classes during the period of puberty, especially employments in warm, ill-ventilated, and crowded rooms and factories; insufficient sleep, prolonged excitement and attention, before and during the period of commencing menstruation; residence in cold, damp, and malarial localities, or low cellars; prolonged exposure to cold, and insufficient clothing; nostalgia and depressing mental emotions.

30. c. The pathological conditions to which amenorrhoea has been attributed are chiefly theoretical—entities of the imagination, such as spasm of the extreme vessels; torpor of the vessels; engorgement of the vessels, &c. The true condition is most probably an imperfect development, or impaired energy, or both states of affairs, and especially of the uterus (especially the ovaries), arising from causes which impair or exhaust the organic nervous energies during the progress of growth, or from circumstances which determine these energies to the brain. Those causes of simple amenorrhoea which are characterized by vascular plethora furnish no argument against this view; as this state of the vascular system may exist in connexion with inactivity of the uterine organs.

31. f. Treatment.—It is obvious that the management of amenorrhoea should be based upon the pathological condition of particular cases as far as it is manifested, and be directed with reference to the abortive efforts which may periodically occur. If the obstruction be attended by general vascular fulness and robust health, local or even general bleeding, but chiefly the former, may be prescribed; and preferably at the commencement of, or a day or two before the periodical effort, or recurrence of the leucorrhoeal discharge accompanying it. In laboured, confined towns, for the former only required, general blood-letting almost never, or only when the complexion is florid, the habit plethoric, and the fibre rigid. It has been recommended, particularly by obstetric writers, to apply leeches to the vulva in these cases, and to take blood by cupping on the loins. Generally, however, the application of leeches to the insides and tops of the thighs, just below the groins, is to be preferred, both as being more agreeable to young females than the other modes, and as being equally efficacious. Indeed, cupping on the loins is not to be confided in for simple amenorrhoea; and it may even be injurious, although prescribed for inflammatory states of the uterine organs. I have seen it cause suppression of the menses when thus employed.

32. Next to local blood-letting, in the more plethoric cases, active purging by means of calomel, aloes, extract of colchycn, &c., and saffo-

nauche is, to be preferred, both as being more agreeable to young females than the other modes, and as being equally efficacious. Indeed, cupping on the loins is not to be confided in for simple amenorrhoea; and it may even be injurious, although prescribed for inflammatory states of the uterine organs. I have seen it cause suppression of the menses when thus employed.
MENSTRUATION, OBSTRUCTED—Pathology.

Partly. During the use of these medicines, and particularly of the chalybeate preparations, a full dose of calomel with aloes should be given once in the week at bedtime, and be followed by the compound decoction and toture of aloes in the morning. The ammoniacal tincture of gumacm has been much used for this complaint, and has been very favourably noticed by Dr. Hannay and others.

35. Various stimulating enemata have been advised, particularly those with spirits of turpentine, asefettida, aloes, rue, salvin (see F. 130, 131, 134, 135, 141, 150). Dr. Shonlein prescribes an enema with aloes to be thrown up at the period when the effort at menstruation takes place. At that time, two or even more of the above substances may be employed with advantage, as proved by some cases in my own practice.

36. The local excitement of the uterine organs by means of medicated bougies and injections was recommended by the ancients and by the older writers, and has been advised by some modern authors. Lavagna prescribed a few drops of the liquor amoniae in an ounce or two of milk to be thrown into the vagina, and several physicians have tried this practice. Dr. Blindell has noticed it favourably. The injection, and has been of cup de Colagne in warm milk was a domestic practice in the complaint in some parts of the Continent. The safety of the practice entirely depends upon the particular circumstances of the case in which it is resorted to. There can be no doubt of the practice being hazardous, if it be not cautiously employed; inflammation not only of the vagina, but of the uterus also, being likely to follow the use of a too strong injection.

37. It has been attempted to excite the uterine organs sympathetically by irritating the mammae. Dr. Loudon applied leeches to the mammae with this view. Siebold recommends warm fomentations; Sir James M'Kay, exhausting glasses; and several writers, blisters, stimulating plasters, sinapisms, &c., to the breasts, with the same intention. I have prescribed blisters, sinapisms, and issues to the insides and tops of the thighs; frictions to the loins and back, with stimulating and rubefacient liniments; and embrocations of a similar nature applied more constantly in the same situations with marked advantage. Electricity and galvanism, directed across the uterine organs, have been advised by Thomann, Alberti, Birch, Capuron, Ritter, Marcus, Aldini, Nauche, Siebold, and many others. The hip bath, or mustard hip bath, and mustard pedilum, are generally of service about the accession of the periodic efforts at menstruation. If these efforts are attended by leucorrhoea, the treatment does not require any material change from that above advised; but if the colourless discharge continues or appears in the inter vals, it then becomes an important complication, which will be noticed hereafter. Of other means which have been tried in this form of obstruction, notice will be taken in the sequel, as being equally appropriate to suppression, as to absence, retardation, or deficiency of the menses.

38. The diet and regimen should have strict reference to the pathological states of each case. In the plethoric, the diet should be spare, and consist chiefly of salt-water fish and vegetables. In the delicate, weak, and chlorotic, the diet ought to be nutritious, digestible, and sufficient in quantity to supply the deficiencies in the blood and frame generally, new eggs, mutton, game, and wine being allowed. Regular exercise on foot or on horseback, and the more active amusements and exercises should also be indulged in, especially in the open air.

39. B. Amenorrhoea from Congenital Malformation and Organic Lesion.—Obstructed Menstruation; Retained Menses.—The following malformations and organic lesions may occasion amenorrhoea: 1st. The ovaria may be wanting or diseased. 2d. The uterus may be absent. 3d. Both the ovaria and uterus may be wanting. 4th. These organs being present, the canal of the cervix uteri may be nearly or altogether obliterated. 5th. A false membrane may cover the os uteri. 6th. The vagina may be wanting. 7th. The vagina may have had its canal obliterated, or the orifce closed by adhesion of the lower portion and labia. 8th. The hymen may be imperforate. The most of these lesions are congenital; others are the consequences of disease previous to full puberty.

40. a. Of the congenital lesions some affect the character and development of the whole frame of body; some affect the tissues of the vesi ce of the ovaria is attended by a more or less masculine development of the body at and after the period of puberty. The mammae and external genitals are not fully developed; the sexual propensities are not manifested; the voice is harsher and deeper than usual; and a beard is observed on the upper lip. The general health may not be affected.

41. b. Absence or malformation of the uterus has been noticed by Siebold, Lavita, Andrab, Chausser, Siebold, and others. The ovaria exist in cases of absence of the uterus, the general development of the body may not be affected; but if they be also wanting, in addition to the masculine character, or mixture of masculine with feminine peculiarities, the vagina, on examination, will be found to terminate in a cul de sac, the cervix and os uteri will not be detected, or not be developed, and the uterus will not be felt from the rectum. In these cases, also, the general health may be little affected.

42. c. When the vagina is wanting, both the ovaria and the uterus being present, the menstrual secretion may take place, its exit only being prevented, producing distention, sometimes to an alarming extent, of the uterus. The fulness in the hypogastrum is augmented at monthly periods, and the general health is very much affected. The outward signs of female puberty are present; but the vulva or external parts present no vaginal malformations or a commencement of it. In these cases, the patient loses her complexion, becomes pale, delicate, and thin. She complains of pains in the back, loins, and hips; of distention of the hypogastrum, and of a sense of weight and bearing down. These symptoms are increased every month. The abdomen increases in size, and the density of the swelling is shown by percussion. The distention of the uterus may proceed into the rupture of its paries, and to the escape of the contents into the peritoneum, followed by rapidly fatal peritonitis; but more fre-
quently death takes place from the general disorder, with prominent affections of some vital organs, before rupture takes places.

43. d. Imperforate hymen may be attended by many of the symptoms accompanying the early stages of absence of the vagina; but even if the cause of disorder be not attended to, the disfigurement of the vagina may remain, even if the hymen be ruptured by a violent blow before a fatal injury is produced. In this case, as well as in the others, careful examinations, which ought always to be made, will show the nature of the mischief, and the mode of its removal.

44. β. The organic lesions occasioning amenorrhoea are as follows: a. Disease of the Ovaries.

—Dr. Churchill states, that Dr. Montgomery met with a case of a female with an obscure abdominal affection, who had, wdist, especially a time, and amenorrhoea occurred. On examination after death, it was found that there was only one ovary, and that one had become completely disorganized. A delicate female was attended by several practitioners in succession, and, lastly, by Dr. Farre and the author. Puberty was imperfectly developed, and the menses had not appeared at the usual term. She subsequently died of acute febrile phthisis. The uterus was found extremely small, and the ovaria remarkably atrophied, and conserved a dense transparent substance. The inspection was made in my presence by two gentlemen who had attended my lectures at the Middlesex Hospital.

Dr. Pott has given the history of a case in which both ovaries were removed, and in consequence of the operation menstruation entirely disappeared, although previously to the extirpation puberty existed, and the function had been well performed. Dr. Ashwell also describes a case (in Diseases of Females, p. 49, Am. ed.) of complete sterility of the ovaries, attended by a similar result.

45. b. The canal of the cervix uteri may have become imperious, or the os uteri may be covered by a false membrane. Cases of this kind are not so rare as was formerly supposed. These lesions, however, are more frequently a cause of suppression than of retention or primary absence of the menses. Instances illustrative of these have been furnished by Rathke, Dubois, Osler, and Sporer; but their importance, from their frequency, was especially insisted upon by Dr. Mackintosh. They are usually the consequences of inflammation, which also may occasion accretion of the sides of the vagina, and obliteration of the canal. Indeed, cases of congenital obliteration of the canal may have arisen from the same cause during, or soon after fetal existence. It is obvious that, in those circumstances, the symptoms of the accumulation of the menstrual secretion in the cavity of the uterus will be the same as those accompanying absence of the vagina (§ 42), but they may not become so extreme, as an attentive examination will show the nature of these cases, and a carefully conducted operation may remove the cause before they become urgent or dangerous. *

* [Dr. G. S. Beford, of New-York, has given us the history of a very interesting case of retention of the menses from a closure of the cervix uteri (A Pract. Treat. on Midwifery, by M. Chailey, Am. ed.—New-York, 1844), in a young married woman, 27 years of age, and who had never menstruated. In this case there was an indistinct and cir-

46. The labia or lower part of the vagina, or both, may have become adherent at any period before puberty, but most frequently before nine or ten years of age. This lesion may follow inflammation of the vulva, or vagina, occurring either primarily or as a simple disease, or as a complication or consequence of exanthemata or other fevers. In these circumstances the menstrual discharge may burst the obstruction, but much more frequently its accumulation is attended by similar phenomena to those which arise from retention caused by imperfect ora imperforate hymen (§ 42, 43).

47. γ. The prognosis and termination of this form of amenorrhoea entirely depend upon the evidence furnished as to the nature of the malformation or organic lesion. When there is reason to believe that the condition of the ovaria or uterus, or both, no immediate risk of life may be dreaded, although pectoral or other disease is apt to supervene and carry off the patient. If, however, these organs are present, and the discharge accumulates in the uterus, the result will entirely depend upon the nature of the obstruction, and the possibility of removing it before the general health suffers so severely as to prevent recovery. All these cases, however, are attended by various contingencies, even after the immediate cause of obstruction is removed, that forbid a confident, or other than a cautious prognosis; and these contingencies relate not only to the state and liability to disorder of the sexual organs, but also to the condition and predisposition to disease in the lungs and other organs.

48. δ. Treatment.—It is obvious that where the uteri and ovaria are malformed and disorganized, (or congenitally absent,) no means can be of service. But where the obstruction is seated in the canal of the cervix, in the os uteri, in the vagina, or vulva, well-devised methods may remove it. Even when it is caused by congenital absence of the vagina, the case may be highly dangerous; but it is not hopeless, as shown by one in which M. Amussat (Gazette Médicale, Dec., 1835) operated. He succeeded in making a passage through the cellular tissue interposed between the urethra and rectum, until he reached the tumour in the pelvis formed by the distended uterus, and punctured it; he afterward established an artificial vagina and os uteri, and ultimately restored the patient to health.

49. When the obstruction consists of occlusion of the cervix uteri, or os uteri, from either of the changes noticed above (§ 45), an artificial opening should be made by a trocar, or by a similar instrument to that employed by Mr. Stafford for dividing strictures of the urethra. If the membrane covering the os uteri be thin, or internal to the orifice, it may be punctured by a strong needle. When the vagina cannot be perforated, as in M. Amussat’s case, the uterus may be punctured from the rectum, and

* unpunctured fluctuation in the anterior portion of the abode men, extending about one inch above the umbilicus; on introducing the finger into the vagina, the os was found wanting, the lower and central portion of the cervix being quite soft and uniform on its surface. By means of a speculum the cervix uteri was brought into view, and penetrated by a trocar at its lower and central portion, when about three parts of the body were discharged from the uterine cavity. Pregnancy followed in a short time afterward, and in due time she was delivered of a healthy child. Similar cases are also mentioned in some of our medical journals.]
its contents evacuated. In cases requiring these operations, both external and internal means should be used to prevent or remove inflammatory action, as fomentations, poultices, laxatives, anodynes, and refrigerants.

50. If the vagina or labia have become united, the adhesion may be ruptured by forcible separation; but if this be insufficient, such an operation as the case may suggest should be attempted. Where the hymen is imperforate, the difficulty is much less, and is readily removed.

51. When the menstrual discharge is accumulated in the uterus, and has only been obstructed mechanically, the removal of the obstruction is followed by the escape of a dark, thick, treacle-like fluid, which continues to run for some days as the uterus slowly contracts. Dr. Churchill recommends the vagina to be syringed in these cases with warm water, and a broad binder to be applied around the abdomen. Care should be taken to leave the passage open, and to promote the evacuation at the usual periods, until it is regularly established. Exercise in the open air, a regular state of the bowels, chalybeate medicines, and the usual means of promoting the general health, are the most appropriate to these cases.

52. In some cases, where the menstrual secretion has been accumulating in the uterus or vagina, or in both, the absorption of the more watery parts has left the accumulated matter not only thick, but gormous and gritty; and the internal surface of these organs has become inflamed and ulcerated, and their parietes thickened; very serious, difficult, and chronic disease of the uterus and its appendages thus becoming disclosed by, and following, the removal of the accumulated matter.

ii. Suppression of the Menses.—Suppressio mensium; Amenorrhoea suppressa; Suppressed menstruation.

53. Definition.—Disappearance of the menses, after they have been established for a longer or shorter period, independently of pregnancy or of their ultimate cessation.

54. Suppression of the menses may take place suddenly or gradually. It may occur during the period of menstruation; or the discharge may not appear either at or after the usual period. It may disappear gradually, each successive discharge being either more scanty or longer deferred. Thus, the suppression may be acute or chronic, although cases will often occur to which the one term may be as applicable as the other.

55. A. Acute suppression of the menses is generally caused by exposure to cold, or by wet feet, bodily shock, or by violent mental emotions either just previous to or during the menstrual discharge. The depressing passions, anxiety, insufficient clothing, and want or misery may also produce it. FEVERS, and acute diseases occurring shortly before the period, and during the interval of the discharge, will often have the same effect.

56. The phenomena or consequences of sudden suppression vary with the habit of body and temperament of the patient. In plethoric and robust females, fever, hot skin, headache, full, or hard, or bounding pulse, &c., are produced; and, not infrequently, most severe attacks of disease, according to the predisposition of the different organs, are the results. Hernorrhages, inflammations, apoplexy, epilepsy, palsy, leucorrhoea, &c., are often thus occasioned. Females of a less plethoric habit of body, or of the nervous temperament, are liable to be seized with hysterical convulsions or spasms; or with hysterical affections of various kinds, these latter often changing their seats and forms, with neuralgic pains in different situations, with syncope, or with palpitations; with aphonia, or with nervous irritable, vertigo; or with headaches; with nausea or vomiting; with pains in the back, sides, or abdomen; with retention of urine, or with partial palsy or paraplegia; or with any of the affections mentioned in the articles Hysteria and Neuralgia.

57. B. Chronic suppression of the menses is commonly a consequence of the acute, or of general debility of health. It may also proceed from diseases affecting the ovaries, or from the gradual development of organic change in some remote or vital organ, as the lungs, liver, stomach, head, or kidneys. This form of suppression may be gradual as to quantity, or the discharge may become pale by degrees, or it may appear after longer intervals, being also more scanty until it ceases altogether; or it may be variously irregular and uncertain, or painful, or difficult, and then disappear. In some instances it ceases, and leucorrhoea takes its place; it may even alternate with leucorrhoea. It may follow low, typhoid, or abdominal fevers, or other diseases which diminish the quantity or impair the quality of the blood, or in which large quantities of blood have been lost. I have met with many cases in which it continued long after recovery from continued fevers, the evacuation having been regular up to nearly the attack of fever, but not returning until many months after recovery from it.

58. Acute and chronic phenomena of chronic catamenial suppression are, impairment of the general health, disorders of the digestive organs, diseases of the lungs, cutaneous eruptions; various nervous, or hysterical, or painful affections; chlorosis or anaemia; partial attacks of palsy, curvatures of the spine; obstinate constipation and faecal accumulations in the large bowels, disorders of the excretion of urine, &c.

59. C. The diagnosis of suppressed catamenia is of much importance. It is necessary to ascertain, first, whether or not the patient be pregnant; and, 2d, if the patient be not pregnant, whether or not the affections or diseases associated with the suppression be the causes or the consequences of it.

60. a. Pregnancy cannot be inferred to be the cause when the suppression takes place suddenly, or from any of the more energetic causes producing it, during the period of the discharge. The menstural menstruation by suppression is generally unattended by other unpleasant symptoms, but it is commonly followed by morning sickness, by alteration of the volume of the breasts, and of the sebaceous glands and colour of the areole. The difficulty of distinguishing between pregnancy and morbid suppression of the menses occurs chiefly in unmarried females, but only during the earlier months of pregnancy; and even during these months, an examination of the mammary, of the abdomen,
and per vaginam, will disclose the nature of the case. Instances, however, may occur of pregnancy with a periodic coloured discharge from the vagina; and this may be as abundant during two, three, or more periods as usually experienced by the patient. In these cases, the evacuation generally possesses a hemorrhagic character, and either proceeds only from the os or cervix uteri, or from a minute separation of that portion of the ovum near the cervix.

61. In most cases of acute disease appearing in connexion with acute suppression of the catamenia there will be no difficulty in determining the exact relation in which the one may stand to the other; but, in cases of chronic or organic diseases occurring in connexion with chronic suppression, it is often difficult to ascertain the relative position of the former or the latter.

The affections themselves, which appear consequent upon suppression of the menses, require to be distinguished from each other, especially those which are truly inflammatory from those which are nervous or spasmatic, or consist chiefly of altered sensibility. What I have stated in the articles HYSTERIA and NEURALGIA will assist the diagnosis; and generally it will be found that, when the disease is inflammatory, the local and constitutional symptoms nearly correspond with each other, and with the state of the organic functions; but when the affection is nervous, although the pain and distress may equal, or even exceed that caused by inflammation, the constitutional disorder will be slight, the pulse and the organie functions being but little disturbed.

63. D. Prognosis.—The opinion as to the consequences and ultimate results of suppression of the menses will necessarily depend upon the nature of the causes, physical and pathologicai, which produced it, and upon the effects of the suppression in those organs which most frequently sympathize with the genital organs, especially the lungs, brain, and vascular system. The prognosis, therefore, depends chiefly upon the antecedent disorder or consequent malady which may present itself; the suppression, however, being a circumstance rendering an opinion of these still more favourable than it might otherwise be; although, in itself, and devoid of all complication, it may be an effect of passing or contingent disorder, which nature alone may remove, or which a judicious exercise of art may assist her in overcoming.

64. E. Treatment.—a. The acute form of suppression of the menses may be inferred, from what has been stated above, to be more amenable to treatment than the chronic. The means usually employed to recall the discharge are more especially indicated for it; but these should be selected with reference not only to the cause of suppression, but also to the antecedent state of health, and to the antecedent symptom or consequent disorders. In many cases, the hippo bath, warm mustard foment, and warm drinks upon getting into bed, if employed immediately upon the occurrence of suppression, will remove it. If fever, or local inflammations, or congestion follow, bleeding, especially by leeches applied below the stomach; or the more emmenagogue purgatives, particularly calomel with aloes, &c., the spirits of turpentine in ennata, and diaphoretics with diuretics, are requisite. If the suppression be followed by severe cerebral symptoms, as phrenitis, com, apoplexy, epilepsy, &c., as occasionally observed, the derivative bleeding should be carried as far as the circumstances of the case will suggest, and be aided by other derivative means, and by cold applications to the other and less urgent cases purgatives should be prescribed, so as to excite, and determine the circulation to the pelvic viscera, without producing copious discharges, which, if produced, may be injurious by deriving the current of circulation from the uterine organs.

65. If, however, the suppression occasion, as not infrequently observed, inflammation of the uterus or of the ovaria, or of both—consequences which are often overlooked, particularly when slight or sub-acute, or when occurring in unmarried females—vascular depletions, cooling diaphoretics and aperients, derivatives, and the other means advised for inflammations of the ovaria or of the uterine are requisite.

66. In most instances, the chief efforts to restore the catamenia should be made shortly before the approach of the next period. Leeches may then be applied to the groins; and the hip bath, or pediluvia; warm clothing, especially around the hips and thighs; and emmenagogue purgatives, may also be prescribed. The following have proved efficacious in many instances:

67. While evacuations are required in connexion with such means as may excite the uterine discharge when suppression occurs in strong or plectoric females, or occasional acute disease of the uterus, and one which occurs in the bones, lungs, liver, or uterine organs themselves, other means are often necessary, when the suppression takes place in spare, delicate, or nervous females. It should not be overlooked, however, that local inflammations or congestions may occur in these persons in such circumstances, and require a somewhat similar, although less energetic practice; but more frequently suppression in them demands a recourse to antispasmodics in conjunction with narcotics. The external and internal derivatives, the emmenagogue purgatives and enemata already mentioned, and, in many instances, the application of leeches below the groins at the proper period, should be prescribed; but, in addition to these, antispasmodics, such as ammonia, asafetida, castor, camphor, madder, capsicum, rue, savin, &c., variously compounded with each other, and with comion, or stramonium, or belladonna, digitalis, &c., may be prescribed, particularly when much pain is complained of, or spasms occur, in consequence of the suppression. In some of these cases, the
suppression is favoured by poor or deficient blood; and in these the preparations of iron should be combined with one or more of the above antispasmodics and narcotics.

68. The treatment of chronic suppression of the menses should also be dependant upon the cause, and upon antecedent and consecutive disorder. If it proceed from progressive organic disease in the lungs, liver, or other organs, the treatment should be mainly directed to the diseased part; although, even in these circumstances, local depletions in the situation already stated, and other derivative means, may be employed with beneficial effect. If it be caused by repeated or severe inflations of the ovaria or uterus, the means should have reference to these. The ovary, however, may be so changed by inflammation as to be incapable of exciting the vascular activity of the uterus so as to produce the menstrual discharge; but these changes are rather inferred from the history of former disorders than manifested by existing phenomena. When the uterus is affected, it is thought that the discharge, or to cause its retention, without preventing its production altogether, the nature of the lesion may be ascertained, and a remedy be found. Inflammation may close the cervix uteri, or cover the os uteri with a false membrane, or may even obliterate the vagina, as noticed above. In these circumstances, the means already indicated (§ 49) should be resorted to.

69. Even when the obstruction cannot be referred to organic disease of the ovary or of the uterus, there may be still great congestion of these organs; requiring local depletions for its removal. Many of these cases present indications of debility, and are attended, moreover, by leucorrhœa, which may be either periodic or more or less continued, this discharge being often considered as a consequence of debility merely. But the local congestion may be considerable nevertheless; and although the general pallor and state of the circulation may indicate some degree of anaemia, the uterine organs may contain an undue proportion of blood. In these cases, the employment of stimulating injections per vaginam, as advised by the ancients, and revived by some moderns, might convert suppression from congestion into actual inflammation of the uterine organs; and in those cases where the congestion and suppression are associated with leucorrhœa, a recourse to astringent injections, in order to remove the latter, may be followed by the same bad consequences, if local depletions, and other supports, are not resorted to. In the removal of this congestion, they have not preceded such injections.

70. When uterine congestion or inflammatory action is not present, or has been removed, the treatment should depend much upon the states of the vascular system, and of organic nervous power. If the former be not plethoric, and if the latter be much impaired, the preparations of iron, with tincture, or other appropriate medicines; the ammoniated tincture of guaiacum, the stimulating antispasmodics, and external and internal derivatives, are generally serviceable.

71. III. Complicated Amenorrhœa. I have already noticed (§ 57) some of the most important associations of amenorrhœa, and shown that the obstruction, particularly when taking place slowly, or becoming chronic, is often owing either to debility or some constitutional infirmity, or to the gradual development of some organic malady, as of the lungs, brain, liver, &c. The complications most frequently observed are, haemorrhage from various parts, inflammations, phthisis, epilepsy, hysteria, chlorosis, anæmia, palsy, retention of urine, chorea, cutaneous eruptions, diarrhoea, and various disorders of the digestive organs. These require a few remarks.

72. Among the most important of these are virous hemorrhagic discharges from some organ, and organic destruction, as it has been commonly, but incorrectly, termed. These discharges, occurring during suppression, have been thus termed owing to their recurrence; but, although recurring, they are not always strictly periodic, or of monthly appearance. Writers have been more desirous of recording cases of this description, than of observing carefully the procession of the morbid states constituting them; and several have viewed the hemorrhagic discharge as an eruption of the meninges in some singular locality in place of from the uterus, instead of observing the sequence of morbid actions, and the relations between the contingent or vicarious discharge and the suppression. Thus haematemesis is a not infrequent form of the vicarious discharge, and is usually attributed to a periodic determination of blood to the villous surface of the stomach, instead of the uterus; but, without denying that such is sometimes the case, I have met with instances which have led me to infer that the hemorrhagic discharge has taken place in plethoric persons, and given rise to hemorrhage from the stomach, which either has anticipated and substituted the catamenia, or has occurred in connexion with suppression, and often in consequence of the operation of the same causes as have produced suppression. The same remarks apply equally to the substitution of a haemorrhoidal discharge.

73. The causes of suppression, also, particularly those which determine the flow of blood from the lower portion of the body to the head, not infrequently induce epistaxis, or even hemorrhagic discharges from the ears, eyes, &c., especially in those who are constitutionally or otherwise disposed to epistaxis, or hemorrhages from these parts. In these cases, the irregular distribution of blood—the diminished determination of it to some parts, and its accumulation in others—is followed by its discharge from these tissues of the congested organ or part, or is caused by the removal of its congestion. The circumstance of these vicarious discharges generally following, and but rarely anticipating, the precise period at which menstruation should have occurred, sufficiently indicates the nature of these occurrences. Besides the situations already mentioned, hemorrhagic discharges may recur in connexion with amenorrhœa, from the bronchi or lungs, the gums, the fauces, the mammae, the urinary bladder, the bowels, from ulcers in any situation, from various veins, &c. Of the associations of amenorrhœa with inflammations, or with phthisis, which are of frequent occurrence, either proceeding the other, no farther notice need be here taken, than that the former are more obstinate and unfavourable when thus allied, and that the latter pro-
ceeds much more rapidly to its usual termination when it is thus complicated.

74. B. Epilepsia is generally consecutive of acute amenorrhcea when observed in connexion with it; but the numerous and varying forms of hysteria, whether assuming a spasmodic or a neuralgic or painful form, may either precede or follow the suppression. The same remark may be extended to chlorosis, chorea, and anema, either of which is often thus associated, and more or less intimately dependant upon amenorrhcea. The different forms of pellagra are rarely seen connected with the suppression of menstruation as a consequence of it. I attended, a few years ago, with Mr. P. Lockrose, a young lady who was afflicted with prolonged amenorrhcea, followed by paraplegia, retention of urine, diarrhoea, and occasional attacks of vomiting, with which the diarrhoea often alternated. She had been many months in this state, and a great diversity of treatment had been employed without avail. The disease was ultimately removed by means which will be hereafter detailed. The sequel of the digestive and cutaneous eruptions are too varied in their characters to require notice in connexion with amenorrhcea.

75. C. The prognosis in complicated amenorrhcea depends upon the nature of the associated disease. It has generally been considered that the hemorrhage which often occurs vicarioulsy in some cases of this description is not attended by any risk, and is not followed by other disease, or even by much functional disorder. Local bleeding may be the case in the majority of cases, particularly as respects epistaxis, hemorrhoids, hæmatometra, &c., it by no means generally obtains, especially as regards hæmoptysis, and hardly as respects hæmatemesis. Hæmoptysis should always be viewed in an unfavourable light, and its dependance as much upon incipient tubercles, or congestive inflammation of the lungs, or both, as upon amenorrhcea, ought to be inferred. The prognosis in other associations of suppression depends much upon circumstances peculiar to the patient as upon the particular complication present, and requires no farther notice than has been taken above (§ 73, 74).

76. D. The treatment of the complicated obstruction should be directed with the same intentions as have already been stated. In the acute complications, particularly those with hemorrhagic, apoplectic, epileptic, and inflammatory seizures, in plethoric habits, general and local bloodletting, emmenagogue ratharies, diaphoretics, &c., are required. In other complications occur in these habits of body, a similar treatment, especially local bloodletting in the situation above pointed out, should be prescribed, and be aided with the other means already noticed, according to the particular associations observed.

77. In the more chronic complications, the means should be adapted to the peculiarities of such cases, which are too numerous to admit of even a partial notice. The most of those, however, will allow of a trial of the means already advised for delayed and suppressed menstruation; and, although the exact recognition of the complication present should determine the mode of treatment, still that which is more immediately directed to the obstruction should not be neglected. The exhibition of the spirits of turpentine in alternative or purgative doses, according to circumstances, is a most useful and valuable means. Thus, in the case of mercury, or of iodine, or of either, or of iodine and iron; a recourse to digitals, conium, stramonium, belladonna, madder, rue, savin, &c., are the most deserving of notice. Where the obstruction is connected with spasmodic or painful disorders, turpentine, iron, stramonium, belladonna, opium, hydrocyanic acid, ammonia, &c., are generally useful. When it is related to chlorosis, chorea, or anæmia, the preparations of the formula of Dr. Hall have been particularly indicated, and the aid of aloetic and warm pack very beneficial.

- (Gallineleodermatum, or electro-magneum, deserves more particular mention as a menopause remedy. We have succeeded in some chronic cases of amenorrhcea, that had resisted all other means, by daily sending a current of electricity through the uterine canal, or by placing one conductor in a tub of warm water, in which the feet were immersed, and applying the other over the seminal vertebra, thus transmitting the fluid through the spinal axis. Dr. As-whel well states, that Dr. Golding Bird has recently employed the same remedy with extraordinary success in the treatment of cases of amenorrhcea at Guy's Hospital. In some of the cases, where, after the condition of the alimentary canal had become healthy, the amenorrhcea continued with slight digestion, and frequent terbutytes, the spasm shocks passed through the bowel, slowly quickened menstruation in others, its continued repetition three or four times a week led to a similar result; and instances were not wanting where half a dozen shock supped the health of the flow. It is a beneficial and peacefull remedy, and should be employed cautiously, lest it may depress the nervous system, and thus protract the disease; whereas, on the contrary, it often assists the cure, in the energy the torpid organs and parts; but, when used in excess, it may altogether destroy their excitability.

It should not be overlooked that many cases of low temperature, general perorl, or during pregnancy, and it should seldom be used alone. An injection of amonnia after the following formula will generally assist, if followed by a pungent sensation of heat, tingling, and some pain particularly in Le. Amon. for., 3i. vel tuss.; Lactis tepid. , Txyv.; M. cit. In- jocto vaginalis, a third part to be passed into the vagina three times daily. This use should be commenced three days prior to the expected period, and the patient, after each in- jection, should apply a napkin to the vulva so firmly as to cause the injected fluid to be retained for ten or fifteen minutes. It is, however, not a safe remedy, where there is uterine congestion, as inflammation of the cervix uteri and upper part of the vagina is apt to follow this; it should be employed only to cases of torpor, without congestion or acute irri- tation. The strong mustard hip bath, used twice a day, the patient lying with it for nearly an hour each time, at a temperature of 90° or 95°, is a very benefi- cial. The reader cannot be too much cautioned against in- jecting stimulants fluids into the uterine cavity, as recom- mended by so many writers, as an emmenagogue. The procedure is very apt to follow. Dr. Ashwell highly recommends pulverized mustard, in doses of 8, 10, and 12 grs. in camphor julep, prior to the menstrual period. Stimulating injections into the rectum, composed of 10 grs. of aloe with 5i. of magne- lute, or three times a day, will often prove a successful remedy. Warm frictions, stimulants, and stomachics, as the flesh-brush to the hypogastrial and lumbar regions, are also to be employed night and morning. The above are the most important of the direct enemagogues, so called; of the in- direct, or those occasioning their effect through the medium of the system, mercury is by far the most important. Dr. As-whelwell cautions against using it in slight cases, or where there is evidence of a precarious state of the patient, or a tendency to phthisical or strumous disease; but in obsti- nate amenorrhcea, where other treatment has failed, where there is change in the organs, or permanent congestion, and any evidence of incipient structural change, he thinks there is no remedy comparable with this, in which opinion our experience coincides. If the pulse becomes more rapid and less strong under its influence, or if constitutional irritation and weakness daily increase, if there be cough or diarrhœa, the discharge previously existed, its use should be immediately discontinued; but with clearing, the tongue becomes clean, moist, and of a healthy colour; digestion improves, and there is some return of healthy ap- etite, the body of the patient becomes more firm; and, as the disease becomes more clear; and the general condition of the patient is greatly improved. Dr. Ashwell thinks that the mar- tial effects produced, on this account, far exceed the dangers of the gums and moderate salivation, and that these should be kept up for twelve or sixteen weeks. We regard strychn- ine and savin as very strong enemagogues, when properly administered, but it requires judgment in selecting the
MENSTRUATION, DIFFICULT—DESCRIPTION.

78. Definition—Menstruation preceded and accompanied by acute pain in the abdomen and hypogastrium, and often in the back or mammae, the discharge being frequently scanty, or presenting morbid appearances.

79. This form of uterine disorder is of frequent occurrence, and is not only productive of extreme suffering, but often of very serious consequences. Dr. Ashwell remarks, that it often prevents conception; and, if pregnancy has occurred during its continuance, there is risk of abortion. Although, in itself, it is not a fatal malady, yet malignant diseases have followed its protracted existence; and it is generally very difficult of cure.

80. Cases. Both married and single females, the latter more particularly, are liable to it. Dysmenorrhea may occur in all temperaments and habits of body; but more frequently in women of irritable, hysterical, and nervous temperaments, and of sparse, strumous, and phthisical constitutions than in others. It is probably somewhat favoured by indolence and full or rich living. The most common exciting causes are, exposure to cold in any form during menstruation; sudden fright, or shock, or violent emotions; or dyspepsia or diarrhoea, especially when occurring at this period; exposures to cold soon after parturition or abortions, &c. Indeed, the same causes which occasion suppression of the menses, or inflammation of the uterus, may occasion dysmenorrhea.

81. Difficult menstruation may occur at any period, and is rarely confined to one or two periods. It may be traced back in some cases to the very commencement of the epoch. The amount of blood lost in the pain may vary much; it may be moderate, and last but a few hours each time, or it may be so severe as to amount to severe torture, and to occasion faintings or severe retchings; and even to render the patient a permanent invalid. The pain may also be neuralgic or inflammatory in its character. Owing to these variations, dysmenorrhea has been divided by Dr. Churchill into, 1st, the neuralgic; 2d, the inflammatory; and, 3d, the mechanical or obstructive. M. Rowe has treated of it as dyspeptic and symptomatic, and latter generally depending upon inflammatory action in the uterus. Mad. Bovin and M. Dugue have viewed it as commonly proceeding from inflammation. Dr. Ashwell has arranged the forms of amenorrhea into, 1st, The irritable or neuralgic; 2d, The pethoric; 3d, The congestive; and, 4th, The obstructive. The chief objection to this division is that the second and third must be necessarily alike; for, if a pethor goes, and a congested state of the body hardly admits of being distinguished from each other, in respect of their physical conditions, how can cases to which they are best adapted. The preparations of codiae and trog, especially combined with aloe, will often succeed, even in very obstinate cases. The mineral waters of Saratoga, containing, as they do, both these metals, will frequently bring on the menstrual flow when all other means have been tried in vain.

they be recognised by aid merely of their physiological phenomena? It would be better, therefore, to consider the second variety as one of congestion which may sometimes go on to, or be attended by an inflammatory state of the internal surface of the uterus, which state, however, may also exist in the first variety, the neuralgic character, however, predominating, and distinguishing it.

82. II. Description.—A. Neuralgic or irritable dysmenorrhea occurs chiefly in unmarried females, and in the married who have not borne children. It may and does occur at any period of the menstrual age, it is most common about the thirtieth year. It is generally observed in nervous or hysterical and irritable temperaments, and in spare and delicate habits of body. The monthly paroxysms of pain have all the characteristics of neuralgia. They are often preceded or followed by headache. The pain often commences in the region of the sacrum, and extends around the lower part of the abdomen and back the thighs. The suffering is often of a great; in some cases it is quite in- stant, in others it is remittent. As it continues, a forcing or bearing down sensation is occasionally present, and aggravates the distress; and in some instances the torture is so extreme that the patient rolls about the abdomen, endeavouring to procure ease from pressure; or is afflicted with constant retchings. These sufferings may endure for only a few hours, or they may continue a day or two before the discharge commences. This is usually scanty at first, or in slight flushes; and the quantity varies in different persons, or even in the same person at different periods. It is often altogether scanty, rarely too much. It is frequently natural in appearance; but it is also often pale, or mixed with small clots, or with shreds, or with a bran-like matter. More rarely it contains shreds of membrane, as observed by Morcagni, Denman, Burns, Blundell, and others.

83. The cervix uteri undergoes the usual change at this painful period; it becomes swollen and softer, with an increase of heat; and the os uteri is somewhat more open than in the interval. As the discharge proceeds, the pain subsides gradually, but not so quickly as in the inflammatory variety; and as it disappears, neuralgic pains are sometimes felt in other parts. The pulse is seldom affected during the attack, farther than being weaker than usual; and febrile symptoms are rarely observed. In a few cases, the bowels are irregular during the period. When the month has not suffered in the interval, yet in the severer cases, or when the complaint has been neglected, the patient complains of headaches, of pains in the back, which are increased by standing or walking, and of various disorders of the digestive organs, consequent upon the general impairment of health, arising from protracted sufferings.

84. The membranous shreds passed in some of these cases, evidently consist of plastic lymph thrown out in the cavity of the womb. In a few cases, this substance has been voided nearly entire as moulded upon the internal surface of the uterus, and has given rise to suspicions of pregnancy, its expulsion being attended by violent foreing pains. It is discharged, in some instances, during several suc-
cessive periods, in others only occasionally. Dr. Dewkes supposed that females could not conceive who voided these membranes; and such is the case in the great majority of instances, although Dr. Blundell and Dr. Churchill believe that conception is possible.

85. B. Congestive and Inflammatory Dysmenorrhæa. In some cases the patient complains of lumbar pain, of a sense of weight and of bearing down in the pelvis for two or three days before the expected return of the menses. Frequent micturition and sometimes nausea, vomiting, feverishness, and irritable disposition, with severe pain in the region of the uterus, restless, and violent forcing supervene. The patient is not febrile, but the pulse is often quick and irregular. The skin is generally perspirable. A sense of exhaustion, with anxious, pallid countenance, is usually felt as the affection proceeds. After some hours, or even after a day or two, the attempts to micturate, or the severe forcing pains, extending sometimes through the abdomen, from the loin, hypogastrum, and hips, are followed by the evacuation of coagula, occasionally of portions of membrane, the discharge being generally scanty, or in irregular gushes, and at intervals sometimes almost colourless. The forcing pains often resemble those of labour, but the suffering is generally more constant than in it. Sometimes the uterine pain is attended by a sensation as if the pelvis contained some foreign body that should come away; and in these cases considerable masses of congloba, or of albuminous concretions or membrane, have been passed, affording much relief. This congestive form of dysmenorrhæa, when severe or prolonged, is often followed, for some days, or even for the greater part of the interval, by leucorrhœa, which tends farther to weaken the patient, and to superinduce more extensive disease.

86. In some females, particularly in the plethoric and in the sanguine temperament, the disorder assumes a more inflammatory form, or the whole frame exhibits more or less inflammatory or febrile commotion. It usually occurs earlier in life than the neuralgic form, chiefly in the unmarried or in those who have had children. It is commonly caused by cold, particularly when applied to the feet, thighs, and hips, as when seated on cold or damp seats. It may also proceed from some sudden shock or constitutional disturbance, and may assume various grades of severity. In its slightest states, it not infrequently affects plethoric and robust females during the first menstrual period until marriage.

87. It usually commences with chills or slight rigours, followed by flushing, feverishness, and headache, a few days before the appearance of the catamenia; with these the patient complains of pains in the back and hypogastrum, of aching in the limbs and lassitude; of intolerance of light and sound, and fever. The skin is hot, the pulse full and frequent, the bowels constipated, and the menses painful and somewhat swollen (Dewkes); but the febrile commotion is rarely so high as to cause temporary or night delirium. These symptoms subside as the discharge proceeds, especially when it is abundant. When it is scanty, they often continue in a less degree, or become aggravated for a time as it disappears; but it is generally more abundant in this than in the other states of the disease. It may be accompanied with the membranous shreds or exudations, as in the other varieties.

88. During the intervals the general health may not be materially affected, although headaches are not infrequent, and leucorrhœa is often constant. The severity of the attacks is not so regular in intensity as in the neuralgic form, and sometimes a period or two elapses with little suffering. On examining per vaginam during the severity of the pains in the congestive or inflammatory states, evidence of engorgement of the uterus is generally furnished, with swelling and increased heat of the cervix uteri, but there is no external tenderness on pressure.

89. All the forms of dysmenorrhœa, when very severe, generally prevent conception; but the slighter degrees of the complaint will not have this effect. In one of the severest and most obstinate cases for which I have been consulted, the patient had a family after marriage.

90. C. Obstructive Dysmenorrhœa. —Dysmenorrhœa from mechanical obstruction consists of a narrowing or stricture of some part of the canal of the cervix uteri. This variety of dysmenorrhœa was noticed by several continental authors of the last century, and was enumerated by M. Capron as one of the chief states of the disease; but Dr. Mackintosh was the first to insist on its frequency and importance, and Drs. Churchill and Ashwell have directed their attention to it; but they believe that cases of this kind are rare, and that the stricture is only a part of the complaint, and often exerts no influence upon it, inasmuch as the dilatation of the stricture was not, in most of their cases, followed by an alleviation of suffering. It is natural to infer that, if the stricture had been the real cause of the disease, an accumulation of the menstrual fluid would have taken place in the cavity of the uterus; but this appears not to have been the case. Although an infrequent cause of dysmenorrhœa, it is of sufficient importance to determine its existence in all doubtful and obstinate cases.

91. iii. Diagnosis of Dysmenorrhœa. —This complaint is readily distinguished; it is only when it is accompanied with the discharge of an albuminous exudation or false membrane moulded within the uterus, resembling the decidual induration of the ovum, that a distinction is required. The duration of the complaint, the state of the menstrual discharge on former occasions, a length of 21 days in the previous period, and the physical characters of the substance voided, are sufficient to determine the nature of the case. Dr. Montgomerie has very accurately described this substance, and has confirmed the account formerly given of it by Morgagni. He states that it differs from the true decidua in not being intended to become a medium of nutrition for the ovum; hence it is not furnished with a structure such as would be necessary for this office. It is thin, and unsubstantial in texture; of a dirty white or yellowish colour, after the agitation of it in water; and is devoid of the soft, rich, and pulpy appearance and vascular colour, and of the numerous foramina for the reception of the nutrient vessels from the uterus, characterizing the true decidua; it is also
MENSTRUATION, DIFFICULT—TREATMENT.

destitute of the little cotelaneous sacculi essential to the latter structure. No trace of the transparent membranes of an ovum can be discovered within it or attached to it; and should it happen to come away entire, in the form of a hollow triangular bag, it never contains a duplication of itself, forming an inner pouch or reflex layer, as in the case of the natural decidual envelopes of the ovum.

92. iv. Complications of Dysmenorrhæa.—Most of the complications presented by suppressed menstruations are also observed associated with painful menstruation; but of those, hysteria and disorders of the digestive organs are among the most frequent. I have met with instances of a discharge of membranes from the uterus during dysmenorrhœa associated with painful discharges of similar membranes from the intestines, and with the severer forms of hysteria and spinal irritation. Leucorrhœa is an equally common complication with hysteria, and is often only a part of the uterine disorder causing dysmenorrhœa. Neuralgic and other nervous complaints are often intimately associated with it; but the observations I have offered on the complications of amenorrhœa (§ 71, et seq.) are equally applicable to those of dysmenorrhœa.

93. v. Prognosis.—Dysmenorrhœa is dangerous only as respects its consequences when neglected, and when it is complicated with some pectoral or other serious disease. Although it be obstinate, severe, and prolonged, as long as the general health does not suffer, and no other local malady appears, its chief importance consists in the distress it occasions, and the effect it may have upon the generative function; for, although a female may conceive who is suffering any of the forms of the mala-
dy, even in their severest states, as when attended by the expulsion of albuminous exudations, still this is an infrequent occurrence, sterility being a much more common result. Generally, however, the disease is cured by medical treatment, or by marriage, and childbearing; and it necessarily disappears at the change of life. The possibility of its being followed, particularly when it continues up to, or past the fortieth year, by organic, or even by malignant disease of the uterus, especially of the cervix and os uteri, ought not to be overlooked; and this contingency is, perhaps, more likely to occur in the neuralgic than in the inflammatory form. The mechanical state of the disease may be viewed as more unfavourable than the others; as the removal of the structure is not always attended by a removal of the malady. Dr. Mackintosh, however, states that he cured twenty-four cases out of twenty-seven, and that of the twenty-four, eleven afterward had children. This rate of success has not been confirmed by the experience of other physicians.

vi. Pathology.—The questions most agitated in respect of the nature of dysmenorrhœa are, whether it depends or not solely upon irritation or altered nervous sensibility, or solely upon inflammatory action—whether it is merely neuralgic or entirely inflammatory. That a degree of inflammatory irritation exists in the internal surface of the uterus, even in the neuralgic form of the disease, is proved by the formation and expulsion of a false membrane in many cases of that form. That this membrane is produced by a similar state of inflammatory action to that which sometimes occurs in other mucous surfaces, and gives rise to a similar exudation, is most probable, notwithstanding the absence of general inflammatory phenomena and the neuralgic character of the pain. The absence of these phenomena is evidently owing to the nervous temperament, and disposition to morbid or excited sensibility, in connexion with the state of the vascular system, and probably, also, to the nature of the more common inflammation of these cases, the inflammatory irritation existing in the internal surface of the uterus excites, or is attended by an inordinate manifestation of morbid sensibility, although it is insufficient to develop general vascular reaction, owing to the general deficiency of blood in the vascular system, and hence the neuralgic character prevails. In those cases which are manifestly congestive or inflammatory, the nervous susceptibility being less, while vascular fullness and disposition to increased temperature of the viscera exist, the conditions are more prominent. That the albuminous exudations, voided in the different varieties of the disease, are the results of states of local action similar to those which sometimes take place in other mucous surfaces, may be inferred not only from their similarity of characters, but also from other phenomena, more particularly from the violence of the pain attending their detachment from the surface on which they are formed, as evinced by their formation on the subjacent parts (see art. Intestines, § 52) as in the uterus. In two of the complicated cases alluded to above (§ 92), one of which was seen also by Sir B. Brodie and the late Dr. Davis, the other by Dr. Ashwell, in consultation, the albuminous exudation or membrane was voided from both the intestines and uterus, with violent suffering referrible to both these situations, and with severe and obstinate sympathetic disorders of an hysterical and neuralgic nature.

95. vii. Treatment.—The indications of cure are the same in all the forms of this malady: these are, 1st. To alleviate the suffering at the menstrual period; and, 2d. To restore during the intervals the healthy condition of the organ.

A. The first of these intentions is, however, to be fulfilled by somewhat different means, in the several forms of the disease.

96. a. The neuralgic variety, as I have already stated (§ 92), ought not be viewed as being entirely devoid of a local inflammatory character, at least in many cases, or in those attended by the production of an albuminous exudation, because the symptomatic phenomena of inflammation are not manifested. Therefore, unless there be manifest deficiency of blood in the vascular system, leeches should be applied below the groins, as above advised (§ 67), and be followed by fomentations with hot sponges. After the bleeding is arrested, the warm bath, or warm bath and the anodynes about to be advised, may be resorted to, and even repeated. Where local bleeding is not indicated, and after it has been employed, opiates, or henbane, or bella donna, or stramonium, conium conjoined with camphor, asafoetida or other antisapmosodies, are generally beneficial. I have prescribed the following with advantage:
97. The narcotics just mentioned may be prescribed in the form of suppository, or in enemas; but they ought not to be given by the mouth, except in such cases where they are prescribed in large doses in enemata, as serious effects may follow. In those cases which are attended by a sensation of a substance pressing down in the pelvis, as if requiring to be brought away, the ergot of rye and the biborate of potash will often afford relief, particularly when there are coagula, or albuminous exudations in the uterus, or passing the cervix. Injections, per vaginam, of the warm decoction of poppies, or of warm water, containing the extract of hyoscyamus or convolvulus, are helpful, and the hot fomentations of the same kind over the pubes and hypogastrum will frequently be of service. Plasters containing the extract of conium, or of belladonna, or of aconite, and camphor, may afterward be placed upon the sacrum, or over the hypogastrum, in the more severe and obstinate cases.

98. b. The congestive and inflammatory states of dysmenorrhea require, with very few exceptions, a general local bleeding, which should be early, as the attack comes under treatment. Leeches applied to the thighs are preferable to the loins in these cases; for I have known instances of suppression of the menses caused by the latter. The bleeding, however, should not be too profuse, as it may thereby interfere with the catamenial discharge; it may, however, be repeated at the return of the period, according to the peculiarities of the case. After vascular depletions, cooling diaphories, and the like, which are generally beneficial; particularly the liquor ammoniac acetas, with camphor, spirits aetheris nitrici, and any of the narcotics already noticed. Warm poppy fomentations, the warm bath, and the other means already noticed (§ 97), will also be frequently of service. The bowels should be kept gently open by means of cooling laxatives.

99. B. During the intervals between the menstrual period, the treatment should be varied considerably, and the heat and cold should be well understood, but also with the circumstances of the case.—a. In the neuralgic form, much attention should be paid to the state of the digestive functions, and to diet and regimen. The biliary secretions ought to be promoted by blue pill, or the hydrarg. cem ereta, taken alternate nights; and by a stomachic aperient, the following morning or night. After the abdominal secretions and excretions have been improved, chilly baths or hypothermic, several times a day: by exercise on horseback, or by regular walking exercise, taken moderately, twice or thrice daily; and with warm salt water baths, followed by cold salt water bathing or the daily use of shower baths.

100. The several preparations of iron have been advised in this complaint. The iodide of potassium is one of the most efficacious. It may be given in the form of sarsa. Dr. Lockock advises the vinum ferri with the spiritus aetheris sulph. comp. The mistura ferri comp. and the alkaline combinations of iron are also very serviceable. Dr. Dewers makes favourable mention of the tinture guttae, and more especially of the tintura guttae ammonii andammonii; and Dr. Chapman advises the decoction senece. Dr. Churchill recommends blisters to the sacrum, or a caustic issue in the same situation. I have prescribed perspiration in the insides of the thighs with success.

101. The more obstinate cases, and those especially which are attended by the expulsion of albuminous exudations, may resist most of the means now mentioned; particularly when the malady is perpetuated by persistence in one of its most common exciting causes, namely, masturbation. In these circumstances, a performer's pill, or the blue pill, may be given every night, alone or with soap and ice and an semovini, until the gums are relaxed; or the soap, or the pencil, or the dose in the dose of about one dram, may be taken at night and upon waking in the morning, on the surface of a cup of milk, or in any other vehicle, for some days before the next menstrual period. Injections, per vaginam, of warm water containing a little of the biborate of soda, especially when the period of the catamenia approaches; the same substance taken internally, alone or conjointly with any of the more powerful medicines previously noticed, or with the more recent suggestions, the bowels require to be kept freely open; and warm pudorulvia, hip baths, or the warm bath, continued or repeated according to circumstances, may farther be resorted to.

102. b. In the congestive and inflammatory states of dysmenorrhea, spare diet, regular and active exercise, particularly on foot and in the open air, with attention to the state of the bowels, should be especially insisted on. In the cases of the obstinate character, notwithstanding the more active means advised for the treatment during the menstrual period (§ 98), it will be necessary to have recourse either to the means already advised for the more severe cases attended by the discharge of albuminous exudations (§ 101), or to a mild mercurial every night, the suppurative of potash with biborate of soda being taken in the morning. In some cases of this state of the disease, the iodide of potassium and the liquor potassae, galls, may also be profitably used, and have proved efficacious. Of the local application of iodine advised by some recent writers, in some obstinate cases of dysmenorrhea, I have no experience; and I know of no circumstance that can render it appropriate. On the approach of the next menstrual period, leeches applied below the groins, and the means advised above (§ 101), should be resorted to. If the bowels be confined, the remedies just mentioned, or the biborate of soda with aloes, may be prescribed. In cases of this kind, as well as in suppression of the menses, Dr. Mead had great faith in hellosebule given until a free operation was effected on the bowels.

103. C. The mechanical or obstructive variety of dysmenorrhea has been remedied by the in-
MENSTRUATION, EXCESSIVE.—Definition.

Classif.—II. Class, I. Order (Author).

104. Defin.—A too abundant or a too frequent return of the uterine discharge.

105. In the article upon Hemorrhage from the Uterus, I have treated of "discharges of blood from the uterus occurring independently of the menstrual evacuation," and have considered them referred to the several periods of life and to the various circumstances in which they occur (see article referred to, § 220, et seq.). I here confine myself to the consideration of excessive or profuse menstruation, as above defined.

106. The quantity of blood discharged from the uterus at each menstrual period has been variously estimated. In temperate climates it varies from four to ten ounces, from five to seven or eight being the usual amount in this country. Less than four may be considered as severe, and more than nine or ten excessive. That climate influences the quantity of this discharge is extremely probable; but I do not believe that it has this effect nearly to the extent estimated by some writers; for it is impossible to obtain precise information on the subject. Even when the quantity is unusually large, the discharge may take place in a short period, or during a longer time in recurring gushes; or it may continue for a long period, as a slight or moderate drain.

That distinguishes three forms of menorrhagia: 1st. That in which the discharge is of the natural character, but is excessive as respects its quantity, continuance, or frequency of recurrence. 2d. That in which the discharge is mixed with clots of blood, but is not attended by alteration of the cervix or os uteri. 3d. That in which there is change in the cervix, or in the size or position of the uterus. This division is not altogether undeserving of adoption; but as the discharge must necessarily present the characters either of the menstrual fluid, or of hemorrhage, it is preferable to arrange the forms of the disease accordingly, namely, into true menorrhagia, and hemorrhagic menorrhagia.

108. i. Menorrhagia, with a natural state of the Discharge.—True Menorrhagia.—In this variety the discharge is excessive, either as to its quantity, its continuance, or the frequency of its recurrence. It may come on suddenly and frequently, thus cardynal or for a longer or shorter period, almost cease for some hours, and then return more or less copiously. It may recur or remit in this manner several times or for several days, the excessive discharge assuming this form at each period. Sometimes it commences and proceeds regularly, in an unusually abundant quantity, the period not being much prolonged; but, more frequently, it lasts for a long time, occasionally for a fortnight or even longer, the quantity not being great at any time, but becoming so from its continuance. In other cases, the discharge returns every two or three weeks, without being in an augmented quantity. This last state is not infrequent among unmarried females of a puerile system, or sanguine temperament, with much activity of the uterine organs.

109. This variety of menorrhagia is often associated with uterine leukorrhoea, which may either precede or follow each recurrence of it. In some cases, also, leukorrhoea only may have been preceded by an excessive period of its continuance; while, in others, it may have followed this malady. An examination per vaginam furnishes no information, excepting of a negative kind. There is neither heat, nor tenderness, nor swelling of the os uteri.

110. After repeated returns of menorrhagia, the constitution indicates the debility and loss of blood produced by it; and the patient complains of weakness or aching across the loins and hips; of languor, exhaustion, faintness, tinnitus, dizziness, and headache; or throbbings in the temples, or palpitations of the heart. The countenance is palid, and the lips, tongue, and gums are pale. If the disease continue, these symptoms become aggravated; the stomach and bowels are deranged; pains in the side, particularly the left, are complained of; the face is sallow, and all the indications of anemia appear. Ultimately, edema of the ankles, masarca, diarrhoea, convulsions, and various nervous affections, may supervene.

111. ii. Menorrhagia with discharges of blood, or coagula.—Hemorrhage. Menorrhagia.—This variety is met with chiefly in married females of a leucoplegmatic temperament, and in those who have been weakened by disease, or by frequent child bearing, or by prolonged suckling; and in these circumstances it is generally complicated with leukorrhoea. But a different, and a more acute or active state of the complaint occasionally is met with, which has been altogether overlooked by Dr. Curnemill. I have observed it on several occasions, and it has also been noticed by Dr. Ashwell. This variety of menorrhagia has therefore been properly divided by him into three states, viz., the active, passive, and congestive. The first and
second of these are generally attended by a natural state of the cervix and os uteri, while the third is usually accompanied with some change in the state and position of these parts.

112. A. Active or Acute Hemorrhagic Menorrhagia—Inflammatory Menorrhagia.—This is the least frequent kind of the complaint. It occurs chiefly in robust or plethoric married women, who live folly, or who addict themselves to sexual excesses; but it is also, although more rarely, met with in young, florid, and plethoric unmarried females; and in both classes of patients it may assume, according to the temperament and habit of body, more or less of an inflammatory, or of a spasmodic character. In this state of the complaint, a sense of tension, weight or fullness in the pelvis, is complained of for a day or two before the accession of the discharge. Sometimes there is also a sense of throbbing in the uterus, with pain, swelling, or tenderness of the mammary; and occasionally even pain in the uterine region. The pulse is quickened, and sometimes fuller and stronger than usual; and there are generally headache, costiveness, and sympathetic fever. In the spasmodic state, the pain in the uterine region is more severe, but it occurs only in paroxysms, and is attended by a twisting sensation in the pelvis and lower part of the abdomen; or it recurs after intervals, and resembles labour-pains. These pains usually precede, for a shorter or longer period, the discharge, which is extremely various as to amount and continuance. Sometimes the discharge comes on in gushes, with coagula, and recurs more or less frequently. These generally afford relief, at least for a time, the febrile symptoms subsiding, and the rest of the period is passed as in the more healthy state. But in some severe or protracted cases, after a shorter or longer remission, during which either a draining merely continues, or the discharge is in almost a natural state, an exacerbation in a more severe form, takes place; and thus the complaint seems to recur sooner than once, and be prolonged for seven or eight days, or even much longer, especially if the patient attempts to keep about, or to use any exertion. On examination per vaginam, the os uteri and cervix, sometimes with the vagina, are often discovered to be fuller, hotter, and more tender than natural. The discharge usually leaves the patient exhausted, and several days elapse before her usual health is restored. This form of the complaint may return during several successive periods, each to a greater or less extent, and thus the complaint is prolonged, and the intervals between them become greatly reduced, and the health remarkably impaired. In these cases, this active form passes into the next, or the passive state of the complaint.

113. B. Passive or chronic hemorrhagic menorrhagia is generally gradual in its accession, unless when it is consequent upon the acuter state. It is the most common form of the complaint, and affects chiefly delicate, hysterical, and nervous females. It exists in various grades, from the slightest increase of the menstrual discharge to the most severe hemorrha
gic prostration. In some cases, the disease at first, or even for several periods, possesses the usual features of true menorrhagia. In other instances, one, two, or more coagula are observed at first upon the accession of the period, and then an intermission takes place. The discharge afterward recurs more abundantly, and with larger or more numerous clots. It may be so abundant, or continue so long as to occasion faintings and great exhaustion; the back being weak and aching, the countenance and lips pallid, the strength exhausted, and the pulse always becoming small, feeble, and quick. The constitutional symptoms and consequences of the malady already noticed (§ 110), become urgent or even dangerous, if the discharge be not checked or arrested. The uterus, on examination, generally betrays no change.

114. C. Congestive Menorrhagia—Menorrhagia with change in the Uterus.—This variety generally occurs after forty years of age, or about, or even after, the cessation of the menses. The discharge is generally more profuse, and its effects more severe in this than in the others, and it takes place in all constitutions, temperaments, and habits of body. The attack is usually preceded for some time by irregularity of the menses, as to quantity and time, as well as to the duration of the periods; and uterine leucorrhoea has generally existed during the intervals. About twenty-four hours after the discharge has commenced, large clots are expelled, and the sanguineous flow becomes still more abundant. The attack lasts from six to ten days; but, in cases of long standing, Dr. Churchill has occasionally known it to continue throughout the interval, and can only be terminated by the next period, or in a shorter or sudden; but it may continue for several periods, with remissions merely during the latter portion of the intervals. The quantity lost, in some instances, has been sufficient, in one attack, to excite fears of a fatal result. The discharge is increased by standing or exertion, but it is not materially diminished by the recumbent posture. In addition to all the symptoms above noticed (§ 113), which are occasionally by exhaustion and loss of blood, and to which an immense amount of air is inducted in this than in the preceding varieties, the patient complains of weight, dull pain, or bearing down in the pelvis. There is also occasionally dysuria; but more frequently irritation only, extending to the urethra and neck of the bladder. The pulse is weak, small, sometimes quick, and the general health remarkably impaired. On examination per vaginam, the os uteri is generally found low in the vagina, and is directed more backward, and is more open than in the healthy state. The cervix uteri is also more swollen, the body of the organ being thrown forward so as to press upon the bladder. There is no increased heat of the cervix or vagina, but the former is slightly tender on pressure, and the body of the organ seems somewhat swollen.

115. iii. Diagnosis.—A. As respects the Forms of the Complaint.—a. The first form of the disorder is readily distinguished by the absence of coagula from the separation of the discharge and from the vagina; when such separation takes place, the complaint is no longer true or simple menorrhagia, but one of the hemorrha
gic varieties.—b. Of these varieties, the first is distinguished by slight fever, pain in the region of the uterus, or spasms in this region and in the abdomen, by slight heat and tenderness of the os uteri, and by the other
circumstances of its occurrence as pointed out above (§ 112).—c. The second of these is not attended by fever or by heat, or tenderness of the os uteri; but coagula are voided, and the parts are generally soft or relaxed; nervous, debilitated, and hysterical females being generally affected, and anemia being either present or resulting. The general or congestive variety is characterized by the state and position of the cervix and os uteri (§ 114), especially by fullness of the former and openness of the latter, and by the class of patients in which it most commonly occurs.

116. B. Menorrhagia may be mistaken for early abortion, or for organic disease of the uterus. —a. Approaching abortion may be confounded with hemorrhagic menorrhagia until the ovum is expelled or detected; the paroxysms of pain, or recurrence of spasms, attending the spasmodic or inflammatory state of menorrhagia, resembling the pains of abortion. The retention of a blighted or of a detached ovum often gives rise to hemorrhage, which may be mistaken for menorrhagia; and the retention, with its consequences, may continue for weeks or even for months, and yet nothing more may be detected on examination beyond greater fulness of the cervix, and more openness than usual of the os uteri. In these the history of the case, the continuance and symptoms of the complaint, and the effects produced by the discharge, will suggest its probable cause; and the adoption of the means about to be recommended will disclose the nature of, as well as terminate, the mischief. I have been consulted in several cases similar to the following: The wife of a friend had passed the usual menstrual period a few days when she was attacked by pains of a spasmodic nature in the region of the uterus, followed by menorrhagia, which subsided upon assuming the recumbent posture. The discharge recurred, sometimes in gushes, after more or less marked remissions, being generally preceded by pain. Cupping, leeches, anodynes, &c., were prescribed by the surgeon who usually attended her during her confinements. The discharge continued, and the consequences becoming serious, I was requested to see her. The ergot of rye was prescribed with the bireorate of soda, an early ovum was expelled, and the recovery was afterward rapid. The active form of hemorrhagia menorrhagia very closely approaches to inflammatory determination to, or even to inflammation of the uterus; and is to be distinguished from it by the severity and continuance of the pain, and by general fever being greater in the latter, the discharge preventing the former from passing into an acute state of inflammation.

117. b. The difficulty of distinguishing between hemorrhagic menorrhagia and hemorrhagia caused by organic disease of the uterus, is often very great. In these the hemorrhage is irregular, and occurs at any time, and without regard to the menstrual period, when it takes place so early in life; it is, moreover, attended by more pain than hemorrhagia, and by various constitutional indications of malignant or other structural change. Corroding ulcer or cauliflower excrecence of the os uteri, polypus when it has descended even partially, and ulcerated cancer of the cervix, are readily recognised on examination, when they occasion frequently recurring or protracted hemorrhage; but whether the discharge is caused by uterine congestion and relaxation merely, or by a polyposis retained in the uterine cavity, or by a sub-mucous tumour, or by organic change of the mucous lining itself, is difficult to determine. This depends on the natural state of the uterus as far as may be determined by examination, on the absence of great emaciation, on the diminution of the hemorrhage from treatment, on the general concurrence of the discharge with the menstrual periods, on the states of the cervix and os uteri during the intervals, and on the appearances of the countenance. A strumous constitution, as Dr. Ashwell remarks, glandular tumours in other parts, hard tumours of the fundus or body of the uterus, broad ligaments or ovaries, increasing hemorrhages and uterine pain, a gradual deterioration of the constitution, and the inefficacy of remedies indicate the dependance of the discharge upon organic lesion, and an unfavourable termination.

118. iv. The prognosis depends upon the evidence furnished as to the existence or non-existence of organic lesion. As long as the complaint presents either of the forms of menorrhagia above described, the menstrual periods being observed, if the intervals or remissions are marked accordingly, if there be no sensible change in the uterus, if the lungs are unaffected, and the general health not remarkably impaired, a favourable prognosis may be given. The first variety, and active form of the second, are more readily removed than the other states of the complaint. The slighter cases of these may even cease spontaneously; but the congestive form is generally more obdurate and severe. In the severer cases, pregnancy does not take place; but in the milder cases it may. When the disease assumes a more severe, chronic, and continued form, causing anaemia, nervous affections, and the more serious consequences above alluded to (§ 110, 113), it is not altogether devoid of danger, and a guarded prognosis then is requisite. The circumstance of menorrhagia, when neglected or unsuccessfully treated, being not infrequently a cause of pulmonary disease, should not be overlooked.

119. v. Causes. —a. The predisposing causes of menorrhagia are, the hemorrhagic diathesis and hereditary predisposition, the earliest and latest periods of the menstrual epoch, a delicate or debilitated constitution, general or local vascular fulness, and excitability of the uterine system. Several causes both predispose to, and directly excite the complaint, particularly venereal excesses; masturbation; prolonged or too frequent sucking; leucorrhœa; indolence, rich living, and hot beds; spirituous and other liquors used in excess; frequent child-bearing and abortions.

120. b. The other exciting causes are, local injuries, falls, concussions of the trunk and pelvis, as when falling on the hips; the use of irritating and exciting purgatives, particularly calomel, aloe, and colocynth; constipation of the bowels; the irritation of worms in the intestines; physical efforts, as lifting heavy weights; exposures to cold, and mental excitement and moral emotions. It is very manifest that these and other influences will often, directly or indi-
rectly, occasion increased vascular action in the uterine or other produce increased fulness of, or of flow of blood into, the uterine vessels, although the vascular system may not be pletoric, or even may actually be deficient in its due supply of blood. In many instances, the sanguineous discharge proves a natural relief to the organ, which, without such relief, may have become the seat of very acute inflammatory action.

121. vi. Treatment.—a. The treatment of the first variety, or true menorrhagia, should depend much upon the hebd of body of the patient, and the period at which it is prescribed, and upon the causes of the complaint. The causes should be ascertained, and removed, as far as this may be done.—a. When the patient is robust or pletoric, a copious discharge is often salutary, and should not be prematurely interfered with, or should be allowed to proceed until it ceases spontaneously. Most writers advise general and local blood-letting, cupping on the loins or sacrum, &c., and, in some cases, these depletions are both indicated and beneficial, but they are as much unnecessary, and the best of several instances they have proved injurious, by suddenly arresting the discharge, which has not returned again in a regular or healthy form; or by giving rise to various hysterical affections, particularly when the states of general or of local pletora have not been such as to require them. In some cases, dry-cupping on the loins, or the application of leeches around the anus, is more appropriate and beneficial than these measures.

122. b. When the discharge is really excessive, especially in respect of the state of the patient, and in the delicate, pulld, and hysterical, the patient should maintain the recumbent posture, on a sofa or mattress, be restricted to a sparse diet and cooling regimen, and take cooling astringents, as the infusion of roses with sulphuric acid, or the infusion of cinchona or other astringent infusions with nitre. If the bowels be confined, the suppository or tartar of potash may be given with the preparations above, or the sulphate or bismuthate of potash in the infusion of morphia for the cir- cir- cumbulations, the acetate of lead with the acetate of morphia, or the sulphate of zinc with opium; or camphor and ipecacuanha with opium; or repeated doses of Dover’s powder, will be prescribed with advantage. The ergot of rye has been very generally recommended in menorrhagia. Dr. Churchill, Dr. Ashwell, and others advise it in this form of menorrhagia in doses of about five grains, three times a day. It is often efficacious, but less frequently so in this than in the sanguineous forms of the complaint. Cold sponging the loins, abdomen, and hips, and cold enema, may be employed; but injections of cold, astrigent fluids into the vagina, as directed by Dewees and some French physicians, are unattended by hazard, especially in suddenly checking the discharge, and thereby risking the occurrence of inflammation and internal effusion. Plugging the vagina, as advised by some writers, or an enema containing a scruple of the acetate of lead, as prescribed by Dr. Mackintosh, is rarely requisite in this variety of the complaint.

123. c. In the intervals between the periods, strict reference should be had to the state of the patient. For the pletoric and robust, a spare and cooling diet, the bowels being kept open by means of the aperients above recommended (§ 122), regular exercise in the open air, early rising, and the avoidance of heating beverages and of too warm apartments, or too soft and warm beds, of full living, luxurious indulgences, and of the predisposing and exciting causes, are especially required.

124. d. For the pulld and delicate, different means are necessary. To this class of patients, the saline, particularly the tonicity of the solution of iron, or the sulphate of iron with quinine and sulphuric acid, are especially appropriate. The chalybeate mineral waters, residence near the sea, or in a dry and airy situation, sponging the loins daily with cold salt water, or with a solution of bay salt; salt-water bathing, or the cold shower bath; avoidance of the causes, as prolonged or excessive sucking; abstaining from, or moderation in, sexual intercourse: the use of enema of cold water; and a light, nutritious diet, with attention to the state of the bowels, are necessary. Wine may be taken in small quantity; and the extremities and surface should be kept moderately warm, but too much clothing around the loins and hips is injurious.

125. B. The second, or hemorrhagic variety of the complaint, should be treated on the same principles as have been stated above.—a. During the acute or inflammatory form of the attack, bleeding, general or local, or both, is more appropriate than in simple menorrhagia. This form of the complaint, I have remarked, approaches to metritis, into which it would readily pass if the discharge did not occasion a resolution of the morbidly increased vascular action in, or determination to, the womb. The cases, however, are comparatively few in which the disease nearly reaches this state; but in these depletions, according to the state of the pulse; cooling aperients and diaphoretics; the preparations of antimony conjoined with sedatives; the acetate of lead with acetate of morphia; ipecacuanha with opium, or Dover’s powder, are principally employed. It is to be noted that Dr. Cholmely prescribed drastic purges for all cases of acute hemorrhagic menorrhagia that came under his care in Guy’s Hospital—a practice, doubtless, attended by success in the great majority of instances, owing to its derivative operation; but, if these purgatives had acted much on the lower bowels, the uterus may have participated in the irritation and consequent vascular determination.

126. When the acute form of hemorrhagic menorrhagia is attended by the hemolymph or spasm, or by hemorrhages, or by exacerbations of either of these, ipecacuanha with opium, in frequent doses; digitalis with camphor and belladonna, and a plaster applied over the sacrum containing the extract of belladonna, are generally beneficial. If there be any reason to infer that the discharge and pain are perpetuated by the retention of an early detached or blighted ovum, the biphate of soda may be given in solution either alone or with the tonicity or powder of the ergot; or an enema may be administered, containing a scruple of the turpentine or confection of rue; and an emetic or embrocation with turpentine, or with some one of the limonious in the Appendix (F. 297, 311), may be placed over the hypoastrum. In these
cases, about half an ounce of turpentine may be taken by the mouth, with an equal quantity of castor oil, either on the surface of milk or in any suitable vehicle, and may even be repeated, particularly when the discharge continues, or resists the other means which have been here advised, the enemata just prescribed being also repeated in these circumstances.

127. During the intervals, the treatment of this form of hemorrhagic menorrhagia should be in no respects different from that advised for simple menorrhagia in plethoric habits. In many cases, it should be conducted with the conviction that more or less local congestion or vascular determination continues during the interval; and, consequently, a cooling regimen, spare diet, occasional local depletions, refrigerants, cooling aperients, and avoidance of the causes, should be recommended.

128. a. The passive or chronic state of hemorrhagic menorrhagia should be treated, when the disease is not severe, nearly as advised for simple menorrhagia occurring in delicate females. In this state of the complaint the ergot is especially useful, and it may be conjoined with the biorbate of soda; or the latter may be given with vegetable tonics, astringents, and aromatics. In the more severe or obstinate cases, the means just advised (§ 126), or those prescribed for HEMORRHAGE FROM THE UTERUS (§ 125), must be resorted to. The cold douche on the loins and hips; cold astrigent enemata, or terebinhinate enemata; terebinhinate epimeds, or embrocations on the hypogastrum; the recumbent posture and perfect quietude, are also beneficial. Dr. BLENDELL resorts "to the injection of astringents, not into the vagina only, but into the uterus itself," in cases where the bleeding goes on until the patient is reduced to extreme weakness. In these, the more astringent tonics and mineral acids, the tinctura ferri sesquisulphuridi, with tinctura lytze, in the infusion of quassia or calumba; the bi-sulphate of potash in the infusion of roses, with tincture of henbane, when the bowels are confined; and, subsequently, the vinum ferri, or other chalybeates, a moderate use of wine and light, nutritious food, residence on the seacoast, or in a dry air, and the use of the mineral waters recommended for convalescence from HEMORRHAGE (§ 251), and the other means advised above (§ 129), during the intervals of simple menorrhagia, are generally appropriate.

129. c. The third form of hemorrhagic menorrhagia requires but slight modifications, if any, of the treatment already stated. Previous to the recurrence or exacerbation of an attack, and when there is evidence of local congestion, the system not being much reduced, cupping on the loins, or leeches in the vicinity of the anus, may be prescribed; the causes of the complaint, particularly the local excitation and intercurrent, &c., being avoided. In this state of disorder tonic astringents are required, even at the time when local depletions are indicated; and when these latter should not be resorted to, dry cupping on the loins may be directed. In this form, as well as in the preceding, the ergot of rye will generally prove efficacious; and the several means just recommended for passive menorrhagia (§ 129) will also be of service in this. If the cervix or body of the uterus be enlarged, the preparations of iodine, especially the iodide of iron or of mercury, or the iodide of potassium and liquor potassae, the iodide and other preparations of arsenic, and blisters repeatedly applied over the sacrum, or kept open for some time, or other counter-irritants in the same situation, will generally prove beneficial. The other means already directed for the preceding states of menorrhagia, during the intermissions of the period, may also be resorted to in this, more particularly the astringent and terebinhinate enemata, and terebinhinate epithems applied over the hypogastrum. If this form of menorrhagia be dependant upon organic change in the uterus, the treatment should be mainly directed to such change. (See art. UTERUS.) When menorrhagia assumes those severe and even extreme forms which are truly hemorrhagic, the observations which have been made at the length on the pathology and treatment of hemorrhagia from the uterus, are together applicable to it. (See art. HEMORRHAGE, § 220, et seq.)

VI. Of certain irregularities of menstruation not comprised under the foregoing heads.

130. I have elsewhere stated that menstruation may take place prematurely, and that when the discharge appears irregularly, or only occasionally at an earlier age than that which has been assigned above to the commencement of the menstrual epoch, it should be often viewed as hemorrhage from the uterus or genitals, rather than early menstruation. On this subject I shall, therefore, add nothing at this place to what I have said in the article HEMORRHAGE (see § 222).

131. 1. Irregular menstruation and its complications.—A. In some instances the menses are premature, but they afterward cease, and again recur, sometimes profusely, after irregular and prolonged periods. In other cases they may be delayed, then recur for a few periods, either scantily or profusely, and thus return after irregular or prolonged intervals. In many cases, these irregular states are complicated with leucorrhoea, and if this association be allowed to proceed, chlorosis or tubercular disease of the lungs may supervene, and place the life of the patient in the greatest jeopardy. They may also occur in connexion with chorea, especially scanty and irregular menstruation, but not so often as delayed menstruation, which generally exists when chorea continues up to puberty. In young females, particularly in the serofulous and delicate, these irregularities, especially when they are connected with delayed menstruation, are sometimes associated with enlargement or chronic inflammation of the lymphatic, parotid, and submaxillary glands. I have been consulted in several instances on account of glandular enlargement in various situations, particularly of the glands just mentioned, which had commenced about the period of puberty, and in all these the catarrhia had been delayed, or had appeared scantily, and at long intervals. These cases occur chiefly in large boarding-schools, where too many sleep in one apartment, and where due exercise in the open air is neglected. They are frequent, also, in factories in which females about the period of incipient puberty are employed. At this period, and also in connexion with delayed or scanty
MENSTRUATION—CERTAIN IRREGULARITIES OF—TREATMENT.

981

menstruation, the slighter forms of goitre are not infrequent, especially where this latter disease is endemic.

132. These irregularities, as to the time and abundance of the catamenia, are often, also, associated with the earlier periods of tubercular consumption, with general cachexia, and with the slighter forms of chlorosis; complete amenorrhoea more frequently accompanying the advanced stage of this latter complaint. In these cases, tubercular disease of the lungs is a frequent sequel to the menstrual disturbance.

133. B. Treatment.—For these irregular and complicated states of menstruation, there is no remedy so much to be depended upon as iodine, in judicious combinations, particularly when aided by change of air, residence on the seacoast, salt-water bathing, chalybeate mineral waters, and walking exercise, or riding on horseback. The iodine may be combined with iron, the liquor potassae, or other substances, according to the features of the case. The preparations of iron, particularly the mistura ferris composita, and eucommage and stomachic purgatives, are also indicated. If heumherba exist, the means adopted for that complaint may be prescribed, or the above treatment varied accordingly. In the summer of 1826, I was requested by Mr. Annesley to see Miss C., aged sixteen years, who had the parotids, sub-maxillary glands, and the lymphatic glands in the neck, near the clavicles, and in the axilla, remarkably enlarged, and in a state of chronic inflammation; the integuments, however, had not become discoloured: the catamenia had not appeared. I advised a course of iodine in solution with liquid iron and tartar, and afterward with iron, and persistence in the course of these for some months in small or moderate doses; the catamenia appeared at first scantily and irregularly, and the glandular disease gradually disappeared without proceeding to suppuration. Several cases of a similar description have occurred to me in the circumstances alluded to. These several forms of scanty and irregular menstruation, especially those with prolonged intervals between the periods, require much the same treatment as was advised for amenorrhoea in delicate constitutions (§ 32–38).

134. ii. Offensive or otherwise morbid catamenia are occasionally observed; and especially in the same circumstances as I have mentioned in connexion with the production of the foregoing irregularity.—I. The discharge may not only be very offensive, but also discoloured, and remarkably irritating to the parts with which it comes in contact. I was many years ago called to a young lady, about seventeen years of age, in a boarding-school, who was suffering in a distressing manner in consequence of the irritating and offensive state of the catamenia. There had been no retention of the discharge, but it was so irritating as to inflame the vagina, the labia, and sides of the thighs, severe erythema extending along the limbs, and for a considerable distance over the hips, and confining her for several days to bed. She had suffered in a much less severe manner in some of the preceding menstrual periods. I have since met with instances of this state of the catamenia being complicated, or otherwise connected, with crypeps. These conditions did not appear to have been caused by retention of the discharge in the vagina, as no obstruction existed, and there was no other symptom of menstrual disorder. Dr. Blandell, however, makes mention of partial closing of the orifice of the vagina as being, in rare instances, a cause of offensive catamenia. In the cases to which I have here directed attention, the catamenia are offensive, owing generally, at least as I have observed, to constitutional disorder, or to a morbid state of the circulating fluids, in connexion with impaired action of the principal organs of deputation. Besides this state, in which the discharge is generally also very dark,
black, or pitchy, or greenish-black and very offensive, and besides the presence in it of membranous exudations, as described above (§ 84), it sometimes is gummy, at other times pale, or serous. These conditions of the menstrual discharge may be preceded or followed by leucorrhoea, or be associated with general cachexia, or be connected with erysipelas. In one case this offensive and pitchy condition of the discharge was so marked that a gangrenous erysipelas in the face, in a female of eighteen years of age.

135. B. The treatment of these states of disordered menstruation depends much upon the affections with which they are associated. In most of those which I have observed, the functions of the liver, bowels, and skin were impaired; and the patients were placed in unfavourable circumstances in respect of air and exercise, and had neglected the state of their bowels. In these, stomachic purgatives, tonics with alcalics, emmenagogues and alteratives, were prescribed with complete success, and were continued during the intervals of indisposition, aided by change of air, exercise, the use of alkaline or chalybeate mineral waters, sea-bathing, &c. In these cases, attention to the state of the general health, and to the assimilating and excreting functions, is the chief indication of cure. The articles on Catarrh of Ectasy, Cholosis, Chorea, Menorrhagia from thermic Affections, Leucorrhoea, Ovaria, and Uterus, may be consulted in connection with disordered Menstruation.

MESENTERY AND ITS GLANDS.—That portion of the peritoneum forming the mesentery is less frequently the seat of disease than that which is reflected over the digestive canal and other visceræ, more especially of inflammatory diseases and their consequences. The mesenteric or lenticular glands are liable to the same changes as the lymphatic glands; but the dis
cases of the former are generally more dan
gers in their consequences than those of the latter. The mesenteric glands are portions only of two kinds of structure which are fully discussed in other articles, I shall consider only those changes of them which, owing to their pathological relations, and to the phenomena they occasion, require a special notice.

CLASS. — II, Class, I Order (Author).

2. Defin.—Pain, deep-seated, and extending from the spine to the umbilicus, increased by press
eur, cough, &c., attended by symptoms of fever.

3. i. Symptoms and Diagnosis.—The existence of mesenteritis is determined with great difficulty; for, as Frank observes, it is seldom observed in an uncomplicated form, but generally associated with enteritis. It also some
times is complicated with peritonitis, nephri
tis, or even with pancreatitis; and it generally escapes detection until disclosed by post-mortem
examination. Mesenteritis, as a rule, occurs in an acute, primary, and simple form; but more frequently in a chronic, secondary, and complicated state.—A. The acute form of the disease is indicated by a constant, deep-seated pain, extending to the spine and umbilicus; increased by cough, sudden motion of the trunk, by sneezing, and pressure; and attended by a sense of heat, by constipation, vomiting, and by fulness and hardness of the abdomen. In some instances the hardness is unequal, and occasionally ischaemia is present, particularly in children. The accompanying fever is generally inflammat
ory.

4. B. The chronic state of mesenteritis is not infrequent, either in a simple or tubercular form; but is usually consequent upon, or com
plicated with scrofulous inflammation or en
largement of the mesenteric glands, with chronic peritonitis or pancreatitis, or with oth
er diseases of adjoining visceræ. In its tuber
cular form it is always associated with tuber
cular peritonitis, of which it is a mere ex
tension. It is hence hardly or never to be distinguished from those maladies, even when most prominently marked, or is very rarely suspected to exist until disclosed by a post-mortem examination; and its symptoms are even more obscure than those of the acute, the

obsecrity being great in proportion to the com
plexity and prolonged duration of the disease.

5. C. Chronic as well as acute mesenteritis is met with chiefly in children of a strumous diathesis, and is caused by the maladies al
ready noticed, by chronic dysentery, by dis
cases of the spinal column, by inflammation of the pso muscles, by enteritis, and by anem
isms of the aorta. The predisposing and ex
citing causes of both the acute and chronic forms are enteritis, those which commonly occasion those maladies, particularly peritonitis.

6. D. The consequences of mesenteritis are enlargement, inflammation, or induration of the chyliferous glands; albuminous exudations on, and adhesions of the opposite surfaces; effu
sions of serous, or sero-albuminous, or sero
puriform matters from the inflamed surface; purulent collections between the laminae of the peritoneum forming the mesentery, and the other lesions described in the article Peri
tonem.

7. ii. The treatment of mesenteritis is the same as that advised for peritonitis, due regard being had to the activity or form of the dis
case, the causes which produced it, and the constitution of the patient, especially the scro
ulous, when that is clearly evinced (see article Peritonem).

CLASS. — IV, Class, I Order (Author).

8. Defin.—Distended and enlarged abdomen; emaciation gradually increasing; irregular and otherwise disordered bowels, and ultimately hectic fever, from enlargement and disease of the mesen
teric glands.

9. Of the numerous designations imposed on the malady about to be considered, tabes mesen
terica, disease of the glands of the mesentery, and marasmus or atrophy from diseased mesenteric glands, are the most generally applicable. Sau
vages, and recently Dr. Joy, have considered scrofula mesenterica to be most appropriate; but, although enlargement or other disease of the mesenteric glands occurs most frequently in scrofulous constitu-
tions, it is not confined to them. The appellation infantile is equally objectionable; for, although the disease is most common in children, the disease is not con
fined to them, or to any age. The term enteromesenterique has been applied to it, on the sup
position that the affection of the glands is al
ways consequent upon, or connected with irrita
tion or disease of the mucous surface of the intestines. Doubtless such is the case in the great majority of instances, but not universally;
for, as in the lymphatic glands, in various situations, especially as observed in scrofulous
constitutions, so in the mesenteric glands, disease may occur primarily and independently of inflammation or irritation in parts related to them.

10. Acute Disease of the Mesenteric Glands.—An acute form of disease of the mesenteric glands has been observed but rarely or never unconnected with some other disease, particularly fever and dysentery. Bauhin noticed this connexion in the fevers occurring in Rome; and MM. Petit and Serres described the association as they observed it in the fever which was epidemic in Paris during 1811, 1812, and 1813. Still more recently, MM. Chevelier, Louis, Andral, and Cruveilhier have noticed an inflammatory, or, rather, a congested and enlarged state of these glands, in many cases of fever, when the internal surface of the bowels was inflamed or ulcerated. I have seen the same association of disease in epidemic fevers, both in temperate and in tropical climates; and not only in these fevers, but also in dysentery. That the affection of the mesenteric glands is merely a complication contingent upon irritation of the intestinal mucous surface and glands in these maladies, and is much more frequently met with in some epidemics, and in certain localities than in others, cannot be disputed; but it has no claims to be considered as a "simple acute inflammation of the mesenteric glands," as some authors have considered it; for it occurs chiefly in connexion with marked asthma or depression of the powers of life; and is indicated merely by enlargement and increased vascularity, changes consequent upon irritation or congestion more frequently than upon actual inflammation.

11. Acute disease of the mesenteric glands can therefore be viewed only as symptomatic, chiefly of the maladies just mentioned. A primary affection I have had no knowledge of in Italy, it rarely exists. In its symptomatic states I have observed it often, both in children and in adults, but in the former most frequently, and only in post-mortem examinations. Although there are numerous circumstances which have induced me to infer that the mesenteric glands had become affected in the course of dysentery and the enteric form of continued or remittent fever, yet there are no symptoms by which its existence can be known with any certainty. When we observe these diseases affecting the stomach, and persons residing in low, humid, or crowded and unhealthy localities, and in ill-ventilated streets and apartments, particularly children so circumstanced; when the stools are irregular, henteric, or chalky, or yeasty, very light, or variously coloured; and when the abdomen is enlarged, and evacuation rapid, there is some reason to suspect acute enlargement or congestion of the mesenteric glands. In these cases the abdomen is often hard, or tense, or tympanitic; but this is occasioned less by the enlargement of the glands than by concomitant flatulent distension of the bowels, as shown by percussion, and by the comparatively little swelling of the abdomen, which is often produced by this state of the glands alone.

12. Chronic Disease of the Mesenteric Glands.—Chronic changes in these glands may occur at any period of life, but much more frequent during childhood than at any other epoch. That these changes are generally tuberculous, and occur in the serofulous diathesis, cannot be doubted; but instances occasionally present themselves of induration and enlargement of these glands, without any proof of tubercular degeneration, and evidently produced by either chronic inflammatory action, or irritation in them, generally consequent upon irritation of the intestinal mucous surface; but of these, farther notice will be taken in the sequel.

13. iii. Causes.—The predisposing causes of mesenteric disease are, the serofulous diathesis, a delicate conformation and weakness of the digestive organs; the epochs of infancy and childhood, especially the period intervening between the commencement of the first dentition and the completion of the second; inappropiate, unwholesome, and insufficient food; exposure to cold, and residence in low, cold, and humid localities. From the undoubted serofulous nature of the disease, in the great majority of instances, the predisposing causes of serofula are to a great extent influential in producing it. Although the serofulous nature of tubes mesentica is denied by a few writers, yet the frequent dependance of the latter upon the former has been so fully shown by Guy-de-Chauliac, Riolan, Morgagni, Portal, Cullen, Richet, Meckel, A. Cooper, Bailly, Cheyne, Joy, and others, that it can no longer be doubted. Indeed, the frequent appearances of tubercles in the lungs, cervical and bronchial glands, and in the mesentery, either in various states of succession or coexistently, is a proof of intimate connexion between both maladies, if not of the dependance of the mesenteric disease upon the strumous diathesis. Nevertheless, congestion, enlargement, chronic inflammation and its consequences, are met with frequently, and are, it is said, produced by the serofulous taint, and consequent merely upon chronic irritation of the intestinal mucous surface, while in other cases tubercular change in the mesenteric glands may be the only manifestation of this taint, although this is rarely the case, as signs of it are generally also evinced in other parts of the body, or in the general conformation.

14. The disease may occur at any age, even as early as the period of birth; and it not infrequently appears soon after birth, particularly in infants brought up by hand, and deprived of the warmth of the mother's bosom; and in those which are suckled by unhealthy, consumptive, or debilitated nurses, or by nurses who have suckled for too long a period. It commences more frequently soon after weaning than at any other time, evidently owing to inappropiate or insufficient food. Residence in close, crowded, cold, and damp situations, without due exposure to the light and rays of the sun; inappropiate, unwholesome, and insufficient food; sleeping in crowded and ill-ventilated chambers, and with insufficient protection from cold or the night air, are not infrequent predisposing causes, but are also influential existing causes of the disease. Indeed, in the majority of cases, improper or insufficient feeding, and deprivation of pure air,
are of themselves the chief, if not the only causes of the malady.

15. The Exciting Causes.—Besides these, overfeeding and incomestible articles of food are among the most common causes of mesenteric disease. These articles not being sufficiently digested, irritate the intestinal mucous surface, and the irritation is propagated thence to the glands. Moreover, the chyle formed from them is either imperfectly elaborated, or retains irritating properties, tending directly to excite these glands, and consequently to inflame, congest, or dilate them. The phenomena of the mesenteries and of the bowels, when neglected or prolonged, especially when affecting children predisposed by the influence of any of the above causes, or naturally delicate, or debilitated by previous disease, may induce lesions of the mesenteric glands, the liability to such lesions being great in proportion to the amount of debility, and to the extent to which a scrofulous taint, original or acquired, may exist.

16. Mesenteric disease sometimes occurs consecutively upon prolonged gastro-enteric inflammation or irritation, upon chronic diarrhoea and dysentery, upon periodic fevers, and especially upon the remittent fever of children, with either of which it may thus become complicated. In both temperate and warm climates, especially in scrofulous constitutions, chronic inflammation, enlargement, induration, and tubercles of the mesenteric glands are not infrequently found in post-mortem examinations of these diseases. In such cases, the changes in the glands are owing as much to the treatment of these maladies as to the gastro-enteric irritation primarily attending them. Excessive purging, the use of drastic medicines, and of stimulating or irritating substances, cannot fail of often occasioning, or of perpetuating where it previously existed, inflammatory irritation of the intestinal mucous surface, which will sometimes be followed by the alterations of the glands now mentioned.

17. IV. Symptoms. Dr. Jow divides the disease into two periods. 1. That in which tubercles exist, in an indolent state, without having produced irritation in the glands in which they are imbedded, or in the surrounding cellular substance. 2. That in which the process of softening and suppuration are going forward. But, as he justly admits, the first period is attended by no symptoms by which the existence of disease of these glands can be inferred, except in the case, which very rarely occurs, of these being so much enlarged at this period as to be detected by touch. Indeed, the only disorder that is observable at this period is referable chiefly to debility, and to the gastro-intestinal surface, and occasionally also to the liver; the mesenteric disease generally originating in these, coexisting with them, and often not manifesting itself until it is very far advanced, or gone on to irremediable disorganization. Cases are continually presenting themselves of the disease having proceeded even to the second stage without its presence having being suspected. Such instances are recorded by Morgan, Bayle, and others, in which the mesenteric glands were in a state of suppuration; and yet the patients, who had died of some intercurrent malady, were in good condition.

18. Garden and Raillanc divide the disease into three stages: the first, or premonitory, which is characterized by languor, debility, pallor, abdominal distention and flatulence, and by disorder of the stomach and bowels; the second, by emaciation, by febrile, and sometimes white stools, by hectic fever, and occasionally by enlargement of the cervical glands, and irregular hardness of the abdomen, caused by the diseased mesenteric glands; the third, by colliquative sweats or diarrhoea, by slight chills or rigours, by extreme emaciation, by weak, small, and very frequent pulse, and by the phenomena of confirmed hectic; and by varied, offensive, and lienteric evacuations.

19. It is very obvious to those who have frequently observed this malady, that all divisions of its course are arbitrary. When its uncertain commencement, its consequent or secondary nature, and its complications and constitutional effects are considered, the attempt, not only to divide its progress into precise periods, but also to describe its phenomena with unerring accuracy, must be altogether futile. To impose an air of constancy on what is always changing is only to mislead, and is calculated to generate a dangerous confidence where a cautious diffidence only ought to be entertained. In these circumstances—in this disease more especially, which is generally the consequence of antece- dent disorder, is merely a portion of that continued chain of morbid action commencing in faulty organization, or in functional disorder, and terminating in organic change—we should content ourselves with ascertaining and stating those phenomena which most commonly attend it, with marking their more common procession, and with cautioning the inexperienced, that, although these phenomena are commonly present, they are not invariably or universally remarked, and that they are variously grouped, and associated with other symptoms, according to the circumstances of individual cases, and to the complications of, or changes produced by the disease.

20. a. Most of the early symptoms are referable chiefly to debility, manifested principally in the digestive organs, and to asthenic inflammatory irritation of the digestive mucous surface. There are general depression, languor, and dulness, with pallor and collapse of the countenance. The lips swell, and become slightly fissurated, especially at the commissures. The appetite is capricious, variable, sometimes ravenous and perverted; and flatulence, abdominal distention, uneasiness, and general disturbances follow a full meal. There is sometimes a craving after the most indigestible substances, and the more voracious the appetite, the more marked become the abdominal symptoms and the emaciation. The belly is large and tense, but not painful on pressure, unless on firm or prolonged pressure. The breath is offensive, the tongue loaded, variable, or streaked; and the perspiration is acid, heavy, or nauseous, owing to the state of the follicular secretion. At an early period, pain is sometimes felt in the back and loins; and sharp, lancinating, or griping pains, of short duration, but recurring three or four times in the day, are often experienced deep seated in the abdomen. Occasionally nausea and mucous vomiting occur, without, in some cases, affecting the appetite.
The state of the bowels is at first variable, but generally much conined, or completely relaxed, the latter being most frequent or prevalent as the disease advances. The stools are unnatural, offensive, mucous, and subsequently yeasty or chalky, and occasionally contain worms, which had been generated probably long before, owing to chronic debility of the digestive functions.

21. With the increased fullness, the hardness of the abdomen becomes more remarkable, and evacuation becomes more difficult. The bowels are usually relaxed, and sometimes the evacuation is preceded by a dark or livid circle. The limbs are so emaciated as to resemble sticks covered by loose and wrinkled integuments, and contrast strongly with the hard and tumid abdomen. The appetite frequently is still ravenous, and generally, also, capricious or perverted; and the ingesta passed insufficiently changed, or altogether undigested. The bowels are very much relaxed, and the stools are lenteeric, and generally deficient, or entirely deprived of bile. Their white or chalky appearance has been imputed to the presence of chyle rejected by the lacteals. It is, however, doubtful whether or no the food is sufficiently digested to form so much chyle as to account for this appearance, which may be partly owing to a morbid secretion from the intestinal glands. Sir A. Cooper supposed that the whitish, earthy-looking state of the stools is owing to the presence of calcareous matter, but the question has not been determined.

Ultimately, the marasmus becomes extreme, but delirium or sleeplessness is rarely observed, and death takes place from exhaustion, or insufficiency of the lungs, and a loss of weight. Many cases of acute intestinal obstruction have been observed which were attended with cholic stools, and with the admission of worms, while the disease was of a chronic nature. Inflammation of the intestinal mucous membrane, the pain felt in the abdomen is to be attributed as much to that affection as to the mesenteric disease, particularly when it is only occasional, intermittent, and griping. That which proceeds chiefly from the mesenteric disease is dull or aching, is referred chiefly to the centre of the abdomen and back, and is not increased by pressure unless it be firmly directed to the back. When severe and continued pain is felt in the back and loins, it is sometimes owing to concomitant disease of the vertebrae. Swelling of the abdomen is very general, but it is owing chiefly to flatulent distension of the bowels, consequent upon debility and chronic inflammatory irritation of their mucous surface; the disease of the glands forming but a small part of this swelling. Accumulation of fecal and indigested matters sometimes also contribute to the abdominal distention. It is comparatively rare that the enlarged glands can be felt through the abdominal parietes, unless the abdomen be much sunk or collapsed, as well as emaciated. The irregular swelling and hardness sometimes mistaken for these glands have occasionally been owing to fecal accumulations in the cells of the colon, to tuberculous disease of the peritoneum, or to some other lesions. The urine is often diminished in quantity; sometimes it is milky in appearance, and contains the earthy phosphates.

24. v. Complications and Consecutive Signs.—This disease is rarely simple even at any one period of its course; and it is but seldom primary, some disorder preceding it, and accompanying its early or advanced progress. These disorders have been already noticed (§ 15, 16) but the most common are chronic inflammatory action in the intestines, machinery surface, tubercular disease of the lungs, intestinal worms, and tubercular enlargement of various glands, more particularly of the cervical, bronchial, and axillary glands. In most cases, the affection of the bowels both precede and accompanies the mesenteric malady, although, in scrofulous constitutions, the latter may precede the former; but the chronic inflammation, enlargement, and infiltration of the mesenteric glands, without scrofulous infiltration of them, which is sometimes met with, particularly in adults, is almost always caused by the intestinal disease, especially by disease of the intestinal glands. The same remarks apply to the form of intestinal irritation attending, and in some respects constituting, infantile remittent fever, in the course of which mesenteric disease is often developed. The connexion of this latter with intestinal worms is shown by the frequent evacuation of them during the course of the malady; the worms existing previous to all the symptoms of the diaphragm, coexisting with, and existing, its early stages, and disappearing as it proceeds to a fatal issue.

25. Pathesis pulmonalis is very frequently associated with scrofulous disease of the glands of the mesentery, and either malady may precede the other. Although the disease of the lungs may not be attended by that of the glands, the latter rarely exists for a considerable time without inducing the former. Inflammation of the peritoneum, especially chronic peritonitis, or even chronic tubercular peritonitis, may be complicated with this malady, but commonly as a consequence of chronic inflammation of the intestinal glands, and mucous surface; the inflammatory action extending, with or without ulceration, from the internal to the external coats of the bowels. On examination of fatal cases of chronic diarrhea or dysentery, in both temperate and warm climates, mesenteric disease is not infrequent, the malady commencing with disorder of the intestinal mucous surface, which has been followed by ulceration, by alteration of the mesenteric glands, and ultimately by some form or other of peritonitis, occasionally extending to the surface of the mesentery. Scrofulous disease of the vertebrae, rhachitis, and inflammation or suppuration of the
mesentery muscles, or of the adjoining cellular tissue, sometimes also complicate the mesenteric malady.

26. Of the above complications, more than two may coexist in the same case. Thus, after death, I have observed extensive disease and agglomeration of the mesenteric glands, ulceration of the intestines, chronic peritonitis, and tubercular disease of the lungs—a combination by no means infrequent.

27. There are also certain alterations, sometimes contingent upon the mesenteric disease, deserving notice. Of these, a serous effusion within the cranium is not the most infrequent. The inflamed and suppurring glands may also give rise to various changes in their vicinity—to peritonitis from perforation of the peritoneum, to ulceration into the intestinal canal, and to pressure upon adjoining canals and cavities, as the pylorus, common bile and pancreatic ducts, &c. Sir A. Cooper mentions the occurrence of adhesion of the suppuring glands with the parietes of the abdomen, and the discharge of their contents externally, or even both externally and internally into the intestinal canal, thereby giving rise to an artificial anus. The appearance of pus in the stools consequently of serous suppuration of the mesenteric glands, has been attributed by Schmalz and others to the opening of the abscesses thus formed in the mesentery into the cavity of the intestines. This result, however, must be rare; the purulent matter observed in the stools being, more probably, formed by the chronically inflamed villous surface of the bowels, and incident toppers. I have seen not only in children, but also in adults, compression, irritation, and inflammation of adjoining parts, produced by the diseased lacteal glands. Pressure upon, and narrowing of the pylorus, or of the common bile and pancreatic ducts, occasioning vomitings of the ingesta, &c., in the first case, and jaundice in the second, are not very rare consequences of the mesenteric disease. M. Andral states that the urcers, and even the vena cava, may be so compressed by the inflamed glands as to obstruct their outlets; and further, render the diagnosis extremely difficult. Still, attention and experience will enable the physician not merely to distinguish between them, but also to recognise this complication, as well as the other associations and consequences of the disease alluded to above (§ 24, et seq.), particularly if the causes, the several concurring influences, and the effects of treatment be taken into consideration.

28. vi. Diagnosis.—From what I have stated, and from the very frequent complications of the malady, it may be inferred that an accurate diagnosis of it, particularly in the earlier parts of its progress, is by no means easy. The diseases with which it is most commonly confounded are chronic inflammation of the mucous surface of the bowels, infantile remittent fever, intestinal worms, chronic and tubercular peritonitis, and sebala retained in the cells of this colony. Although it is of importance, especially in respect of the prognosis, to ascertain the exact pathological condition, and how far either of these may exist singly, or be associated with one another, or with some different malady, still a mistake in their diagnosis is rarely attended by serious results, owing to the general indications of cure being nearly the same for all, although the means should be varied for each.

29. The phenomena more particularly indicating mesenteric disease at an early period are: the serofulous diathesis and phthisial state of the patient, with a blanched and relaxed skin; irregularity of the bowels and stools, or diarrhoea, the evacuations being undigested matters rather than morbid secretions; the ingestion of food not being followed by immediate inconvenience, as increase of pain, or calls to evacuation; the nature of the ingesta not sensibly influencing the disease; the absence of thirst, heat of skin, and of tenderness of the abdomen; emaciation, and collapse of the features; and absence of indications in the stools of irritation of the intestinal mucous surface.

30. A. Infantile remittent fever is liable to be mistaken for mesenteric disease; and as I have above stated (§ 24), it often occasions this malady. It is very difficult to distinguish between these diseases, especially during the early stages of the latter; but in the mesenteric disease there is a more general manifestation of the serofulous diathesis, often with enlargement of the cervical and other glands, than in the infantile remittent. The emaciation is greater and more rapid, while the appetite is more ravenous and more perverted. The remittent fever is attended by short intervals of apparent improvement, and always with regular diurnal remission which are not so evident in the mesenteric disease until the last stage, when it assumes the truly hectic form; and, in this stage, the extreme emaciation, distention and knotty hardness of the abdomen, the chalky or lenteric state of the stools, and the general appearance of the patient, will readily distinguish it from infantile remittent (see article Fever, § 278, et seq., for the history of that disease).

31. B. Chronic inflammation of the intestinal mucous surface, while it very frequently occasions mesenteric disease, is readily confounded with it in its early course. But the intestinal affection is attended by greater heat, pain, and tenderness of the abdomen than are observed in the mesenteric disease; and by more thirst, more febrile excitement, and more mucous or greenish stools, the symptoms being all increased by the ingestion of food, especially of stimulating food. The common association of the intestinal with the mesenteric disease, and the frequency (§ 24), if the latter is of the former, render the diagnosis extremely difficult. Still, attention and experience will enable the physician not merely to distinguish between them, but also to recognise this complication, as well as the other associations and consequences of the disease alluded to above (§ 24, et seq.), particularly if the causes, the several concurring influences, and the effects of treatment be taken into consideration.

32. C. The symptoms of the common round worms of the intestines resemble mesenteric disease, particularly in respect of the ravenous appetite, the tumid abdomen, and emaciated extremities; but the absence of the characters of serofula, the itchings of the nose and anus, frequent startings, grinding of the teeth, and the effects of remedies in the former, will distinguish between them when they are not associated; but when associated, as is sometimes the case, the diagnosis is much more difficult.

33. D. Chronic peritonitis, simple or tubercular, may be mistaken for mesenteric disease, and is not so readily distinguished from it as stated by Dr. Pemberton. It is generally attended by more tenderness and pain on pressure than the latter, and by superficial pricking pains.
In chronic peritonitis the abdomen imparts the sensation of more superficial hardness, or of being bound down, and it is more generally dull on percussion than the mesenteric malady. Vomiting, also, are more frequent in the former than in the latter. Peritonitis, however, is generally a consequence of chronic inflammation of the intestinal mucous surface, which may develop mesenteric disease either previously to, or co-extensively with the peritonitis. In this case, the peritonitis will mask the mesenteric disease. In many cases of chronic peritonitis which I have seen thus developed in children, I have met with very few where the mesenteric glands were not found diseased upon dissection.

34. E. The frequent association of phthisis with mesenteric disease above alluded to (§ 25) may be detected, particularly when the former is advanced, by shortness of breathing, by short, hacking cough, by the expectoration, by peritonitis, and by the stethoscopic signs. When the bronchial glands are the seat of tubercles, and the lungs are comparatively free from them, the diagnosis is extremely difficult. Moreover, tuberculous disease within the chest may be confounded with mesenteric disease, the diarrhea and state of the stools attending an advanced period of the pulmonary malady increasing the difficulty of the diagnosis. It is only by a careful examination of the thorax and abdomen, by auscultation and percussion, that the difference between them, as well as the association of both (which is more common than is usually suspected), can be fully ascertained.

35. F. When the mesenteric disease is far advanced, it generally manifests itself so as not to admit of doubt, unless it be masked by chronic peritonitis, or by serous effusion into the peritoneal cavity. At this period the enlarged glands may be sometimes felt, especially if the patient is examined early in the morning, and when fasting. But seryhala retained in the cells of the colon may be mistaken for them. The enlarged glands, however, are found nearer to the centre of the abdomen, and are attended by slight pain when examined with firm pressure. Scybala, on the other hand, are detected in the course of the colon, particularly in the left iliac fossa, and are not usually accompanied by tenderness on examination; nor by much emaciation, or lenticular stools. In these cases, which admit of doubt as to the presence of scybala, the use of purgatives, aided by enemata, will generally assist the diagnosis. I have met with instances of indigestible substances retained in the cells of the colon for many months, occasioning abdominal fulness, with hardness, emaciation, and constitutional disorder, which were mistaken for mesenteric disease, but which were removed by the strenuous use of stomachic purgatives, the substances causing the disorder sometimes masking the operation of purgatives for many days.

36. VII. APPEARANCES AFTER DEATH.—The mesenteric glands present, in the disease now described, particularly as it occurs in all climates and at all ages, although most commonly after weaning and in childhood, all the changes described in the article LYMPHATIC GLANDS (§ 54, et seq.), the tubercular changes being very much the most frequent. At an early stage the glands are redder, larger, and denser than natural; and subsequently tubercular matter is deposited either within or around them, or both; its accumulation causing atrophy, and ultimately destruction of the glands, this matter occupying their places, and, in some instances, accumulating to such an extent as to give rise to an aggregation of them into one very large mass. Those glands, containing tubercles which are advanced, are of a dull white colour and firm consistence; and, when the deposit is not very large, the lymphatic vessels in the glands still allow injections to pass through them. This circumstance has induced some to suppose that the tubercular matter is not accumulated in these vessels, but is deposited in the cellular tissue of the glands. Ultimately the tubercular matter softens, and presents appearances and produces changes similar to those observed in tubercular disease of the glands.

37. Besides the diseased mesenteric glands, inflammation and ulceration of the intestines, particularly of the lower portion of the ileum; inflammation and adhesion of the peritoneum, often with tubercular formations; and tubercular disease of the lungs, and of the bronchial and cervical glands, are found in most instances. There are very few cases in which these alterations of the digestive mucous surface and lungs are not observed in addition to the mesenteric disease. Tubercles are also occasionally found in other situations, as in the liver, brain, &c.; and serous effusion in the peritoneum and between the membranes of the brain, with or without tubercular formations, is also sometimes met with.

38. VIII. THE NATURE OF THE DISEASE is manifest from its early history and ultimate changes, both classes of phenomena showing that the mesenteric alterations are a part only of a general or constitutional malady; that the alterations with those often associated with them in the lungs, peritonem, and other glands, are generally manifestations of scrofula, which, as they become developed, react upon the frame, increasing debility, and producing irritation, fever, and its usual consequences. The common procession of disease is generally as follows: at first, constitutional vice and debility, impaired digestive and assimilating functions, irritation of the digestive mucous surface, and imperfectly elaborated chyle; subsequently, irritation and enlargement of the mesenteric glands, followed by tubercular deposits in them, and in other organs or parts; and, lastly, constitutional irritation and hectic fever; the extreme emaciation ultimately produced being not so much a consequence of obstruction of the mesenteric glands, as of the hectic or irritative fever, and of the changes in the bowels, lungs, and other parts.

39. IX. PROGNOSIS.—When the disease is clearly established, the prognosis is unfavourable; and no hopes of recovery should be entertained when it is associated with tubercles in the lungs, or with chronic peritonitis. On the other hand, when the disease is not far advanced, and before hectic symptoms are established, or the emaciation become great, or the stools have assumed a chalky or lenticular appearance, hopes of recovery may be entertained, although,
even in these cases, a cautious prognosis should be given. The younger the child, the greater is the danger. The causes and complications of the disease should also in some degree influence the prognosis. When these causes admit of removal; when unwholesome food and impure air produce the malady, and may be removed; and when intestinal irritation is the only complication, then a more favourable opinion may be given than in other circumstances. An improvement in the colour and expression of the face, a reduction of the size of the abdomen, a more feculent character, and less frequent passage of the stools, a gradual recovery of flesh, and a diminution or disappearance of evening accessions of fever, are indications of recovery.

40. x. Treatment.—The indications of cure are, 1. To ascertain the predisposing and exciting causes, and to remove them. 2. To support the constitutional powers, to restore the diseased glands to their healthy state, and, at the same time, to allay irritation of the alimentary canal. 3. To remove associated disorder, and to prevent the occurrence of disease in related organs or parts.

41. A. The removal of the causes, when fully accomplished early in the disease, will sometimes of itself restore the patient to health. It is true, that the early progress of these cases admits of great doubt as to their being cases of mesenteric decline. But, although they may not be fully-developed instances of this malady, they are fast progressing either towards it or towards as dangerous a malady, namely, to chronic ulceration of the intestines and consequent peritonitis. If, in infants at the breast, the nurse's milk has disagreed, or if the milk be poor, unwholesome, or disordered by prolonged suckling or ill health, the nurse should be changed; and the infant should have the advantage of wholesome milk, and the warmth of the bosom, and the young and warm nurse. When the disease manifests itself at an earlier age, and the enjoyment of vital warmth is next in importance to wholesome and nutritious food. If the disease be caused by weaning, or by inappropriate, too much, or incongruous food, causing irritation of the digestive mucous surface and an imperfectly elaborated chyle, a change of diet, a trial of the more digestible and less irritating kinds of food, and a liberal use of asses' milk warm from the animal, sometimes with lime-water, when the bowels are much relaxed, are means which should not be neglected. In other instances, but particularly when the patient resides in large towns, or in close, ill-ventilated situations and chambers, change of air into the country, or to the seaside, selecting dry and elevated localities, is one of the most successful means of cure that can be adopted. These advantages will be greatly enhanced by regular exercise in the open air, and by exposure to light and sunshine.

42. The frequent commencement of tabes mesenterica, or chronic irritation of the intestinal canal, in infantile remittent fever, and in other disorders mentioned above (§ 24), points out the importance of removing these diseases as soon as possible; and as they originate in the same circumstances and causes which are so productive of this malady, treatment will often be unavailable for them, if unaided by change of air and its consequent advantages.

43. B. Before developing the second indication of cure, which comprises the strictly medical treatment of the disease, I shall take a brief view of the means recommended by other writers. These consisted, in this country, until a comparatively recent period, chiefly of mercurials in some form or other, generally conjured with purgatives or alteratives; the use of other more rational means being commonly stigmatized with the designation of "inert practice," nothing appearing to many either good or appropriate, or efficacious, to which the term "active," as regards its immediate operation, was not applicable. No small mischief arose in those days from attempts made to reduce a tumid abdomen by means of cathartics or purgatives, the improper use of which often increased the flatulent distention, perpetuated intestinal irritation, and thereby, as well as by reducing the constitutional powers, augmented the mesenteric malady, and developed several of its most fatal complications.

44. a. Mercurials, and more particularly the chloride of mercury, have been prescribed for this disease by Baillog, Border, Portal, White, Curry, and many others. Underwood gave calomel twice or thrice a week, and the carbonate of soda during the intermediate days. He also had recourse to an infusion of burned sponge and senna; and afterward to bitters and chalybeates. Dr. Bohns recommended calomel with mild purgatives, and gentle tonics and frictions of the abdomen. Dr. Pemberton advised calomel to be given at bedtime, salts in the morning, and tonics with conium in the intervals. Mr. Bernethy and his disciples prescribed calomel, with rhubarb and ginger, on alternate nights; or blue pill and laxatives, followed by a prolonged course of Plummer's pill and sarsaparilla. Sir A. Cooper always resorted to the bi-chloride of mercury, one grain being dissolved in two ounces of the tincture of cinchona or of rhubarb, and a tea-spoonful given twice a day. He also advised plasters over the abdomen, or frictions, and a nutritious diet. Farre and others confined in mercurial frictions. Cullen, with much justice, has condemned the use of mercurials if otherwise prescribed than as occasional purgatives or alteratives; and there is no doubt of their having been hitherto too often employed in this disease in an indiscriminate and empirical manner. Still, when a liver is torpid, the stomach is irritable, and the lower bowels inactive, the milder mercurial preparations, conjured with rhubarb, or with rhubarb and magnesia, or an alkaline carbonate, are often of essential service; and I have found the practice advised by Sir A. Cooper, modified according to circumstances, sometimes of service.

45. b. The same remark applies to the use of purgatives generally. The advantages which arise from them can be realized only by a judicious selection of them, and by administering them appropriately to the circumstances of the case. Forbyce preferred rhubarb, and conjured it with the neutral salts, especially the tartrates. Herx and Beaumes also preferred rhubarb, the former giving it with the acetate of potash. Most writers and modern practitioners have prescribed it, either in substance or infusion, with
the sulphate of potash. Dr. A. Thomson has praised the combination of the two with calumba, directing ten grains of sulph. of potass., six grains of calumba, and three of rhubarb, thrice daily, and frictions of the abdomen with soap liniment. While purgatives have been thus generally employed, the selection has been chiefly limited to those which are the least weakening, or the most likely to produce deobstruant effects. The exhibition of tonics with these, or in the intervals between them, has been very generally adopted; and, although the practice has been inveighed against by Brous-
sais and his followers as being injurious, in regard not only of the combination of the two classes of remedies, but also of the employ-
ment of either of them singly, still it is appro-
riate to many cases, and to certain states and stages of the malady; and, as regards the results, more successful than the application of leeches to the abdomen, and the employment of demulcents recommended by this physician and his once numerous disciples.

46. c. Various alternatives, or substances inten-
tended to produce an alternative and a deobstru-
ent or tonic effect, have been prescribed for this disease besides mercurials. Pinel, Herbeard, Hofeland, and others, have recommended the martrate of barytes, but Ferriar and Thomson have not confirmed the opinion expressed of it by these writers. Dr. J. Hamilton was favour-
able to the use of antimonials when aided by a warm bath every night, by frictions with an opiate liniment, and by nourishing diet. There are few alternatives more serviceable in mesen-
eric disease than alkalies and alkaline carbonates, conjoined with mild tonics, and there is none more generally prescribed for it. Still, neither these, nor any of the medicine salarely recommended, should be depended upon solely, different means being required with the varying characters of the malady.

47. d. It is obvious that, when disease is so far advanced as to enlarge the mesenteric glands, or to occasion symptoms usuallyattend-
ing or indicating this lesion, it becomes nec-
essary to support the constitutional powers, while we endeavour to restore these glands to their healthy functions and condition; and it is equally obvi-
ous that neither can the constitutional powers be supported nor the glands be restored to health as long as irritation is allowed to exist in the alimentary canal. Therefore, having cleared away morbid secretions and fecal accumu-
lations, those substances which are most calculated to correct, improve, or restrain morbid action and secretion should be prescribed. With this view, small doses of hydrargryum cum ereta may be given at bedtime, either with Dover's powder or with ipecacuana and extract of poppy or of hop; and, during the day, crea-
sote or calumba, taken with demulcents, and with creasote and nutmeg, and the compound tincture of camphor, if the bowels be much relaxed. A warm bath should also be used at bedtime, and the abdomen be afterward rubbed with a lin-
iment composed of the compound camphor and the turpentine liniments, to which a little of olive oil and of cajeput oil may be added. The patient should wear flannel next to the skin, and sleep in blankets or in cotton sheets; and be allowed light, nutritious diet. If the bowels become confined, rhubarb and sulphate of pot-
ash, or castor or olive oil, may be given; or their action may be solicited by means of an enema containing these oils, alone or with spir-
its of turpentine. Having in some degree al-
layed irritation and corrected morbid secretion by these means, or even without having attained these ends, these remedies having been pre-
scribed, the patient in the preparation of doses of iodine* should be cautiously resorted to.

48. But, in order that any advantage may be obtained from these preparations, and even that mischief may not be caused by them, it is es-
Sentially requisite to prescribe them in small doses, and to carefully observe their effects. If the bowels be too much relaxed, the tolid of lead or of iron may be given with ipecacuana and extract of hop or of poppy in the form of pill; but in other circumstances, and at an ear-
ly stage of the disease, the tolid of potassium may be prescribed with the liquor potassae in the infusion or decoction of cinchona, or in any tonic tincture, with the compound tincture of camphor. The turpentine liniment, or embrocation, should also be applied over the abdomen, and the diet and regimen advised for this (§ 41, 53) and other scrofulous diseases strictly pur-
sued.

49. The diseased state of the digestive mu-

cous surface has been considered by Brous-
sais and his disciples to contraindicate the use of iodine, and all tonic and stimulating sub-
stances. But the affection of this surface is not a true inflammation, at least not a sthenic form of inflammation, but rather a state of as-

thenic capillary congestion, which is more readily removed by tonics and stimulants, es-

specially such as are also astringent, than by relaxants or depressants, and which not infre-
cently passes rapidly into ulceration if the former be not resorted to.

50. The principal error in the treatment of this malady has been that of viewing and treat-
ing it as limited to the mesenteric glands, and without reference to other lesions often assoc-
iated with it, and to the states of vital de-
pression and of anemia, attending not only its advanced, but even its early progress, in many instances. In these states, and even in those associated with tubercular disease of the lungs, the preparations of iron, in suitable forms of combination, are especially beneficial. Al-

though curious, it would be almost endless, to notice the various preparations and numerous modes of combining them, recommended by authors in this and in other diseases with which it is often associated; each one, with a more ardent desire to appear original than to prove useful, raising his own way of exhibit-
ing them. Having had no small experience of most of the preparations of iron, I can state

---

*The author was probably the first in this country, and certainly among the first in any country, to prescribe these medicines in this and in other constitutional maladies. When he returned from London to the Continent in 1820, he brought with him these preparations of iodine which had then been tried abroad; and as soon as they and others were introduced into this country by Mr. Morson, he had recourse to them in private and public practice. The same remark applies to creosote and some other substances. The first dose of creosote prescribed in this country was by the author, in consultation with Dr. Roscoe. This medicine, however, was not then to be procured in London; Mr. Morson, who was, and still is, the principal manufacturer of it, being then obliged to obtain it from abroad before the prescription could be prepared.
that most of them are more or less beneficial in those states and associations of this disease just mentioned, but that some of them are to be preferred to others. The iodide of iron prescribed in the sirup of sarsa, and sirup of poppies, if the bowels be too open; the mistura ferris composita with the tinctura camphorae, and extractum comi; combinations of the oxides of iron with the alkalies or alkaline carbonates; the tincture of the sesqui-chloride of iron, or of the ammonio-chloride, with or without a small dose of the dilute nitric acid, and two or three drops of the tinctura opii, or tinct. camphora comp.; the sulphate of iron with the carbonate of an alkali, and with rhubarb or powdered cascarilla; the compound steel pill with soap, or the compound soap pill and ipecacuana, are preparations and combinations of them severally employed by me in those conditions of the disease in which the support of the vital energies, and the promotion of assimilation and sanguification, are more particularly indicated; but I have never overlooked those external means and applications alluded to above (§ 47, 48), and have generally employed them at the same time. There are various other recently-introduced preparations of iron, which are more fashionable than efficient. I have tried them sufficiently, particularly the lactate, the citrate, the ammonio-citrate, and the ammonio-tartrate of iron. Of these, the first and the last are the most efficacious, and to children especially the most palatable. The others are also sufficiently palatable, but this is their principal virtue.

51. While these or other tonics are being employed, the bowels will generally require due regulation, by means of narcotics and astrin- gentes when they are too relaxed, and of stomachic or cholagogue purgatives when they are too costive. In all cases, care should be taken to preserve a due secretion of bile, as this fluid is necessary not only to the elaboration of healthy chyle, but also to a healthy state of the intestinal mucus surface. Hence I have (since 1818) always prescribed the insipissated oe-gall with the above or other medicales, when the secretion of the bile has been deficient, and the digestive mucus surface irritated and relaxed; although, for some years, this substance could not be procured at the principal chemists or druggists until I directed the preparation of it, so entirely had it been overlooked in this country. Numerous formulae containing it will be found in the Appendix and in the early part of this work. Long subsequently to the publication of these, and very recently, some writers in periodical works have lauded its properties, with attempts at originality to which they had not the smallest claims.

"Miranturque novos fructus, et non sua poma."

52. C. The third intention, viz., to remove associated disorder, and to prevent the occurrence of disease in related organs, as far as either object can be attained, can be accomplished only by fulfilling the indications already developed; for the chief complications, namely, irritation of the digestive mucus surface, infantile remittent fever, tubercular disease of the lungs or of other glands, &c., are best combated by the means already specified, aided by change of air, diet, and regimen; and these, at the same time, are the most likely to prevent the occurrence of more extensive disease, by supporting the constitutional powers, and promoting the digestive and excreting functions. Whatever complication may appear in the course of this disease is necessarily characterized by a moxica or tubercular, or inflammatory, or excretory action of the vital powers, and to imperfect sanguification and assimilation, and is irremediable, unless by restorative means, in conjunction with such as the nature of the complication may require. But in most of these complications, as well as in the more simple states of the disease, external derivatives, and means which will allay or diminish excessive action and secretion, where either is augmented, or which will increase either or both, when impaired or arrested, are chiefly indicated. A careful diet and regimen will also materially advance these objects.

53. D. Diet and regimen constitute a principal part of the treatment of this disease; but the former cannot always be assigned with sufficient precision, no particular kind of food proving beneficial in all cases, and rarely even in the great majority. For the youngest class of patients, the milk of a healthy nurse, the warmth of her bosom; light, farinaceous food, with warm or boiled milk; ass's milk or goat's milk, waxed, or with salt, are finally recommended, particularly to the seaside; warm salt-water bathing, and gentle, but regular exercise in the open air and sunshine; and flannel clothing next the skin, are generally beneficial. If the disease appear after weaning, nearly the same diet and regimen as now advised, with small quantities of the lightest kinds of animal food, or animal broths with boiled rice, or with stale or toasted bread, &c., are required. At a somewhat later period of life, the farinaceous kinds of food boiled with milk, and the more digestible articles of animal diet, may be allowed in such quantity as the peculiarities of the case and the amount of exercise may suggest. Sea bathing in summer and autumn is also necessary. In general, bulky vegetables and fruits should not be given; and the intervals between meals ought to be duly regulated, as well as the quantity of food, according to the age and strength of the patient, and stage of the disease.

54. E. For the prevention of the disease, when it is threatened, the means just specified, particularly change of air; sea, or country, or pure air; sea bathing, and flannel worn next the skin; sucking by healthy nurses for a sufficiently long period—from nine to fourteen months; nourishing and digestible food; exercise in the open air, and attention to the states of all the secretions and excretions, correcting and promoting them as circumstances may arise, are the means on which only dependance can be placed.

MILITARY ERUPTION—Definition.

CLASSI.—1st Class. 3d Order (Cullen). 3d Class, 3d Order (Good). III. Class. II. Order (Author).

1. Defin.—An eruption of vesicles, seldom ex- ceeding the size of a miller seed, over a large sur- face, generally symptomatic of serious disease, or caused by a heating regimen and confined air.

2. The symptomatic miliary eruption here to be considered is more correctly designated by the term sudamina than by any other, and is often difficult from the "epidemic sweating fever" described in another article (see Fe- ver, § 416), and which is often attended by a military eruption, as there shown. This form of epidemic fever has rarely occurred in modern times; and the miliary eruption, formerly not infrequently met with in lying-in women, is now rarely seen, owing to an improved regimen and practice in these circumstances. Bes- sides being caused by irritation of the skin, and especially by profuse perspiration, however in- tended, and besides being an attendant upon the epidemic fever just referred to, the erup- tion of miliaria or sudamina is met with as an occasional symptom: 1. In those puerperal diseases which are characterized by fever, and a morbid state of the circulating fluids, and are caused by impure air and a heating regimen. 2. In the early stages of smallpox, measles, and other eruptive fevers, and in the acutest state of adynamic or typhoid fevers. 3. In the course of fever depending upon gastro-intes- tinal or internal irritation or inflammation. 4. In connexion with acute rheumatism; and, 5. In the course of puerperal inflammations of serous membranes. In all these circumstances, this eruption is more correctly denomina- ted sudamina than miliaria, as it is always attended by a copious perspiration and increased heat; and, although it formerly was not infrequent in those maladies, when a heating regimen was so generally adopted during their treatment, it is now seldom, and even very rarely observed.

3. i. The symptoms of epidemic, military, or sweating fever are fully detailed in the article Fever (§ 420); it only remains for me to notice the characters of the eruption, when it is symptomatic of other maladies, or when it occurs after lying-in, or in consequence of copious perspirations and a heating regimen. From what I have already stated, it will be seen that I consider the epidemic fever there described to be more correctly designated by the name of sweating fever than by that of military fever; and that the term miliaria is here viewed as synonymous with sudamina. The vesicles of this eruption, seldom exceeding the size of a miller seed, are sometimes arranged at some distance from each other, but are generally distinct, and form patches. They are seldom confluent, and rarely coalesce so as to form bullae. They are at first small and prom- inent, transparent, and globular, their contents appearing as clear as limpid water, but becom- ing more opaque or milky. The surface upon which the vesicles are scattered varies in colour: 1. With the nature of the disease upon which they are contingent; and, 2. With the state of the vascular system as regards pletthora, &c. When this eruption accompanies any of the exanthemata, or when the pa- tient is plethoric or robust, the vesicles form upon a red or erythematous surface, and sub- stitute the miliaria rubra of authors, the colour of the surface appearing through the limpid and transparent fluid of the vesicles. But when the fluid becomes opaque, white, pearly, or milky, and when the vesicles appear on a com- paratively pale surface, the term miliaria alba has been applied to them. When they thus occur without inflammatory appearances in the skin, the term sudamina is most appropriate.

4. The vesicles naturally terminate in resolu- tion without forming scars or scars, but the cuti- cule covering them almost desquamates. The duration of the eruption varies with the circumstances which develop them; but it is gener- ally from three to eight days, or longer. It is sometimes prolonged by the appearance of the eruption in different situations successively, or of a second crop in the same place. The dis- appearance of the eruption has little or no in- fluence upon the course of the disease, of which it is symptomatic, although some writers have considered a retrocession of it injurious. But
where this has appeared to have been the case, the
retrogression may have been the consequence of
pre-existing internal mischief, rather than those
within.
As the sudden disappearance of the

MUSCULAR STRUCTURE—DISEASES OF.

993
vided into two orders or parts—into the muscu-
lar system of organic life, and that of animal life;ethe
former being un influenced by the will, and the
latter being exertively influenced by volition, and hence
called voluntary. The power or property of
animal
bodies, usually denominated IRritability
(see that article), is especially manifested by this
system, and more particularly by the voluntary
order of muscles, or those of animal life. Ir-
ritability may indeed be viewed as the vital man-
ifestation most especially belonging to this sys-
tem, although not confined to it in respect of
its lowest grade, or that which I have called, in
the article above referred to (§ 11), the "vital
contractility." I have therefore also referred
this function of muscles to the nervous system,
or systems supplying and endowing them (§ 17,
et seq.).

5. ii. The diagnosis of miliaria is easy, owing
both to the appearance of the vesicles, and to
the circumstances in which they are observed.
The only eruption with which it can be con-
founded is orzeina, the vesicles of which are
crowded in a small space, and are very confluent;
whereas, in miliaria, they are distinct and
spread over a large surface, always accompany
an acute or febrile disease, are rapid in their
progress, and of short duration.

6. iii. The prognosis of the acute diseases of
which miliaria is symptomat is not affected by it.
The eruption itself only indicates a state of
increased action with determination to the
cutaneous surface. In connexion with epidemic
fervor, as shown elsewhere (see FEVER, § 419, et seq.), it evinces a serious state of dis-
case.

7. iv. Treatment.—The eruption itself requires
comparatively little attention, the disease of
which it is symptomat demanding the chief
care. In most of the maladies in which it oc-
curs a cooling regimen is necessary. Refrig-
erant drinks, and sub-acute fluids, particularly
those containing dilute hydrochloric acid, may
be allowed. The patient's room should be well
ventilated, and the clothes on his bed ought to
be light. The bowels should be kept gently
open, and the surface of the body sponged
freely with tepid vinegar and water, or by any
other agreeable fluid.

125

1.

The muscular system has usually been di-
or severely injured, the parts supplied with nerves proceeding from that part, and from the chord below the seat of injury, are paralysed; and when any part of the medullary, or white structure of the brain, is injured, the muscles more especially related to that part are paralysed, or removed from the influence of volition. In all these cases sensibility may be preserved, the stimulus of volition originating in the brain being no longer conveyed to the voluntary muscles, owing to lesion either of the white or fibrous structure of the brain, or of the spinal chord, or of the nerves. Owing also to irritation of either of these parts of the cerebro-spinal system, the muscular structures connected with them may be excited into inordinate action; and lesions of either, when slight, may merely impair, without entirely destroying, the voluntary motion of the muscles related to it.

5. While the muscular system of animal life is thus subjected to the cerebro-spinal nervous system, it is not to be entirely ignored that this dominion solely and entirely; for many phenomena connected with disease, and even with health, particularly during sleep, show that conditions of the internal viscera, or of the organs supplied either altogether or chiefly with the organic nerves, often affect the voluntary muscular system in a very remarkable manner. In all such instances, the change in this system is produced through the medium of the organic or ganglial nerves, which convey the impression to the spinal chord, or even merely to the roots of the spinal nerves. Thus, in cases of intestinal worms, or other visceral irritations, the morbid impression is not infrequently transmitted by the ganglial and sympathetic nerves, and ultimately expressed upon the voluntary muscles; and, in most instances, without any intermediate change in the brain, or even in the spinal chord itself, the impression being conveyed directly from the viscous affected, by communicating branches to the spinal roots, or to the roots of the spinal nerves. Cholera, and several states of convulsion, are proofs of this mode of transmission of irritation from involuntary parts to voluntary nerves and muscles; and the phenomena presented by fetuses without brains, or without both brains and spinal chords, are also illustrations of it, as shown in the articles Cholera, Chorea, Convulsions, &c.

6. Those inordinate actions of voluntary muscles resulting from visceral irritation, are muscular spasm; they are not to be entirely beyond the control of the will, as in the diseases just noticed, or unless volition be very strongly exerted, as in some instances of hysteria. Most of the contractions of voluntary muscles that occur during sleep are induced by irritation of internal viscera; and the irritation may immediately affect the brain and occasion dreaming, according to the nature of such irritation or impression, or it may be more immediately transmitted to the voluntary nerves and muscles ultimately affected, without in any way impressing the sensorium.

7. 3d. That the state of circulation of blood in muscles materially affects their contractile power has been fully proved by experiment and by pathological observation. It is not alone necessary that a sufficient circulation or supply of blood should exist in muscular parts in order to preserve their functions and organization, but also that the blood be duly oxygenized or changed from the venous to the arterial state. It is fully shown by disease and experiment that interruptions of the changes produced by respiration on the blood impair or disorder the contractility of muscles, by affecting not only the cerebro-spinal axis, but also the muscles themselves; the highly venous or unoxegenated blood affects both the cerebro-spinal system and the muscular structure itself. The phenomena of asphyxia, of the advanced stage of pestential cholera, and other diseases attended by interruption of the respiratory processes, fully illustrate this proposition.

8. When the principal artery of a limb is tied, and when the supply of arterial blood to the muscles is not kept up by a collateral circulation, the muscles are paralysed, the limb is benumbed, and it soon dies. When the venous current is entirely interrupted the limb is rendered remarkably congested, livid, benumbed, paralyzed, and as if locally asphyxied. On the other hand, when the supply of blood to muscular parts is free, abundant, and of a healthy and duly oxygenized quality, the contractile power of muscles is thereby increased and perpetuated.

9. 4th. It is evident that the original conformation, the organization, and the nutrition of the muscular fibre very materially affect the amount of its function, or of its contractile power. Muscular parts acquire increased vascularity and development with the frequency of action, and with these, augmented power; while they become pale, atrophied, weak, and at last almost paralyzed by disuse. These changes are chiefly owing to increased or diminished determination of nervous power and of arterial blood to these parts, according as their functions are discharged; but they are also owing to the states of nutrition consequent upon the amount of function performed.

10. Other agencies, of disorders of the contractile power of muscles, the most frequent are those which are seated in some portion of the cerebro-spinal system of nerves, and at the same time they are productive of the most manifest effects. This fact is demonstrated by disease. The palsy of a single or of a few muscles is generally caused by lesion of the motor nerve or nerves supplying them. Palsy of a portion of the body transversely, or paraplegia, is commonly produced by disease in or implicating the spinal chord; and palsy of one side, or hemiplegia, is occasioned by lesion of the brain. Chorea, paralysis agitans, or shaking palsy, the trembling or shaking caused by mercury or other metals, or by age, or by the abuse of spirituous liquors, generally depend upon the state of the spinal chord, and are often aggravated, as in chorea, by exertions of volition, the contractions produced by volition being weak, vacillating, and uncertain, owing to the state of the spinal system, or to the diseased movements caused by the state of this system. On the other hand, tetanus, eclampsia, epileptic and hysterical convulsions, cramps, &c., are manifestations in the muscles of irritation of some part of the cerebro-spinal system, more particularly of the spinal chord, the irritation either existing primarily in it, or being propagated to it by ganglial
or other nerves, and thence reflected by motor nerves on the muscles.

12. Lesions of Sensibility in Muscles.—These generally proceed from repeated, prolonged, or excessive contraction or exertion, and vary from the slightest feeling of lassitude or fatigue to the excessive pain attending spasm and tetanus. In some forms, also, of rheumatism, severe aching pains are referred to the muscles, a myalgia, which may be owing to alteration of the sensibility of the nerves supplying the muscles.

13. The muscular fibre is rarely the seat of inflammation. Indeed, it is doubtful whether or not it is ever inflamed, or can admit of being inflamed, owing to its organization. Most probably, in those cases in which the muscles have been found exhibiting evidences of inflammation, the fine cellular tissue connecting the fasciculi of their fibres have been chiefly or solely affected, this being the most vascular part of their structure. There can be no doubt that some of the cases which have been viewed as instances of myositis have been cases either of rheumatism, in which true inflammation of the muscles does not exist, or of inflammation only of the cellular substance surrounding or connecting muscles. In rare cases, however, the muscles, in the manner now stated—chiefly as respects their connecting and surrounding cellular tissue—are the seat of inflammation. The muscles are no farther affected in rheumatism than as respects their sero-fibrous sheaths and aponeuroses, which sometimes are implicated in that disease, the muscular fibre itself not being inflamed.

14. The causes of myositis are chiefly external injuries: bruises, wounds, sprains, excessive contraction, or over-exertion; sudden contraction of a muscle when volition has not been distinctly directed to the part, rupture of the fibres of muscles from over-exertion, or from contraction with imperfect volition; dislocations, lifting heavy weights; injuries or wounds of aponeuroses or tendons; and caries or other diseases of adjoining bones, especially of the vertebrae. The muscular fibre is very rarely inflamed when the bones are healthy. These causes and effects affecting the vital condition—the sensibility and vascular actions of muscles—individually and collectively, although the sero-fibrous sheaths of muscles and tendons, and aponeuroses are often inflamed in the course of rheumatism, owing to internal causes and influences affecting their vital states. (See art. Rheumatism.)

15. The symptoms of myositis are, extreme pain, stiffness, and tenderness of a muscle or muscles, the pain being so much increased by contraction as to render all attempts at motion most difficult, or altogether impossible; increased heat, and indistinct or diffused swelling of the part; sometimes subsultus of the tendons, or rigid contractions, or spasms of adjoining muscles; and always symptomatic inflammatory phenomena of the usual constitutional phenomena of such fever.

16. With the exception of traumatic myositis, which may occur in all situations, the muscles which have been the most frequently inflamed are, the psoa, the tongue, and the diaphragm. The muscles of organic life are often the seat of inflammation than those of voluntary motion, particularly the urinary bladder, stomach, oesophagus, heart, &c.; still it is doubtful, even in these, whether or not the muscular structure is inflamed, rather than in being implicated consecutively. It is most probable that the inflammation originates, and is seated chiefly, in adjoining or connecting tissues, the muscular fibres being, from their organization, incapable of experiencing those changes which have been usually termed inflammatory, although their functions are disturbed or interrupted by the disease in which they are implicated.*

17. The consequences of inflammations of muscles are chiefly exudations of serum or lymph, softening of the tissue, induration, suppuration, and gangrene. A. Exudations of serum or of lymph may take place, in the course of myositis, between the fasciculi of fibres, or from the surface of the fibrous sheaths or aponeuroses enveloping muscles. Such is the case, more especially, when muscular parts become involved in the course of diffusive or asthenic inflammations, particularly of the connecting or interposed cellular substance.

18. B. The softening is caused by the cellular texture in consequence of inflammation is rarely met with in the muscles of the skeleton, unless in some of the worst instances of diffusive, erysipelas, or asthenic inflammations; and after poisoned wounds, and the inoculation of animal poisons. But it is not infrequent in the muscular coats of the alimentary canal and urinary bladder, in conjunction with a similar change of their other coats, more especially in the course of dysentery and adynamic or enteric fevers. It is also observed secondarily in the diaphragm, particularly when this muscle becomes inflamed consecutively upon hepatitis; and more rarely even in the heart, during the course of malignant, continued, and exanthematic fevers, in cachetic diseases, and in the course of some cases of true carditis. In most of the instances of inflammatory softening of muscles, the colour of the part is changed to a more dark or dusky red than natural, or to a dirty brown. In some cases, however, the softened part is rendered whiter than usual. The muscles of the thigh and leg were intensely painful, swollen, and hard almost as a board; motion was impracticable. The parts were very hot, and there was much constitutional fever. The result of the ease we never learned.*

* [We recently witnessed a case of inflammation of the muscular tissue in a hod carrier, who had over-exerted the muscles of the leg in climbing to the top of a high building with a heavy burden on his shoulder, his thigh and leg were intensely painful, swollen, and hard almost as a board; motion was impracticable. The parts were very hot, and there was much constitutional fever. The result of the ease we never learned.]
MUSCULAR STRUCTURE—Structural Changes of.

caries of the vertebrae, the disease of which has extended to the adjoining muscles and cellular substance, the matter which has been formed infiltrating this substance to a considerable distance. The exudation of serum, or of a serous lymph, may, according to the states of vital power and of the circulating fluids, give rise to various changes—either to purulent collections, or to an offensive sanguine, contaminating the adjoining parts, and splanchnizing the cellular and adipose substances which it infiltrates.

20. D. Gangrene is sometimes observed consequent upon acute inflammation, occurring in an unhealthy habit of body, or during the progress of malignant fevers. It may destroy large masses of flesh; but this rarely takes place except some previous or co-existing change exists in the nerves or blood-vessels supplying the gangrened part. In a case to which I was called many years ago by my friend Dr. J. Davies, of Hertford, a gangrene of all the muscles of one limb occurred, produced from inflammation of the iliac artery and vein associated with neuritis.

21. E. Induration or hardening of muscles, with change in their structure, is generally a result of slow inflammatory action, and of the exudation of lymph, thereby produced, into the cellular tissue connecting their fibres. It is met with in both the voluntary and involuntary muscles, in different degrees, and usually is attended by some swelling or enlargement. In the more advanced stages of this change the hardening is increased: the muscle becomes pale, loses its usual texture, and assumes either a leathery, a tendinous, or even a cartilaginous appearance, while, at the same time, its bulk is more or less diminished.

22. IV. The treatment of inflammation of muscular parts is in no respects different from that of acinic inflammation of other structures. The usual antiphlogistic remedies and regimen should be enforced, with various modifications accordant to the extent, nature and variety of the means to be employed, which the seat of the disease, its causes, and the constitution of the patient, will suggest. In cases where muscular parts are involved in inflammations of an asthenic or diffuse character, incisions are often required to prevent the contamination which would follow if the morbid matter formed in the part was not allowed a free exit. In all respects the treatment, both constitutional and local, should be conducted according to the form the disease assumes, and conformably with the principles fully developed in the articles Inflammation, Erysipelas, and diffuse inflammation of Cellular Tissue.

III. CHANGES OF MUSCULAR STRUCTURES NOT STRICTLY REFERABLE TO INFLAMMATION.

Class.—IV. Class, III. Order (Author).

23. A. The size of muscles is much influenced by disease.—a. Atrophy of muscles is very common; in consequence of deficient nutrition, to the extent of the healthy state of the system, of febrile action, of muscular, and venereal excesses, and of visceral and constitutional disease. In these circumstances the wasting is general; but it is often partial, as in the muscles of the legs and lower limbs, particularly in persons addicted to the excesses just mentioned, and in those who are lame. Disuse of the muscles of voluntary motion always occasions their atrophy. Long-continued pressure has a similar effect, whether occasioned by tumours, dropical effusions, or by swellings of any kind. In cases of this description large muscles frequently become expanded, and reduced to a membrane.

24. b. Hypertrophy seldom occurs in the voluntary muscles, excepting as a consequence of active exercise, and it then cannot be considered as a morbid state. It is met with in the involuntary muscles, as in the structure of the heart, stomach, and urinary bladder, and is then owing to morbidly increased action. If ever observed under other circumstances in the muscles of the skeleton, it is merely apparent, and occasioned by the deposition of lymph or adventitious structures between the muscular fibres.

25. c. The colour of muscles varies exceedingly, according to the abundance of haematine in the blood, and to the quantity of this fluid which is hydrated from infiltration of the interstitial parts of the skeleton. In muscular ecchymose, the muscles are congested with blood, as is frequently the case in persons dead from asphyxia, drunkenness, tetanus, sanguineous apoplexy, narcotic poisons, &c, they are usually of a deep red or dark colour, the blood in the vessels being semisolid. In inflammatory and pulmonary diseases, they are either red or purple-red; in typhus, pestilential cholera, plague, yellow fever, and other pestilential maladies, they are bluish-red, or of a very dusky red. In scorbutic persons they become, in places, of a dark brown colour. In all those diseases in which there is a deficiency of blood—in chlorosis, rickets, tubercular affections, dropsies, in many very fat or leucophaeugmatic persons, and in visceral affections diminishing the assimilating processes, the muscles are more or less pale. When limbs have been disused, are lame, the joints anchylosed, &c, the muscles become not only atrophied, but also remarkably pale or even white. A pale state may also arise in muscles of the natural size, from great venereal depletion. Changes of texture are often attended with alteration in the colour; when the muscles are converted into fatty or adipocereous substance, when indurated from inflammation, and when affected with seirrus, they often become unusually pale.

26. d. Contractions of muscles arise chiefly from irritations affecting the origins of nerves supplying them, or certain parts of the encephalon in intimate correspondence with these nerves, or the ganglial nerves accompanying with them. This alteration of muscles may also be connected with injury to, or with irritation or inflammation of their tendons and aponeuroses. After long contraction, the muscle becomes atrophied, pale, and reduced to a state approaching to that of aponeurotic fibres. Remarkable contractions of the circular fibres of portions of the hollow viscera are sometimes found many hours after death, when these viscera have been shortly before dissolution the seat of severe irritation. This alteration of muscles may also be connected with injury to, or with irritation or inflammation of their tendons and aponeuroses. After long contraction, the muscle becomes atrophied, pale, and reduced to a state approaching to that of aponeurotic fibres. Remarkable contractions of the circular fibres of portions of the hollow viscera are sometimes found many hours after death, when these viscera have been shortly before dissolution the seat of severe irritation. This alteration of muscles may also be connected with injury to, or with irritation or inflammation of their tendons and aponeuroses. After long contraction, the muscle becomes atrophied, pale, and reduced to a state approaching to that of aponeurotic fibres. Remarkable contractions of the circular fibres of portions of the hollow viscera are sometimes found many hours after death, when these viscera have been shortly before dissolution the seat of severe irritation. This alteration of muscles may also be connected with injury to, or with irritation or inflammation of their tendons and aponeuroses. After long contraction, the muscle becomes atrophied, pale, and reduced to a state approaching to that of aponeurotic fibres.
ing, and some degree of atrophy when the con-
traction has been of some duration. Firmness
and dryness, when considerable, are common-
ly local changes affecting chiefly muscles which
have been long contracted, or pressed upon by
swellings, tumours, &c. LENFLAM and Otto
have, however, recorded instances in which
the muscles were hard and dry throughout.
These alterations are most frequently observed
in very aged persons.

28. k. The consistence of muscles is often more of a jelly-like substance throughout, particularly in the advanced stage of adynamic, typhoid, and putro-adynamic fevers, in yellow fever, plague, scurvy, dropsy, and still more so in persons killed by lightning, or by a blow on the epigastric centre, also in cachectic diseases, and whenever the blood becomes vitiated by animal or other poisons. Softness and flabbiness in all these maladies are generally the results of impaired vital cohesion of the struc-
ture, and the colour of the muscles is, in these circumstances, generally deep red and the derma
and is owing to the dark and morbid state of the blood. In tubercular and visceral diseases, in
paralysis, certain chronic affections of the heart, in chlorosis and anaemia, the flabbiness or softness of the muscles is owing more to deficient circulation of blood in, and impaired nutrition of, the muscles, than to diminished cohesion, the muscles thus affected being of a pale yellow or fawn colour. Softness of muscles may be remark-
able in the systems both of organic and animal life. I have met with it in both, in all the
diseases just enumerated, and even in the heart itself. I observed it in the heart associ-
ated with unusual pallor of the tissue in a case of chlorosis (see London Med. Repos., vol. xv.). Softening sometimes occurs locally to a great extent in the vicinity of malignant af-
fections, as in the lips and cheeks from watery cancer, and near carcinomatous and fungoid forma-
tions. In some marked cases of the kind, a large portion of muscle has been con-
verted into a jelly-like, pulpy, or fungous mass, constituting the myomataxax of some authors.

29. e. Fatty or adipocereous degeneration of mus-
cles—Mysostatosis, Myoelemia of Lobstein, and stecatosis of Cragie—is rarely observed.
In this state the fibrous structure of the part is entirely lost. Otto states that it occurs chiefly
in the lower extremities after diseases of the knee joint. In fat persons there seems to be an
approach to this state, in the extreme parts of the subcutaneous fibres, as an adipose in-
atoms of fat between them. This change has likewise been observed to occur in the heart by
Laennec, Adams, Andral, and others.

30. d. Fibrous, cartilaginous, and osseous transfor-
manions of muscles are sometimes seen. Muscles which have been long retracted, particu-
larly in old men, after rheumatism, often assume a fibrous, or even a fibro-cartilaginous state. M. CREVELLIER has found the muscles of the leg transformed to this state in a case of elephantias. A similar change may occur after fractures. The muscles at first the frac-
tured part being partially converted to a fibro-
cartilaginous, a cartilaginous, and osseous structure successively. Taverne r and An-
drel have observed ossification of muscles to
a great extent. In most of the cases in which it has been seen it has been limited to the cellu-
lar tissue between the larger fasciculi of fibres, or dipping into them from the fibro-serous ex-
tractions and aponeuroses, beneath which the ossific matter is deposited. As the osseous change proceeds the muscular fibres become atrophied, and ultimately disappear. Earthy or phosphatic concretions are sometimes met with in the same situation, and in the cellular sub-
stance between the muscles, especially in gouty persons.

31. c. Tubercular degeneration is very rarely seen in muscles, and is met with only in the
vicinity of serofibous disease of the knee joint, or of tuberculous masses in the neck, armpit,
mastidiatum, &c.

32. f. Malignant degenerations of muscles are ob-
erved only secondarily. Scirrhus is thus met with, changing the muscular structure to a dense, whitish, fibrous substance, which sub-
sequently runs into malignant ulceration. Cancer, in the vicinity of the muscles, enter-
ally sarcoma or fungo-haematoid disease, are some-
times found to invade the muscles, particularly the pectoral, to a considerable extent. Me-
lanoid formations are also observed, but chiefly
in the connecting cellular tissue.

33. g. Simple cysts, cysts containing hyda-
toids, and others containing small worms, have
been found in the substance of muscles. The
former have been observed by Werner, Lon-
stein, Cruveilhier, and others; the last by
Mr. Owen—the trichina spiralis—who found this worm in subjects who had died of differ-
dent diseases, of a low character.

34. h. Fluids are sometimes effused between
the muscular fibres. These consist: 1. Of a
watery serum, in some cases of dropsy and leu-
cophlegmasia. 2. Of a gelatious matter, infiltr-
ated between the fasciculi and around the
muscle, in acute rheumatism. 3. Of puriform or sanious matter, infiltrating the fasciculi of muscles, found only in rare instances, and in cases where puriform or ichorous fluids have
been carried into the circulation from a distant
situation; and, 4. Of blood. This last has been met with in various proportions, and has pre-
sented various appearances—fluid, serulent, and
dark, or almost black—in small specks, or
ecchymoses, or in larger deposits. The effu-
sion of blood between the muscular fibres has
very rarely caused rupture of them. To this
alteration, the term muscular apoplexy has been
applied by several French pathologists. It is
very rarely met with in the voluntary mus-
cles, unless in secretory state, and amyotro-
phic. It is sometimes seen in the involuntary
muscles, and even in the heart itself, after
death from malignant, putrid, or pestilential fevers.

35. i. Inflammation and obliteration of blood-
vessels are often followed by marked altera-
tions of the muscles, which the diseased vessels
supply. Thus, Cruveilhier and others have trac:
phlebitis from one of the principal veins of a limb to the branches proceeding from a
muscle; purulent matter infiltrating it, and
numerous small abscesses being interposed be-
tween its fasciculi. Obliteration of the blood
vessels is generally followed by gangrene, and
particularly when the arteries are obliterated,
unless a collateral circulation is formed. The
NERVES—DISEASES OF.

gangrene following ergotism is chiefly occasioned in this way, although some change is also early produced by the morbid food on the nerves of the part. Ulceration rarely takes place in muscular structures, and chiefly in consequence of the pressure of tumours. In the involuntary organs it sometimes extends to and invades the muscular structure, in its progress from the adjoining parts. It has also been observed in Malignant ulceration, softenings, and destruction are often met with consecutively upon local malignant maladies, particularly in the pectoral muscles, and in the face.

35. k. The physical and mechanical changes to which muscles are liable consist of rupture of their fibres, rupture of the aponcratic envelopes, or luxations of muscles, contusions, etc. The consideration of these does not fall within the scope of my work. I may, however, remark, that the contiguity of the muscular tissue may be destroyed by external violence variously applied, by spontaneous rupture after antecedent softening, by suppuration and ulceration, and by violent involuntary contraction. When these accidents are not the result of previous organic change, they are generally repaired by means of a reddish jelly-like substance, poured out at the point of separation. This substance changes into a vascular and reddish cellular tissue, becomes subsequently compressed, of a lighter colour, more solid and less vascular, forming the medium of union of the divided parts, and restoring the continuity and functions of the injured muscle, but itself not consisting of true muscular tissue.

37. l. Rupture of the fibres of a muscle generally occurs upon some sudden, involuntary, or unconscious and violent contraction of it; is attended by extreme pain, sometimes by a crack or noise, and by inability to contract the muscle, each attempt to do so remarkably augmenting the suffering; and is followed by some swelling, exhalation, occasionally by ecchymosis. The treatment of these accidents consists of constant relaxation of the muscle, favoured by position, and of suitable bandaging of the part or of the limb, continued until repARATION has taken place.

NERVES—DISEASES OF.—The various affections and structural lesions of nerves have been insufficiently investigated; and the existing state of knowledge respecting them is without precision, even as respects those which are the most frequently observed. Sciatica is a proof of this want of precise knowledge; for information is still required as to the state of the nerve in this affection. Corcoran, one of the earliest investigators of this complaint, imputed it to inflammation. This opinion was considered incorrect by later writers; and now it has been demonstrated that certain states of sciatica actually proceed from inflammation of the sciatic nerve. In cases of morbid sensibility also of other nerves, it has not been shown whether the affection be functional merely, or whether it be really inflammatory, or dependant upon alteration of structure. And it is often difficult to determine how far the trunk of the nerve is implicated, or whether or not the affection proceeds entirely from disease at the origin of the nerve in which it is manifested. These remarks apply also to impaired or abolished function and sensibility of nerves. The real mischief may be seated at or near their origins, in their trunks, or in parts closely connected with either; and the same species of lesion which in either situation may induce exaltation of sensibility or spasm, or convulsive actions of the muscles supplied by them, may, in a higher grade, produce loss of sensation, and in a still higher grade occasion loss of motion, or loss of either, or of both functions, according to the nature and precise seat of lesion. Since the researches of Sir C. Bell have appeared, some light has been thrown upon this department of pathology; still the light has been sufficient only to render our darkness more visible. In the brief account about to be given of diseases of nerves, I shall notice, first, the lesions of structure observed in them; secondly, inflammations of nerves; and, thirdly, morbid exaltations of sensibility, or neuralgic affections; certain other disorders of nerves being comprised under different appellations, as paralysis, &c.

1. Structural changes of Nerves.

Classif. IV. Class. III. Order (Author).

1. There are few parts of the animal body less subject to organic lesion than the nerves, particularly those of voluntary motion; and the lesions most frequently observed in them are chiefly those of injury or mastication of the parts connected with their origins, or of inflammations of some portions of their trunks.

2. A. The size of nerves varies materially, and the change may be either original or acquired. —a. Congenital or original smallness is not infrequent, either in a simple state, or conjoined with other morbid changes. It is generally connected with absence or imperfection
of the organs to which the nerves thus affected belong. In internal dropsy of the head and hy-
drencephalocele, the cerebral nerves, while
within the skull, are often very thin, as are the
spinal nerves in the vicinity of the tumour in
spina bifida.—b. True atrophy of the nerves,
wasting or acquired smallness, is generally met
with in particular nerves; it is seldom or nev-
er general, excepting in a very slight degree, in
general emaciation, or in very old persons. In
hemiplegic and paralytic persons, the nerves of
the paralyzed parts are seldom very remarkably
smaller than those which are capable of con-
voying volition. The nerves, however, of the
organs of sense waste, shorten, or lengthen,
&c., as the cause and consequence of diseases
impairing or abolishing the functions of these
organs. This has been most commonly re-
marked in respect of the optic nerves, which,
alone, or with the optic beds and quadrigeminal
bodies, have been found atrophied. Wasting of
nerves frequently arises from pressure of
any kind, and that of tumours, a portion of
fluid, or &c., and is sometimes connected
with neuralgia and epileptic affections. Wasting
of the trunks of the nervi vagi has been observed
in consumption, and of the ganglial nerves sup-
plying the organs of generation some time a-
fter the disappearance of the mesenchyme.
3. c. Irregular increase of the size of nerves is
rarely congenital; but is sometimes met with
as a consequence of inflammation, dropsy, can-
cer. In such cases, single nerves are only af-
fected; but the increase of size is sometimes
three or four fold. The ganglia and sympat-
hetic nerves are not infrequently enlarged.
Laumontier, Pixcl, Romberg, Lobstein, and
Duncan have found them unusually large in
idiots, hemiplegic monsters, and diabetic pa-
sients; but Meckel and Otto, in their dissec-
tions after death from those diseases, have not
observed this appearance. [Lobstein has often
noticed the thoracic ganglia and semilunar
plexus very much engorged with blood, and
florid from inflammatory congestion; and Dr
Oliver, a pupil of Dr. Meckel, at Natchez, Miss.,
observed disease of the thoracic and abdomi-
nal portion of the great sympathetic, in the yellow
fever which prevailed in that place in 1823.
Seventeen out of twenty yellow fever subjects
presented intense congestion and inflammation
of the semilunar ganglia and plexuses; and
the cardiac and pulmonary plexuses were often,
as also, in the same pathological condition, though
the latter were less frequent and extensively
affected than those of the other viscera. In
connexion with these appearances there was
usually more or less lesion of the cerebro-
spinal axis, the duodenum, stomach, lungs, or
Dr. R. LcK has demonstrated the remarkable
enlargement of the uterine nerves upon concep-
tion and during pregnancy. (Philos. Trans.,
1842.) Thickenings of the nerves is not an un-
usual consequence of chronic inflammation of
their sheath and the cellular tissue connecting
their fibrils. In several cases of this descrip-
tion, the nerve assumes a yellowish or grayish-
yellow color. The sympathetic nerve is often
found enlarged, sometimes to six or eight times its
natural diameter. A case of this kind is recorded
by Czernylicher (Path. Anat.), in which all the
cervical ganglia of the left side were enormously
enlarged, especially the middle, which was
two inches and a half in length by one inch in
thickness. They were of a grayish-white col-
our, of a very dense, compact consistency,
creaking very sensibly under the knife. They
were evidently fibrous, so arranged as to form
a large number of cells, filled with a sort of ge-
latinous substance; the component nervous
filaments were completely atrophied, the only
part left being their neurilemmic covering.
The nervous cords between the diseased gan-
glia, as well as those which passed off from
them, were very much enlarged, of a pale gray-
ish colour, and abnormally firm in their consist-
ence. (Gross.)
A. B. The nerves may also present anomalies
of form, position, and ramifications. These are
too numerous, in respect of every nerve, to ad-
mit of particularizing them.—a. Their colour
varies with their structural changes. When atrophied or softened, they usually lose their
gloss and whiteness, become somewhat opaque,
grey, or yellowish, or grayish-yellow. Con-
tused or inflamed nerves are more or less red
throughout, or spotted or streaked with red.
In ulcers and gangrened parts, they are usually
more or less discoloured. In complete atrophy,
or near a cancerous part, they present various
shades of brown or rust-colour. In jaundice,
they very seldom participate in the general dis-
coloration.
5. C. The consistence of nerves is sometimes
either diminished or increased.—a. Diminished
consistence is most common: instead of being
firm and elastic, the nerve becomes soft, with-
ered, or shrivelled, easily torn, and appears as
if macerated. In some instances, their sheaths
are of their natural firmness, but their fibrils
seem loosened, and somewhat separated from
each other. In other cases, the medullary part
of the nerve is remarkably softened and dis-
coloured, appearing as if it had been dissolved
by a solution of a fixed alkali; and, in the more
extreme cases, they completely disappear, so
as to run out upon the division of the nerve like
a jelly, or even like water. This state is anal-
ogous to that described under the name of pulpy
disorganization of the medullary structure of
the brain, and proceeds from the same causes,
one of the chief being a high degree of inflam-
mation. Softening of the nerves may also be
conjoined to atrophy. The nerves, in some
parts, are sometimes entirely deprived of me-
dulla, the hollow sheaths alone remaining.
This occurs chiefly within the skull and spine
in children, or from imperfect development of
the brain and water in the head, or with hydren-
cephalocele, and spina bifida.
6. b. Induration of nerves is a rarer occur-
rence than softening, and seems to be chiefly
attributable to a state of chronic inflammation,
causing the deposition of a plastic lymph in the
cellular tissue connecting their fibrils and gluing
them more firmly together. Induration may also
be conjoined either with atrophy or with hyper-
trophy of the nerve. The medullary substance
is never actually converted into car-
tilage or bone.
[e. The fatty degeneration of nerves, or, rath-
er, a deposit of fat within the neurilema, has
been noticed in some instances. A case of this
kind is recorded in the Loud. Med. Gaz., Aug.
26, 1842, from MULLER'S Archives, in a man affected with anasarca and ulcers of the leg. Portions of the saphenus nerves, and other large branches of the ischiatic, in the neighbourhood of the diseased part, were enlarged, and appeared as if composed of mere fat. On examination with the microscope, an extraordinary quantity of the substance was found interposed between the sheath and the fibres of the nerve, which increased in irregular gradations as it was traced downward, till it constituted the whole structure of the nerve. The fat globules appeared to be arranged concentrically on the inner surface of the sheath, into which the primitive fibres could be seen running. They gradually disappeared lower down, till at length no trace of them could be found, the fat globules having entirely taken the place of the primitive nervous fibres.]

7. D. The continuity of nerves may be broken, as in external injuries, wounds, &c., by which they may be partially divided, torn asunder, contused, their fibres forcibly separated, &c.—a. If they be stretched gradually, as by soft tumours, swellings, &c., they often yield remarkably without their functions being destroyed. But when suddenly and forcibly extended, as by hard tumours, aneurisms, dislocations, &c., they may be torn, although this can rarely happen without breach of continuity in the surrounding or more superficial parts.—b. When a considerable nerve is wounded, neuralgic and sympathetic affections sometimes arise in addition to the necessary paralyzing of the part which it supplies, and to the usual phenomena proceeding from such injuries, as redness, swelling, effusion of coagulable liquor, and reunion. If a nerve be completely divided, both extremities swell, particularly the upper; the more distant or separated portion of nerve becomes somewhat thinner, and the lymph effused between the divided ends unites them both into a more or less large and solid knot, consisting of cellular tissue, into which new and irregularly-disposed nervous threads are produced after some time. There is no part of the soft solids which are more disposed to unite than nerves, even although the division has been made with loss of a considerable portion of the nerve, or their ends have been far removed; but the union is always made through the medium of a cellular tissue produced from the divided ends, into which medullary fibres shoot irregularly some time afterward. Even after amputation, the divided extremities of different nerves will unite in this manner, forming a loop. When union does not take place, the divided ends cicatrize with a permanent swelling, with loss of motion and sensation of the part supplied by the divided nerve. [When a portion of nerve is removed, the divided extremities, in the course of twenty-four hours, become enlarged and vascular, and the surrounding cellular tissue becomes inflamed, containing coagulating lymph, which finally coagulates and cements them together. After some time, varying according to the thickness of the nerve and the distance between the divided ends, the matter thus effused is organized, assuming a whitish, gritty appearance, and the function of the organ is either partially or wholly re-established. Sensibility commonly returns more quickly than voluntary motion. Mr. May found that the

sentient nerves, when thus mutilated, generally began to regain their functions early in the third week, while the motor nerves did not recover any of their powers till after the fourth. It is proper to observe, that if the interval between the divided extremities is very great, as from one to two inches, the union is either extremely long, or impossible, because the condensed cellular tissue, or, what is more commonly the case, nature entirely fails in her efforts, and the function of the part is thus forever destroyed (Gross.) After amputation, the ends of the nerves appear swollen, inflamed, spotted, or red, from the blood effused between their fibres at the divided surface. This state subsides into a grayish, thick, firm, and fibrous-like knob, from which delicate nervous fibres proceed, serving as nervous ramifications to the surface and divided parts.*

8. c. Continuation of a nerve is followed by effects varying with the severity of the injury. When the contusion is slight, extravasation of blood in the cellular tissue connecting the nervous fibres is the chief consequence; if it be more violent, the fibres themselves may be crushed. In the first case, severe pain and numbness in the course of the injured nerve, and temporary or partial paralysis, are the results, which generally cease after a time. In the second the effects are more severe, and the palsy more permanent.

9. d. Punctures are among the frequent injuries to which nerves are liable. They occasion extreme pain, which is often protracted long after the infliction of the injury, is extended in the course of the nerve, and is sometimes accompanied with spasms, tremors, or convulsive motions of the muscles supplied with the punctured nerve. Cases illustrative of this lesion have been recorded by Sabattier, Wilson, Swan, Bosquillon, and others. Punctures often occasion a circumseribed swelling of the nerve, with slight effusion of blood in the cellular tissue connecting the fibres, and in the enveloping neurilema. It has been shown by Wolff, Descott, and Béclard that, when the acute inflammatory symptoms consequent upon this injury have subsided, and when the effused fluids are absorbed, there still remains in the situation of the puncture a hard, opaque, and circumscribed enlargement, of a fibrous consistency, formed by a thickening of the cellular-fibrous tissue of the nerve. This change in the part may occasion severe pains of the nerve, which may not be subdued until the nerve is divided in the situation of the puncture.

10. e. Section of a nerve may give rise to severe suffering, whether it be complete or incomplete. When the division is incomplete, severe pains, as in cases of puncture, are felt, and are remarkably increased by attempts to contract the muscles supplied with the partial-
ly divided nerve; perfect repose, appropriate bandaging, and, if these fail, complete division of the nerve, being the chief means of relief. Complete division of a nerve may occasion severe pain, which, however, is generally much less violent or prolonged than when the nerve is punctured or partially divided. When the sections in various parts of the body are close together, it is instantly followed by insensibility and loss of motion of the parts supplied by the divided nerve, the divided ends of the nerve undergoing the changes described above (§ 7).

11. A ligature drawn tightly around a nerve instantly produces effects analogous to division of it. After a time, the ligature occasions swellings above and below it, and close to it, that above being the greater. When the ligature causes division of the nerve the ends remain in contact, surrounded by the inflamed cellular tissue, and by coagulable lymph, which soon becomes organized. Union takes place, as after division from a wound; but the enlargement, especially that which was above the ligature, still continues more or less. Ligature of nerves sometimes occasions very severe or even violent effects, but not so generally as commonly supposed.

12. Wounds, even when very small, occasion most severe effects when a portion of a foreign body remains imbedded in a nerve. Very interesting cases of this description have been published by Denkman, Joubert, Descor, Jeffreys, &c., in the works referred to in the Bibliography. These effects are especially severe when the wound has cicatrizd, the foreign substance lodged in the nerve occasioning the most painful irritation in the course of the nerve and its ramifications, or violent neuralgia, with spasms of the muscles supplied by it. In some instances, tetanies has been the result.

13. A nerve may be involved in a cicatrix following a wound, amputation, or burn, and become the seat of intense pain or irritation, owing to its exposed, or insufficiently protected state. The actual or potential cautery—the latter even when performed with a caustic alkali—may, either previously or subsequently to the cicatrization of the part, occasion very severe effects when the branch of a nerve is involved in the injury. M. Frère (Revue Med., Mai, 1839, p. 207) has recorded an instance of an issue made by the caustic potash having thus been followed by severe local effects, which terminated in fatal tetanus. But this is a very rare, if not a singular occurrence.

14. E. Lesions of nerves of a malignant nature have not been satisfactorily observed, nor have they been found to form primarily in nerves. Otto and others have remarked, that the medulla has appeared more or less diseased in the vicinity of carcinomatous or cancerous swellings or ulcerations, the nerve being discoloured in parts, hardened, swollen, and knotty, and degenerated in its structure to a greater or less extent throughout, both in its sheath and medulla.

15. Definition.—A violent, sharp, lacering pain in the situation of a nerve, with a feeling of numbness, increased by slight pressure, and often attended by greater fulness than natural, sometimes by redness, in the course of the nerve, and by inflammatory or irritable fever.

16. Inflammation of nerves has been generally passed over by writers on practical medicine. Boerhaave remarks: "Nemo forte unquam vidit inflammationem in nervo; haec vero in nervis principia continenter diabolica longa est." (De Medic. Nerv., p. 265.) That the inflammation is seated chiefly in the neurilemma cannot be doubted; but it is not the less an affection of the nerves, and that it is, in a most demonstrable shape, a not very infrequent disease, will be acknowledged by most experienced pathologists. Although it is not manifest that several affections of nerves, such as neurouma, cramps, partial loss of sensation, or of motion, sciatica, and the severe attacks of pain usually termed neuralgia, proceed from inflammation implicating a trunk or branch of a nerve, yet there is much reason to infer that such is actually the case in some instances, and more frequently than has been admitted, although the inflammation may not be seated or manifested exactly as it is in the more unequivocal instances of the disease to which the term has been generally conceded. It was contended by Cottuano, with much reason, that the trunk of the sciatic nerve is always more or less inflamed in sciates; and I will endeavour in the sequel to show that neurouma, or painful tabes, is the consequence of a chronic inflammation of the sheaths of the nervous fibres, and of the connecting cellular tissue.

17. I. Acute Inflammation of Nerves.—Neuriitis acuta; Neurilemmatitis, neuritis, Auct. Neurilemmatitiss, Hidenbrand. Acute neuritis is rarely met with in a primary or idiopathic form, or independently of wounds or external injuries; but not so rarely as was very generally supposed. The researches of Martinet, Gendrin, and Dukes have shown that the changes in the nerve, in the idiopathic and traumatic forms of the disease, are the same; and that these changes are not limited to the neurilemma, but extended to the nervous substance itself, which was found in several cases (Martinet’s 4th, 5th, 6th, and 10th cases) of a dark red colour, softened, and even “ injected by very manifest vessels.” Indeed, as M. Ollivier has remarked, there is no reason that the nervous substance should be less capable of inflammation in its finer ramifications than in its central masses. However, it cannot be disputed that the chief marks of inflammatory action are seated in the neurilemma. The differences in the symptoms caused by inflammation limited to the one, from those produced by inflammation extending to the other, have not been shown; although Hidenbrand supposes that when the pulp or substance of the nerve is affected—neuromyelitiss—the symptoms are less acute and distinctly evolved than in neurilemmatitis, and are attended by nervous symptoms indicating severe acute sensibility, and greater disposition to spasm. This distinction is, however, extremely doubtful and imperfect; careful post-mortem investigation is required to elucidate this subject, but opportunities of determining it are very rarely afforded the pathologist.*

* M. Gendrin has shown, by his “ Researches,” that inflammation of a nerve, when artificially induced, always
18. The symptoms of acute neuritis are a lacerating, sharp, or lancinating pain in the situation of a principal nerve or branch of a nerve, attended by a sense of numbness, generally following the course of the nerve affected and of its branches; exacerbations of the pain after slight and variable remissions, and upon the slightest touch or pressure, or upon exciting the most remote part of the affected nerve, and in some cases, numbness, or partial or even complete palsy, of parts below the seat of pain, which in these also may be acute, remitting, and lancinating. Even when the pain is most continued, the slightest touch may exasperate it; while very firm pressure above, but not upon, the affected part of the nerve, will assuage it. 

When the nerve is superficial, as in the extremitities, a longitudinal swelling or hardness may be detected in the seat and course of the nerve. The heat of the part is increased, and a burning sensation is also often felt in it. The usual phenomena of symptomatic inflammatory or of irritative fever are generally present, in varying grades, according to the intensity of the local affection, the size of the nerve implicated, and the temperament, habit of body, and visceral conditions of the patient.

19. Neuritis sometimes occurs in the puerperal state—Neuritis Puerperalis—and attacks chiefly either of the lower extremities soon after parturition. M. Duclus (Rev. Med., Aout, 1824) first directed attention to the disease as it appears in this state; and since that time I have seen three or four cases of it. The first of these I attended in 1825, with my friend Dr. John Davies, now of Hertford. It was complicated with both phlebitis and arteritis, and terminated in fatal gangrene of the whole limb; the nature of the disease being farther shown by the examination after death. M. Duclus has endeavoured to distinguish for varieties of puerperal neuritis. 1. The simple or circumscribed. 2. The edematous. 3. The phlegmonous. 4. The edematophlegmonous; and, 5. The gangrenous. It is evident that these varieties are chiefly the result of the association of neuritis with inflammation of either the veins, the lymphatics, or the arteries; my own experience proving that these associations are even more frequent in the puerperal state than the simple form of the disease.

20. M. Duclus attributes the first or simple variety of puerperal neuritis to the pressure of the gravid uterus on the pelvic nerves. It is usually seated in the sciatic nerve, and occasions acute lancinating pain; and in the more severe cases, partial palsy of the limb. M. Duclus states that this variety is readily removed by warm baths; but the slighter cases which are thus remedied cannot amount to actual inflammation, or to anything beyond congestion of the vessels of the nerve, or of the part surrounding it. The presence of fever in connexion with the pain is sufficient proof of the puerperal state, sufficient proof of the existence of inflammation, as in nervous and irritable females in this state, febrile commotion is often readily excited by pain.

21. The phlegmonous variety of M. Duclus is in all respects the same as the common form of the disease already described (§ 17). He characterizes it, in the puerperal state, nearly as follows: 1. The pain follows the direction of the nerve, particularly the erural, or the more superficial nerves of the lower or upper extremities, and is more neuritic, and insensible than that in other inflammations. 2. The swelling, as well as the pain proceeds in the direction of the nerve, is dense, unequal, and precedes any external redness. 3. The pain and swelling in the seat of the nerve are of longer duration than in common phlegmon; the pain always precedes the swelling, and the chillis and rigours accompanying their commencement are of longer duration, and more severe, and the consequent fever is more intense.

22. The varieties of neuritis which M. Duclus has denominated the edematous, the edematophlegmonous, and the gangrenous, are complications, as I have above suggested, of neuritis, with either phlebitis or arteritis, or both. In the case already alluded to (§ 18), neuritis was associated with inflammation of both the veins and arteries.

23. The diagnosis of acute neuritis from neuralgia is often difficult. Some authors have supposed that the latter depends upon inflammation of the nerve; and it is not improbable that, in some of the cases characterized by a more or less persistent pain in the nerve, and by a limitation of the pain to a single nerve or its ramifications, some degree of inflammation may exist in a part of it, or at its origin. Generally, however, the presence of fever, of fixed and constant pain in the situation or course of a nerve, of tension, dense swelling, and tenderness on pressure, of partial palsy of, and increased pain on contracting the muscles supplied with the affected nerve, &c., indicate inflammation; while the absence of fever, the erratic and intermittent character of the pain, its subsidence upon firm pressure, mark its dependence upon irritation in a related part, or upon some other cause.

24. The appearances in fatal cases consist chiefly of redness, more or less marked, of the affected nerve, proceeding from injection of the capillaries of the neurilemma, or of the cellular tissue connecting the fibrils; of minute punctiform and numerous ecchymoses; of sero-sanguinaceous exudation; even of puriform, infiltration of the fibro-cellular envelope. In addition to one or more of these changes, the size of the nerve is increased, most frequently without any appreciable change of consistence, but occasionally with more or less softening of the affected part. Bichat found numerous small varicose dilatations of the veins in the sciatic nerve of a person who had experienced severe pain in this nerve; and Van de Kee found the sciatic softened to a deliquescent pulp, of a grayish, dirty appearance, which, when not too soft, were hard granulations. The neurilemma was thickened, red internally, opaque and white externally, but granulated and more or less injected. These changes were manifestly consequent upon inflammation, and confirmatory of the opinion of Correa, who attributed, too exclusively, sciatica to inflammation of the nerve.

25. II. Chronic Neuritis—Neuritis Diuturna—in certain of its conditions or results, has not
been satisfactorily elucidated. *Neuroma*, or the tumour which is sometimes found in a nerve, is undoubtedly a consequence of chronic inflammation of the tunneled part, inasmuch as the changes observed in it are similar to those which result from chronic inflammation in other parts of a like structure. *Uleration* may also be added; but it is very rarely observed, never, perhaps, limited to a nerve; and only when a nerve participates in the ulceration of adjacent parts. When this is the case, the suffering thereby occasioned may require the removal of the diseased portion of nerve, or its excision, as advised by M. Ollivier; and, in some extreme cases, when the bone becomes affected, or adjoining parts much disorganized, even the amputation of a limb may be rendered necessary, as in a case adduced by Mr. Swan, in which the popliteal nerve and surrounding parts were extensively ulcerated, excision of a portion of the nerve having been found infallacious.

26. *A. The only form, or result, of chronic neuritis that has been satisfactorily investigated is *neuroma*, or painful tumour of a nerve. Numerous writers have noticed this kind of tumour, and, among others, Camper, Boerhaave, Gooch, Home, Spangenberg, Petit, Chassier, Delpech, and Meckel. But J. Frank, Abonsohn, Descot, and W. Wood have more fully investigated its nature than other writers. M. Odier, of Geneva, applied to it the term *neuroma*. A modification of the same disease, or painful tumours of the subcutaneous or smaller nerves, has been fully described by Mr. W. Woon, under the name of "painful sub-cutaneous tumour." These tumours, whether formed upon small subcutaneous nerves, or upon large or small nerves of the extremities or of the trunk, are essentially the same, but vary in structure, size, and appearance, with the activity or grade of vascular action which produced them, and with the particular tissue of the nerve itself has been chiefly or principally affected. The tumour is sometimes round, but more frequently oval or elliptical. Its size varies from that of a pea or bean to that of a turkey's egg, but it rarely exceeds that of a hen's egg. More than one tumour is often found in the same case. It is met with at all ages; but of sixteen cases, four were in persons above forty-six years of age, and twelve in persons under that age. Of twenty-four cases, fifteen were stated to have occurred in men, and six in women. The disease is met with chiefly in the trunks or larger branches of the nerves of the extremities, particularly the upper, and near the elbow-joint. It occasionally occurs in the internal parts of the body; and, if these parts, and the size and distribution of the nerves supplying them, admitted as readily of examination as the extremities, it might be found more frequently in them, constituting the cause of some painful internal complaints. Of the cases adduced by Mr. Woon, sixteen were seated in the upper, and five in the lower extremities; one in the neck, one in the thoracic cavity, and one in several parts. When once formed, the tumour generally increases more or less rapidly, and is rarely much influenced by treatment, but it seldom attains a very considerable size under two or three years. It may, however, remain stationary, as to bulk, for a very considerable time. The sub-cutaneous tumour is particularly slow in its growth, rarely attaining a greater size than that of a bean, and often remaining without increase of bulk for several years.

27. a. The *diagnosis* of *neuroma*, when superficial, is not difficult. The tumour is most frequently hard and firm to the touch, occasionally elastic, and admits of motion in a lateral direction, but not upward or downward, or in the direction of the nerve. The skin is moveable over it, and is natural in appearance. When it is very large, the cutaneous vessels, particularly the veins, are enlarged, and the skin is somewhat livid in rare instances. The tumour is extremely painful on the slightest pressure; the pain extending to the parts supplied by the nerve—to the ring and little finger when the ulnar nerve is the seat of the disease. If a blow is received on it, the pain darts through different parts of the body. In three cases, referred to in the references, epileptic fits were distinctly caused by these tumours, and were cured in two of them when the tumours were removed. In some instances the pain is not severe when the parts are kept at rest; but, in most, tickling or tingling, creeping or numbing sensations, or a combination of these are felt in parts near or below the tumour; and, in many, a most excreting pain, independent of, but much increased by pressure, exacerbated at intervals, is complained of at a distance from it, but in the direction of the trunk or branches of the nerve affected. The powers of sensation and of motion are, however, seldom impaired, but motion aggravates or brings on the pain; and prickling, accompanied or alternated with numbness, is felt in the limb, and severe pains dart in the direction of the nervous branches. In the smaller forms of the disease, which Mr. W. Woon designates "painful sub-cutaneous tumour," paroxysms of pain occur often without any apparent cause, and after irregular intervals, of from five to twenty minutes' duration. In most instances, the severity of pain produced by pressure, the extension of it in the course of the nerve, the lancinating pains associated with numbness, and the increased suffering caused by attempting motion of the tumour in the direction of the nerve, of which it does not admit, are sufficiently diagnostic of the nature of the disease.

28. b. Tumours of the nerves, when carefully examined after death, or after removal by operation, present different appearances in different cases, owing probably to the originating seat of the disease, and to the state and progress of it. Mr. W. Woon remarks that it is often difficult to determine in what particular tissue the diseased action had commenced. In some cases this action appears to have begun in the cellular tissue in the proximity of the nerve, to which it had gradually extended, so that, in its progress, the nerve and its coverings had become completely involved in the disease; in other cases, the tumours are external to the sheath of the nerve shall implicate the nerve itself, they cannot be considered as cases of neuroma. I believe, however, that the diseased action under consideration commences most frequently in the neurilemma, forming the external sheath of the nerve or its connecting cellular tissue, or in the minute
processes of neurilemma sent off from the general sheath to envelop the several nervous fibres which form the nerve. In rare cases, the tumour consists chiefly of a cyst containing a fluid; in other cases, it is partly solid and partly fluid; but much more frequently it is solid throughout. The solid part assumes different degrees of consistency, and presents a different colour and appearance in different cases, and even in different parts of the same tumour. In some, the whole mass is firm, of a whitish or yellowish colour, and of a fibro-cartilaginous appearance, very much like nerve, but harder, and somewhat more shining; the fibres running either in a serpentine or parallel manner with interlacing fibres. In others, one part is firm and of a reddish colour, and another part is cellular, the cells varying in size, and some being empty, and others containing a fluid or a soft medullary-like substance. Others, again, consist of a number of small lobes, closely connected with the diseased nerve. Some are fatty, or tubercular, or consist chiefly of coagulated albumen. Nearly all present the appearance of having a firm, dense sac, shining externally, and seemingly formed of the altered neurilemma. This covering is either loosely or very intimately attached to the contained parts by cellular tissue.

29. The nerve is sometimes sound as it enters, or emerges from the tumour; but it is often more or less diseased for a little distance above and below, being somewhat redder than natural, and thickened. The nerve can be traced distinctly to the diseased part, where the fasciculi, being separated from each other, run into the substance of the tumour, where they are either lost, or traceable through it, or near its surface. When, however, the tumour is very large, the nervous fibres often cannot be traced through it, they being so completely altered, or atrophied, or entirely removed by the pressure of tumours, or hypertrophy of certain elementary parts of the mass. Some writers have considered this tumour of nerves as being of a scirrhouss or cancerous nature; but that such is not the case is proved by the circumstances, 1. Of its not invading the adjoining tissues nor implicating the skin, however large it may be, or however long it may have existed; 2. Of the complaint not returning when the tumour has been removed.

30. B. These tumours sometimes closely resemble the oval tumours which often form on the extremity of a nerve after amputation. These latter tumours are frequently three or four times as large as the nerve on which they form, but of the same colour, of a firmer consistence, and of a different structure. The texture of the tumour is fibro-cellular, and dense, in which the nervous filaments lose themselves or become indistinct, probably by being wasted in proportion to the hypertrophy and induration of the cellular tissue of the affected part of the nerve, or by the result of chronic irritation or inflammation.

31. C. In some cases, consequent upon chronic inflammation, the cellular tissue forming the nervous sheath, and connecting the nervous fibres, has been found infiltrated with serum, lymph, or sero-albuminous or sanguineous fluid, and rarely with purulent matter unless in acute or sub-acute cases. These changes have been observed chiefly in the ischiatic and other large nerves. Bony and earthy concretions have, in rare instances, been found in the cellular tissue connecting the nervous fibres, but exterior to the medullary matter. These have probably resulted from a state of chronic inflammation, or have been the residua after partial absorption of morbid deposits.

32. D. Inflammation and its consequences may occur in either the cerebro-spinal or the ganglial or soft nerves, probably in the latter more frequently than in the former, but, owing to the situation of the ganglial nerves, and the marked peculiarities of their structures, either escape detection, or give rise to different phenomena and to different lesions in them from those observed in the cerebro-spinal nerves. When the ganglial nerves are inflamed, they are generally enlarged, of a lively or deep red; sometimes softened, and occasionally firmer than natural. These are the only changes in this particular class of nerves which I have observed.

33. iii. The causes of acute and chronic neuritis are chiefly those productive of inflammations of other tissues and organs. The circumstances which predispose to the disease have not been fully elucidated, owing to the infrequency of it, and to its being confounded with other maladies, as with rheumatism, neuralgia, etc. My own observation induces me to infer that all lowering influences, copious hemorrhages, prolonged pressure, and vicissitudes of temperature, humidity, and electrical states of the air, both favour and more directly produce it, particularly when aided by the application of cold in any form, by wet or damp clothes, by sitting or lying on the ground, or on cold stones, or on damp seats or couches, by exposure to malaria, or to foul air, or other contaminating agents, by induration exertion, by suppression of accustomed discharges, by injuries, wounds, bruises, contusions, and, as a result, by any local source of irritation. The idiopathic form of neuritis is occasioned chiefly by the same causes that give rise to rheumatism. The puerperal state certainly favours the development of it, in its severest forms; the circumstances which are most efficient in causing it being then frequently in concurrent operation, particularly soon after delivery, when it may be complicated with phlebitis, and even also with arteritis, as in the case above alluded to (18).

34. iv. The prognosis in neuritis depends chiefly upon the circumstances in which it occurs. In the puerperal state, or when associated with inflammation of either of the circulating systems, it is a serious and even dangerous disease; the latter chiefly on account of the complication, and the exhausted or otherwise diseased state of the patient. The prognosis should be equally unfavourable if it occur in the course of fevers, or in connexion with other maladies, or even in a bad habit of body; it will all depend upon the circumstances to appear. In a large proportion of the cases recorded by MM. Martinet, Dugas, and others, the disease, in its acute form, terminated fatally when it thus appeared; the inflamed portion of nerve being either injected, enlarged, red, softened, or infiltrated with serum or with puriform matter (§ 23). The simple or uncomplicated disease, occurring in a previously
healthy person, and the chronic form, especially in the state of neuroma, and admitting of an operation, is most frequently removed by judicious treatment.

35. v. Treatment.—a. My own experience leads me to agree with the remark of Hildenbrand, that acute neuritis is never resolved by a recourse to blood-letting and antiphlogistics alone. That local blood-letting—much more rarely general blood-letting—is required, according to the circumstances of the case and the condition of the patient, is admitted; but additional means are also required, and should be adapted to these circumstances. Local depletions and fomentations; the more chologogue purgatives, as calomel, &c.; and anodynes, particularly opiates with calomel and camphor, or with the acetate of lead, or with the oxide of bismuth, are most applicable to the more acutely acute cases; but when the disease is associated with other serious maladies, or when it occurs in a case of advanced age, in cachectic patients, or in patients characters, actively restorative agents are generally then required, even while local depletions and anodyne fomentations are being employed; and, in some cases, they should be most energetically prescribed in order to be successful, and be combined with the most powerful narcotics, the functions of the several emunctories being at the same time duly promoted, and morbid or effete matters eliminated from the circulating fluids.

36. b. If the disease pass into, or primarily assume a chronic state, alteratives conjoined with tonics, as the preparations of echinola with alkaline carbonates or the liquor potassae, and iodide of potassium; camphor with opium, or with the extract of aconite; blisters in the course of the diseased nerve, if it be deep-seated, and kept discharging for some time, and stimulating and alterative embrocations (F. 296, 311), appear to be most successful. To some of these chronic cases the treatment advised for the constituent parts may be of service.

37. c. In cases of neurona and painful subcutaneous tubercle these means will generally fail, and even the narcotic alkaloids applied locally are not more serviceable. In these cases, the extirpation of the tumour becomes necessary; and even, in certain circumstances, amputation of a limb may be required. Mr. Wood states, that in twenty-four cases of neurona, the following were the results: in eight cases the tumour was successfully excised; in two, the patients died after the operation; in four, amputation was successfully performed; in three, no operation was attempted; in three, the tumours were accidentally met with on dissection; in two, the disease was seared in internal parts of the body; in one, the tumour was laid open in order to bring on suppuration, but the patient died of quotidian intermittent; and in one, the disease was cured by destruction of the nerve by caustic.

38. III. Lesions of sensibility and function. To conclude the third class to which the disease of nerves may be divided. As the principal part of alterations of sensibility, or that consisting of morbid excitation of sensation, has very generally had the term neuralgia imposed upon it, and as this morbid condition has been usually discussed under this name, it may be considered in a separate article, without the relation between it and other diseases of the nervous system being in any way interrupted by this mode of treating it. And as those painful affections of the nerves which have been considered to exist independently of inflammations, and to which the name neuralgia has been given, are somewhat diversified in character and severity, the more general appellation of Neuralnic Affections may be applied to them. The disorders of function to which these nerves are occasionally the seat of, as transmitters of sensation and of muscular contractions, or of impairment or irregularity of sensation and motion. Class.—IV. Class, II. Order (Good).
II. Class, III. Order (Author).
1. Defin. — Violent pain seated in the trunk or branch of a nerve, occurring in paroxysms of ir.
regular duration, and after either irregular or regular intervals.

2. Neuralgic affections were confounded by the ancient and older writers with toothache, rheumatism, gout, &c., according to the seat of the pain. Ling. Fothergill, Andor, Peyot, Fournier, and Chausier were among
the first who directed attention to these affec.
tions with precision, and distinguished them from the disorders with which they had been formerly confounded. Since the commence.
ment of the present century several writers in this country and on the Continent of Europe

(see Biblio. and Refer.) have advanced still further our knowledge of this subject. At first
the study of neuralgia was confined to the oc.
currence of it in the nerves of the face and lower extremities, and the terms neuralgia and tie douleurs were applied only to the most
excruciating states of pain experienced in these parts; but more recently these terms, or a
qualitative one, implying very close resem.
blance, as neuralgic affects, &c., have been
extended to all morbid exaltations of sensibil.
ity in parts not manifestly inflamed; so that
they have been made to comprise, by French
pathologists in particular, disorders formerly
very differently named, and seated in internal
viscera.

3. That morbid exaltations of sensibility, in.
dependent of inflammation, in a recognisable
form, occasionally affect internal organs, can
not be doubted, and that they are quite as often
seated in the ramifications of the organic or
granular nerves as in the cerebral or spinal,
nerves, is equally evident to the close observer,
although their characters may vary with the dis.
cuss of the nerve; and that they actually do thus
vary in character is well known. The pain
experienced during a paroxysm of neuralgia in
one of the branches of the fifth pair of nerves,
hower ever recurring, is not attended by that
intolerable feeling approaching almost to vital
extinction, which characterizes those pains in
internal or vital organs, that have been more
recently termed neuralgic, that formerly had
different names imposed on them, but that,
however named or described, undoubtedly be.
long to the category of neuralgic affections.
Therefore, I shall comprise under this head, as
succinctly as may be compatible with a due dis.
cussion of the subject, all those very painful
disorders, wherever seated, which are ap.
parently unconnected with inflammation, and
which are not the result of some important or
recognisable lesion.

4. Adhering to this view, as well as to the
mode of considering the subject adopted by
some recent writers, several disorders, particu.
larly toothache, headache, the different forms
of colic, certain manifestations of hysteria,
&c., might with propriety be considered as
forms of visceral neuralgia; but these disor.
ners, as well as some others, which have
actually been thus viewed by a few of these
writers, are generally so intimately connected
with more or less complex or recognisable
mischief, and so dependent upon it, that the propety of retaining them as the special occasions of
this knowledge the pathological relation they
have insisted on, remains unaffected by the more
partial view entertained by them. In naming
and arranging, as well as in discussing these
and other disorders, prominent phenomena
should not alone be noted, to the neglect of
other important, although more latent, morbid
relations, but all sides of the subject ought to
be only viewed.

5. General Character of Neuralgia.—
The pain of neuralgic affections sometimes is
slight and obtuse at its commencement, and
augments in violence with more or less rapid.
ity, becoming sharp, lacerating, darting or lan.
inating, and being attended by excessively acute,
constrictive, or plunging sensations, which at
short intervals dart through the pained part:
the fulgura doloris of Cotugno. More frequently the pain is sudden in its accession, and it is occasionally preceded by an itching or heat in the part, or by numbness and pricking sensations, or by slight and fugitive pains, either or most of which may recur during the remissions between the more violent paroxysms. In some cases, the attack of neuralgia is preceded by nausea and general disorder, with more or less of derangement of the digestive and biliary organs; and in others, by anxiety at the premonitory, or by slight chills followed by heat. At the commencement the pain is attended by numbness or torpor, and formation; and it is commonly lancinatting or darting, although sometimes pulsative, or acutely smarting or burning. Whatever character the pain may assume, it is often instantaneous in its occurrence and disappearance, resembling a shock of electricity. It is frequently confined to the trunk of the nerve, but as often it extends itself to the ramifications, and even to the terminations of the nerve. More rarely, it extends from the ramifications to the trunk. Sometimes it affects only a few of the branches, or even one or two merely of the fibres. Accompanying the pain, especially during its greatest intensity, other phenomena are observable: tremors, spasms, cramps, or convulsive motions of the muscles connected with the affected nerves; general exaltation of sensibility, with restlessness and agitation; sometimes a tensive rigidity of the muscles; and, rarely an inability of contracting them, with loss of sensibility towards the surface. Generally, neither redness, heat, nor swelling of the part can be detected. Occasionally, however, the arteries in the vicinity pulse more strongly, and the veins are somewhat distended. M. Ollivier states that he has observed, in a few instances, where the nerve was superficial, that its volume was somewhat increased. These were doubtless cases of neuritis, which has very generally been confounded with neuralgia, and to which the latter is probably generally supposed, or than can well be demonstrated; for neither swelling, heat, nor redness attends neuralgia, but they all accompany and indicate neuritis; still, they are so limited in extent and amount, when inflammation is confined to a nerve, as hardly to admit of appreciation or detection during an examination of the surface of the part affected.

6. The duration and return of the paroxysms are extremely variable. Sometimes the affection is intermittent, or the paroxysms occur irregularly, and more rarely after regular intervals. Some authors have supposed, from this latter circumstance, and certain of them, even although the intervals may be of irregular or prolonged duration, that the disease is a local or masked ague, originating in such cases in malaria. Often when the paroxysms become more frequent, they become also more violent, and sometimes of longer duration. When the attack is very sudden it frequently continues without any inability of contracting the affected part, but generally short period, and then as suddenly ceases. The most intense attacks are often of the shortest duration, but generally they vary from two or three minutes to several hours. When they continue much longer, the intensity of the pain varies, and slight remissions, with acute, lancinating, constrictive, or laceration pang's dart through the part like shocks of electricity, occasioning irregular spasms or twitchings of the muscles, and intense suffering. A critical evacuation, as haemorrhages, particularly epistaxis, menstruation, hemorrhoidal discharges, salivation, cutaneous eruptions, an abundant general or local sweat, or a copious discharge of the lochia or of urine, bilious or mucous diarrhea, the formation of an abscess, discharges from the ear or from its vicinity, or a regular attack of gout or rheumatism, or prolonged exertion, attended by a copious and sustained perspiration, sometimes are observed, and serve to account for the sudden or even for the more gradual cessation of suffering.

7. The accessions of the attack often cannot be attributed to any appreciable cause; but more frequently they are occasioned by overloading the stomach; by neglect of the biliary functions, and of the states of the bowels; by excesses in the use of intoxicating liquors; by exposure to cold, damp, humidity, or malaria; by injurious over-exertion, &c.; or by any of the remote causes of the complaint acting even slightly or inappreciably.

8. In comparatively few cases is the health quite restored at the end of the paroxysms, or during the interval; nor more or less disorder of the digestive or biliary organs may be detected in the great majority of them, with impaired tone of the organic nervous system, and general lassitude or debility, although the patient may seem quite well in the intervals, and be able, with few interruptions, to pursue his usual avocations. In many, more or less un easiness, numbness, prickings, soreness, smartings, or sudden but momentary pangs, are felt at times in the part between the more severe paroxysms; and in some the general health, or the digestive organs, betray more or less marked disorder.

9. As to the duration of the disease, it is impossible to state anything with precision. A person who has once suffered an attack is liable to a return of it, although he may have been completely restored; and a return or returns of it may take place in a short time, or not till after many months or even years. As respects the paroxysms, it is an acute malady; but as regards the repetition of them, the liability to their return, or even their actual recurrence, it is generally a chronic and most prolonged disease, often remittent, the attacks occurring after irregular, and much more rarely after regular intervals. Some authors have supposed, from this latter circumstance, and certain of them, even although the intervals may be of irregular or prolonged duration, that the disease is a local or masked ague, originating in such cases in malaria. Often when the paroxysms become more frequent, they become also more violent, and sometimes of longer duration. When the attack is very sudden it frequently continues without any inability of contracting the affected part, but generally short period, and then as suddenly ceases. The most intense attacks are often of the shortest duration, but generally they vary from two or three minutes to several hours.
that the affecting the face and head are the most severe, frequent, and important.

11. i. Facial Neuralgia.—Neuralgia Faciei.

—The Douloureux.—It is more easy to say what this affection is not than what it is. It is not, as M. Berard has remarked, acute neuritis, nor chronic inflammation, nor any structural change of the nerve; and, although various lesions have been detected in connection with this affection, these have rarely been observed in the nerve itself, and are neither so constant in occurrence nor so uniform in character as to account for it. The pathological and symptomatic phenomena of the complaint can only be stated in connexion with the morbid exaltation of sensibility which constitutes it; and this lesion of sensibility cannot be otherwise defined than as a pain varying in its character, always excessive, generally intermittent, returning sometimes at regular intervals, but more frequently after irregular periods; seated in one of the branches of nerves of the face, and extending in various directions through certain of their ramifications; existing without evidence of inflammation or of fever; and, although occasionally connected with organic changes in some part related to the affected nerve, yet as often occurring without such morbid relations, or without any obvious connexion with them in some cases where they are found to exist.

12. a. Although the douloureux was not described by the ancients as a distinct affection, it was certainly known to them, but confounded with various forms of headache; and as such it was described by Astræus (see De Causa et Sig. Dolorum, I., cap. 2). It was first described as a distinct affection, and the name "douloureux" given to it by M. André, of Versailles. Very soon afterward, Dr. Fothergill published an account of it in the Medical Observations and Inquiries. Since then it has received the various apppellations above stated as synonyms of neuralgia in the generic acceptance of the word. That this is an affection of a nerve, numerous considerations and proofs sufficiently demonstrate; and that it is seated in some one or more of the ramifications of the trifacial or fifth pair, is also proved by the seat, direction, and phenomena of the affection. The researches of Sir C. Bell, Shaw, Magendie, Mayo, &c., have shown this nerve to be chiefly, if not entirely, a nerve of sensation; and the ramifications of its principal branches from a large ganglion, the Casserian, farther proves this to be its chief function, and demonstrates its relations to the ganglionic system. That a morbid exaltation of sensibility should, therefore, more frequently occur in the more superficial ramifications of a nerve whose office it is to transmit sensations from the face to the brain, these ramifications being the most exposed to any of vicissitudes of temperature, weather, &c., than in any other nerve, may be readily admitted, and explained by this circumstance; and Professor Riberi on the frontal branch of this nerve farther illustrate this fact, and prove that the facial or seventh pair of nerves is not the seat of this affection. Not only is this shown by the seat of the pain, but by the experiments of the physiologists just mentioned, and by those made by Fodeba, Buedach, Scheff, Becker, and Esocher.

19. Admitting, therefore, that the ramifications of the trifacial nerve are generally the seats of tic, or neuralgia of the face, the question may still be asked, are the branches of the facial or seventh pair ever similarly affected? The free inoculations of the branches of the one nerve with those of the other, and the consequent extension and direction of suffering, render it very difficult to prove an affection of the latter nerve. Still, although pure tic may never be seated in the facial or seventh pair of nerves, inflammation, or any powerful source of irritation, may excite a most intense pain in the trunk and principal branches of this nerve closely resembling tic, although more closely allied to the more diffused neuralgic pains occasionally affecting other situations. Halliday and Chaponnier have added cases which they believe to be neuralgia of the seventh pair; and within a few months of the period in which this was written. I attended a patient suffering neuralgia of this nerve, the pain extending to the whole side of the face, and to the neck and occiput. The affection was evidently seated in this nerve, but was considered as inflammatory, and treated by local depletions and blisters to the nape of the neck, which permanently removed it. M. Berard has seen neuralgia of the second cervical nerve. I have been, during the last few years, consulted respecting three remarkable cases of neuralgia of the nerves of one side of the head, extending from the occiput to the forehead and vertex: one was sent to me from Mans, and another from St. Omer. It was difficult to determine, in these cases, which of the nerves supplying this part was the seat of the disease; but the facial and branches of the first and second cervical were considered as chiefly implicated. In these the attacks continued, on each occasion, from two or three to several hours, with the most agonizing exacerbations, and were ushered in, in one case, with vomiting, by horripilations, and a free discharge of pale urine. In another case, the attacks frequently commenced in the night or early in the morning, and were kept off during many months by the treatment about to be recommended.

14. b. The symptoms of tic are chiefly the intensity and paroxysmal nature of the pain constituting it. The pain occurs, or is exacerbated, in fits; the succession of a various number of fits constitutes an attack, which may be of uncertain duration, and leave the patient comparatively well in the intervals, which also are of uncertain continuance. The accession of the fits is generally sudden, but is often preceded by various indications of its approach, as itching of the nose, sneezing, tickling, pricking or coldness, crepitations or formation, &c., in the part about to be affected. In some cases it is preceded or attended by an abundant discharge of urine, by horripilations or puncia
tions, especially when the complaint assumes a regular or periodic character. After these phenomena, usually of the preceding day, the patients through one or more ramifications of nerves, and either instantly, like a shock of electricity, or very rapidly, acquires its utmost intensity. The pain is most acute, burning, sensitive, pungent, stabbing, lacerating, &c. (§ 5), and so poignant as to excite the agonizing cries of the patient. The pain has been so intolerable as to cause the patient to terminate
his existence (Deval). The suffering is generally referred to one of the branches of the trifacial nerve, and darts along the minute ramifications, but it is not always so limited to a branch or fibris as to admit of its precise seat or source being indicated. It sometimes radiates in several directions, and seldom is concentrated in one point without extending in the direction of the smaller branches. In the great majority of instances, tic douloureux is limited to one or other of the three branches of the fifth pair of nerves, but it is perhaps more frequently in either the ophthalmic or the superior maxillary branch than in the inferior maxillary.

When it is seated in the first or ophthalmic branch, the frontal ramification of it is oftener affected than the lachrymal or nasal; but in rare cases it extends to two or all of these ramifications in the same case; and often, when the frontal nerve is affected, an abundant secretion of tears takes place, or pain is felt in the eye, and sometimes uneasy sensations are experienced in the side of the nose, with dryness, itching, &c.

15. When the second or superior maxillary branch of the trifacial is the seat of suffering, the infra-orbital is the part most commonly affected, although the pain may extend more or less to the other ramifications of the maxillary. Generally the pain is referred to the infra-orbital nerve as it passes from the foramen, or proceeds from it to be expressed upon the upper lip, ala of the nose, and gum. It sometimes affects the posterior dental ramification, and resembles a severe attack of toothache. It more rarely is seated in the extreme branches supplying the pillars of the fauces and adjoining parts, in which, however, I have observed one instance.

16. Tic douloureux of the third branch is generally seated in the inferior dental nerve, and particularly its mental portion as it emerges from the mental foramen, extending to the inferior lip. In some instances the pain affects the branch which the inferior maxillary branch sends to the seventh pair; and when this is the case the affection appears to implicate the latter nerve. In others, the tie is seated in the anterior auricular branch, the pain extending to the temple in the course of the temporal artery. In very rare instances it is seated in the lingual branch of the inferior maxillary. Of this variety I have met with one case, in a female about fifty years of age.

17. c. Neuralgia faciei may thus be divided into frontal, infra-orbital, and mental, according to its common seat, the other ramifications of the three principal branches of the fifth pair being much more rarely affected. Whatever variations the complaint may present, the pain rarely or never passes from one side of the face to the other; and seldom has it been observed to exist in both sides at the same time: of this latter occurrence, however, Frank, in his extensive experience, met with two instances. During the neuralgic paroxysm, the muscles of the face are often contracted, so as to give the countenance most singular expressions; but the muscles of the unaffected side are rarely or never similarly affected. The least motion or noise occasionally aggravates the pain, and when the ophthalmic branch is the seat of the complaint, a strong light has generally the same effect. On examining the seat of suffering, little or no alteration can be detected beyond a slight blush occasionally of the surface, or a little redness of the conjunctiva, when the first branch is affected, and a somewhat stronger or fuller pulsation of the arteries going to the affected parts; but there is no febrile commotion of the system, nor acceleration of pulse, which often beats slower than usual during the fit.

18. d. The duration of the fit varies from less than a minute to one, two, or several minutes, or to a quarter of an hour, or even longer. The severer the complaint becomes the longer are the attacks. The termination of the fits are often as sudden as the commencement, and sometimes more so; and in some cases, particularly of frontal neuralgia, a copious discharge of tears or of mucus from the nostril attends it, and seems to be critical; but occasionally the fit subsides more gradually. Some cases of tic are irregular, or atypetic, in respect of the intervals between the paroxysms, while others are more regular, and resemble a masked intermittent. The most trivial circumstance, or the slightest vicissitudes of temperature, a moral emotion, or exposure to the air, &c., will often suffice to bring on a fit. According to Frank, the attack takes place more frequently during the day than night.

19. e. The whole duration of the complaint may be very long. It may cease for months or even years, and return in a more severe form than before, generally in the same branch of the trifacial as before, but sometimes in another branch of this nerve. In some instances the fits become more frequent with the duration of the complaint. An increased severity or frequency of the attacks is generally followed by a failure of the general health, and by more or less emaciation, owing to want of sleep, anxiety, and dread of the recurrence of the fits, and impairment of the digestive, assimilating, and excreting functions.

20. ii. Toothache—Odontalgia. Dolor Dentinum. Dolor Dentis. Doulouer de Dent. Fr. Der Zahnschmerz; Gift. Odontalgia. Dolur di Denti. It.—Toothache is undoubtedly a variety of neuralgia, although it may be more frequently referred than any other variety of the complaint to some source of irritation in one or more teeth, or in the gums or antrum. Yet, even without these obvious causes, and often when they very prominently exist, an attack of toothache is often brought on by the same causes as those which produce the other forms of neuralgia (§ 52, et seq.), the local sources of irritation being often insufficient to produce this morbid effect, until aided by other agents or influences.

21. Odontalgia may be divided into, Ist. The inflammatory, or that caused by inflammation of one or more of the constituent structures or tissues of the teeth; 2d. The ulcerative or carious, or that caused by ulceration or caries of a tooth, and consequent exposure or irritation of a nervous fiber; 3d. The nervosa, or neuralgia of the nerves supplying the teeth and gums, independently of inflammation or caries of a tooth—neuralgia dentalis. Besides these varieties, toothache may proceed from inflammation or abscess of the gum or in the antrum, from caries of a portion of the alveolar processes, or of the upper or lower jaw; from
fungus, exostosis, or other growths, on the root of a tooth; from retention of one of the first set, and from a wrong direction being given to one or more of the second set. It may affect, moreover, the gouty or rheumatic diathesis, and thereby assume a modified or more extended form; and it may be developed by exposure to cold, malaria, &c., and be characterized accordingly.

22. There can be no doubt that, even when the most energetic of these sources of irritation are present, little or no pain or uncerase is sometimes felt, until disorder of the digestive organs occurs; until the functions of the stomach, duodenum, or intestines are deranged, either by improper ingesta, or by morbid secretions poured into or accumulated in them; or until bile collects to an injurious amount in the gall-bladder and ducts, and depresses the organic nervous influence. When, however, these disorders of the digestive organs occur, the affection of the dental nerves is developed, particularly in those parts more immediately irritated; and as soon as those disorders are removed, or morbid matters evacuated, the pain subsides, even although the local source of irritation remains; still, as long as it remains, toothache recurs whenever local or constitutional causes of neuralgia occur to develop its effects.

23. The attacks of toothache vary much in character and intensity, according to the nature of the local mischief, to the states of the digestive organs, and the temperament and diathesis of the patient. In some the paroxism is most acute and intense, but of short duration; in others it is much less severe, but continues a much longer and a very indefinite time, it being of an aching kind with occasional exacerbations. In many, the pain, whether acute or chronic, is limited to the seat of local mischief, or even to the tooth itself; in others the pain extends to the whole jaw, or to the cheek, or even to the whole side of the face, particularly when the upper jaw is the seat of irritation, and after exposure to a current of air or to cold. In those states of the complaint which have, by some writers, been called catarhal, rheumatic, and gouty, the pain often extends to a great part of the same side of the face, and it is often difficult to localize it with much precision.

24. III. NEURALGIA OF THE NECK AND TRUNK.

—A. M. Irad has described, under the name of oculgia, a neuralgia of the ear, seated chiefly, as he supposes, in the chorda tympani and acoustic nerve. It is sometimes associated with neuralgia of the face. The pain in the ear is very acute, is sudden in its accession and disappearance, and is independent of any indication of inflammation of the ear. It is often attended by noises in the ear, and by temporary deafness (see art. Ear, § 6).

25. B. Neuralgia of the cervical nerves is very rare. M. Bossiellion met with a case which was apparently caused by the puncture of a nerve in bleeding from the jugular vein; and M. Jolly has alluded to another which appeared to be produced by the application of leeches to the side of the neck. A less severe or chronic form of neuralgia of certain of these nerves, resembling rheumatism in many respects, but attended by spasm or contractions, more or less permanent, of some of the muscles, sometimes occurs in connexion with caries or other disease of, or in the vicinity of the upper cervical vertebrae. Of this state of the complaint I have seen two or three cases, but in neither was the pain so intolerable as in the most acute cases of neuralgia.

26. C. Neuralgia of the thoracic or intercostal nerves, and painful affections of the other nerves of the trunk, have been described by Siebold, Nicoll, Jolly, Allnatt, Valleix, Térale, and Brown as neuralgic; by Parrish, Darwall, Griffin, Oliver, and Bennett as resulting from spinal irritation; and by Tate, Addison, and others in connexion with hysteria and uterine irritation. That these painful affections, whether amounting to neuralgic acuteness, or hardly exceeding a rheumatic aching, may depend, in some instances, upon vascular congestion of a portion of the spinal cord, or of its investing membranes, or upon inflammatory irritation, or some other morbid state of the circulation in these parts, is very probable, although the exact state of these structures has not been satisfactorily demonstrated in connexion with these affections. Still, cases not infrequently occur of neuralgic or painful states of the thoracic and abdominal nerves, without any evidence of congestion or irritation of the spinal cord; while, on the other hand, proofs of these states or spinal disorder are often furnished to the close observer, without any painful expression of it in those particular nerves. When treating of the painful manifestations of Hysteria (see that article, § 14, et seq.), I had occasion to remark, that disease of the spinal chord or of its membranes is not necessary to the production of these painful affections; and that when such disease is observed in connexion with them, it is to be viewed rather as a contingent result of the same irritation as produced them, or as an associated complaint, rather than as the primary and necessary source of these affections (Hysteria, § 23-61). A similar view may be entertained respecting the connexion of neuralgia of the nerves of the trunk with spinal irritation, in cases where no evidence of hysteria exists.

27. That neuralgia of these nerves is often connected with hysteria, as often with evidences of disorder, congestion, &c., in a corresponding portion of the spine, and often also without one or other of these, and even without both, I believe to be nearly the truth. The much greater frequency of the affection in females tends to prove the first of these positions. Thoracic neuralgia commonly occurs about the union of the seventh, eighth, and ninth ribs with their cartilages, and chiefly on the left side. The pain often extends from this point, in the course of the nerve, to the spine, and sometimes it associates itself with a similar pain in the mamma and mamma situs. In general it generalizes in the course of the nerve; and, although it has little influence on the state of the organic functions, it sometimes embarrasses the respiration. It is occasionally associated with pain in the epigastrum or in the bowels, or with hysterical colic, or with pain in the region of the uterus or ovaria. These neuralgic pains may be distinguished from rheumatism by the latter being accompanied with soreness of the muscles on pressure, and on
contracting them; while the former are attended by extreme sensibility of the skin and parts supplied by the affected nerve. These pains sometimes occur on either side of the chest, rarely successively, and often they are periodic. They are frequently independent of any evidence of disorder in the spinal cord or its coverings.

28. Intercostal neuralgia is a frequent complaint. The greater number of cases usually denominated pleurodynia ought to be classed under this head. It chiefly affects females: of 148 cases noticed by Messrs. Guizot, 26 were males, 49 married women, and 73 girls. It is most frequently observed between the ages of 15 and 25, and is more or less influenced by the states and vicissitudes of season, weather, and temperature. It is commonly most severe in cold or snowy weather. In many the affection assumes a regularly intermittent form, and it is then of long duration.

31. The course of this affection is often irregular. The pain usually increases gradually, and subsides in the same way; but in some cases is much influenced by the states and vicissitudes of season, weather, and temperature. It is commonly most severe in cold or snowy weather. In many the affection assumes a regularly intermittent form, and it is then of long duration.

32. d. Neuralgia of the lumbar nerves has been mentioned by several writers, but true neuralgia is rarely observed in this situation. Most of the cases which have been thus termed have evidently been instances of severe pain, symptomatic of irritation in the kidneys, ureter, or urinary bladder. Sir A. W. M. Chalmers, Richerand, and Delpech have described cases of neuralgia, which they have referred to the anterior branch of the first lumbar nerve, and in which the pain has extended from the loins and crest of the ilium to the groin and labia of the vulva of the female, and to the chord and scrotum, or testicle.

The pain was very acute, and recurred daily, with the testicle, but without any disorder of the urinary excretion. Some similar cases have been noticed by Mauboussin, Barras and Campignon, but in these the pain, affecting chiefly females, was experienced near the neck of the bladder and vulva, and was unattended by any disorder of the urinary functions.

Sir Astley Cooper has added some cases, in his work on the Testis (p. 110), which he believed "to be seated in the nerves, and to be of the nature of tic dououreux." In these, the pain darted in the direction of the sperrmatic chord; and one of them seemed to have been caused by an injury received some time previously in those parts. Sir Astley Cooper states that the affected testis hung lower than the unaffected, and he adds, that he dissected all the testicles which he had removed for this complaint, but there was no apparent structural change in any of them.

33. Certain states of lumbago are more nearly allied to neuralgia than to rheumatism. In respect not only of the characters of the pain and of the accompanying, but also of the aggravating and alleviating circumstances and agents. Even in those cases where the pain is evidently seated in the lumbar muscles, it is nevertheless to be referred to some change in the circulation in that portion of the spinal chord, or in the roots of the nerves supplying these muscles. (See articles Rheumatism and Spinal Chord.)

34. iv. Neuralgia of the Extremities.—Neuralgia Membranum.—Neuralgie des Membranes. Fr.—Neuralgia is comparatively rare in the upper, but not infrequent in the lower extremities.—A. In the former situation, cubito-digital or cubital neuralgia, as it has been termed by Chalmers, or neuralgia of the cubital nerve, is most frequent. It is generally seated in that portion of the nerve which passes between the internal tuberosity of the humerus and the olecranon, from which it darts in the course of the nerve. Sometimes it appears below the antrum, following the inner margin of the forearm, and extending to the cutaneous branches of this nerve, and to those sent to the little and ring finger. In recent attacks the temperature of the arm is occasionally increased during the paroxysm, which frequently occurs
during the night. In very severe fits the patient experiences much anxiety, often holds the arm up, and grasps it forcibly with the other hand. Besides neuralgia of this nerve, M. Martinet has mentioned neuralgia of the supra-spinatus and external musculo-cutaneous nerves. In both these the pain is seated in, and extends more or less to, the ramifications of the nerve. In these three different seats of suffering the complaint presents similar phenomena.

35. B. SCITICA NEURALGIA.—Neuralgia Sciatica. N. femoro-poplitea, CHAUSSEY. Sciatica, Aut. var. Ischius nervea postica, Cotugno. Ischias, Sciatica, dolor ischiaticus, Ischiagra, Malum ischidicum, &c. This form of neuralgia was formerly confounded with all painful affections of the hip and adjoining parts, whether inflammatory or rheumatic, primary or syphilitic; and the pain was referred to the joint, to the muscles, to the bones, to the tendons, to the nerves. &c., according to the views of the writers. Hence, among the synonyms of the complaint we find Morbus Cozenhovius, Morbus Cozianus, Dolor Coze, Cozagra, &c., names which belong to different affections. Sciatica has also been viewed as a variety of rheumatism, until the comparatively recent writings of Chaussey and others have shown that, although often very closely allied to certain states of that disease, it is essentially a form of neuralgia. It is a common disease in advanced age; it is very rare in infancy and childhood; and it is somewhat more frequent in females than in males, particularly in females during the puerperal states. It attacks in preference the nervous temperament, and the rheumatic and gouty diathesis. It is most frequent in cold and wet seasons, during stormy and changeable weather, and in low, humid, clayey, and marshy localities. It is common among fishermen, sailors, soldiers, and all those who are liable to wear wet clothes, or who are exposed to currents of damp air or to cold. Owing to the state of weather, season, locality, and occupation, I have observed it assume an almost epidemic frequency.

36. An attack of sciatica generally commences with acute pain in the sciatic slope or curve between the great trochanter and the ischium; and the pain follows the course of the great sciatic, or femoro-popliteal nerve, extending sometimes upward to the sacrum, but generally downward along the posterior surface of the thigh to the popliteal space, and often along the nerves, &c., according to the views of the writers. It is sometimes very severe in the tibial nerve. The accession of pain is occasionally sudden, but it is often preceded by painful pricking or tingling along the thigh, by slight numbness, or by chills, formation, &c. Usually one limb only is affected, and very rarely both. The motions of the extremity are extremely painful and difficult. During the exacerbations some patients suffer most in the sciatic slope, others in the posterior part of the thigh, and others in one or both of the popliteal or tibial nerves. The pain is in every respect similar to that felt in other kinds of neuralgia. Exacerbations of it occur generally in the evening or during the night, and cease in the morning; but several may take place during the day, with remissions more or less complete, during which the pain is more dull, and is attended by numbness and pricking or tingling. The slightest cause may bring on the exacerbation, as motion or exertion, the heat of bed, or mental excitement. The duration of the exacerbations of pain, as well as the frequency of their recurrence, is very various, and differs but little from other forms of neuralgia. The continuance of the attack is equally uncertain; the causes of the commencement, the constitution of the patient, and various other circumstances, influencing it. In some cases, the accessions of suffering are followed by convulsive or trembling movements of the limb, by slight numbness, or partial paralysis; and an attack generally leaves the limb emaciated, flabby, and weakened. When the attack has been very severe, or of long continuance, lameness, a dragging of the leg; great emaciation of the limb; a weakened or partially paralyzed state of the muscles; and disorder of the digestive organs, are experienced for some time after the attack.

37. C. FEMORAL OR CRURAL NEURALGIA.—Neuralgia Cruralis.—Ischius nervea antica, Cotugno.—Neuralgie femoro-pertibialis, Chaussey—occurs much less frequently than sciatic neuralgia. It may affect any portion of this nerve from the groin downward. It often commences in, or a little below, the groin, and extends along the anterior and internal aspect of the thigh and leg to the foot, and even to the sole. In a case of neuralgia seated in this nerve, in a gentleman who had returned from South America, at present under my care, the pain is experienced chiefly in the middle of the thigh and of the leg, and in both extremities. The pulse is somewhat frequent and irritable, and the bowels disposed to be成本. The muscles are soft and flabby, and the spirits depressed. The complaint has been of long duration, and the intermissions few and of short duration, since his arrival in England.

38. V. NEURALGIA OF MUSCULAR AND MEMBRANOUS STRUCTURES has been noticed by several modern writers; and, adhering to the definition of the term (§ 50), and of the occurrence of severe pain in these structures independently of fever, it may be viewed as often allied to neuralgia, although passing, in its characters and in its various morbid associations, in some cases into chronic rheumatism or gout, and in others into hysteria. But in true neuralgia of the muscles the pain is much more acute than in rheumatism, recurs in frequent exacerbations, and is rarely or never altogether absent in a dull or numb form. In all the cases I have seen, the remissions were attended by weakness or partial palsy of the muscles affected; and the complaint was symptomatic of organic lesion in either the brain or spinal chord; apoplectic, epileptic, or paralytic attacks generally occurring after longer or shorter periods. A lady from Gravesend consulted me a few years since for neuralgic pain of the muscles of one side, and particularly of those of the shoulder and arm of that side. After many months of suffering, maniacal delirium and paralysis supervened. Several large tuberculous formations were found in the brain after death, similar to those described in the article Brain (§ 111). Indeed, as Dr. Seymour has very justly insisted, these severe neuralgic pains in the muscles or limbs should always lead to suspicion of the existence of softening
or other organic lesions or formations in the substance of the brain. In two cases, when the muscular pains were most acute in the thighs, and were attended by occasional cramps, and were followed by weak and irregular action of them on volition, amounting to partial paralysis, extensive organic change was found in the spinal chord and its membranes. (See Spine and Spinal Cord.)

39. b. The painful affections of the periosteum, attributed to syphilis or to mercury, as Dr. T. Thomson has suggested, are in many respects neuralgic. The painful affection is mentioned so fully in the article Hysteries (§ 14, et seq.) that we are driven to believe that the disease is but another form of neuralgia. This is manifestly the case, and the symptoms constitute the disease in question, which is termed neuralgia in its category. The symptoms of neuralgia are skin diseases, and are manifested in many and various ways, in the skin and upper and lower extremities, alternating with numbness. But these symptoms were accompanied with so many others, which often predominated, that they cannot be viewed as constituting a form of neuralgia, although illustrating certain manifestations and morbid associations of this affection.

40. VI. VISCERAL NEURALGIA. — It is unnecessary to notice, otherwise than by enumerating the several visceral affections which, if not truly neuralgic, are in many respects related to neuralgia. Most of these have been dealt with in the several articles or sections of articles devoted to them. — a. Certain forms of headache, particularly the nervous forms, and those which are limited to one part, or which are attended by violent shooting pains, or are remittent or intermittent, are closely allied to neuralgia, and are generally aggravated and alleviated by the same agents and influences as it.

In these cases, the pain is to be referred to the state of some portion of the ganglial nerves supplying the organ in question, in consequence of some change in the state of the cerebral circulation. Indeed, visceral neuralgia, with few exceptions, which will be noticed, may be referred to the ganglial nerves, or may be termed ganglial neuralgia; a seat of those complaints pointed out by me as early as 1821 and 1822, in the works noticed in the references to this article.

41. b. Ganglial neuralgia most frequently occurs in delicate constitutions, and in nervous, melancholic, or lymphatic temperaments. It is more frequent in females than in males, and is caused by all the moral and physical influences which powerfully impress the nervous system. As in external, so in visceral neuralgia, the course of the affection is intermittent or remittent; but the recurrence of the attacks are less regular in the latter than in the former. And in the visceral as well as the external complaint, it may be presumed that more or less of vascular determination or fluxion follows the excessive exaltation of sensibility, at least in some cases. Visceral or ganglial neuralgia may thus be followed by increased secretion, or by other evidences of increased vascular reaction or determination. It is also apt to perpetuate itself, or is more prone to return or to continue after having once appeared; and it seldom leaves after it, or presents upon the examination of fatal cases, lesions sufficient to account for the amount of suffering experienced during life.

42. c. The chief special forms of visceral neuralgia which present themselves in practice are, 1st. Neuralgia of the heart, and particularly that form of it which has been termed angina pectoris 2d. Gastralgia or gastric colic, and its various morbid associations, Cecide and duces, more frequently local colic; 4th. Hepatalgia and splenicalgia; 5th. Nephralgia; 6th. Hysteralgia; and 7th. Mastodynia. These are all fully noticed either in the articles devoted to them especially, or in sections of the articles on the diseases of the organs in which they are stated; and their pathology is still further illustrated in the article on Irritation and its sympathetic relations. The subject of nephralgia (see KINNEYS, § 249) is well exemplified in the case of intermittent neuralgia of the kidneys described by Dr. Maccollow, in which there was an excretion of urine which had been recently expelled. In some slighter states of this affection, occurring in hysterical females, and generally associated with more or less of hysteria, this influence of morbidly exalted sensibility of the nerves of the organ upon secretion is also fully shown.

43. d. Many of the cases of hysteralgia, or irritable uterus, as it has been most commonly termed in this country, may be considered as neuralgia of the uterus, although it is ascribed by some writers to congestion of this organ.

Doubtless cases of attacks of pain in the uterus, depending upon, or at least associated with, congestion or chronic inflammation of the neck and mouth of the womb; but there are others of a more truly neuralgic character, which may be discriminated from these by a due exercise of tact and observation (see art. Uterus, Painful affectio of), and which are most successfully treated, according to the principles of cure recommended for neuralgia.

44. e. Neuralgia of the vagina has been noticed by a few writers. It has been variously described by patients as a most acute burning, or lancinating, or lacerating, or plunging pain. It is usually of short duration, and of frequent recurrence; but it is sometimes attended by a more continued aching or soreness; and the attacks are after intervals of various and sometimes of very long duration. In its idiopathic form there is no appreciable lesion of the vulva, vagina, or uterus, but it is occasionally symptomatic of organic lesions of the womb, and the patient is usually fearful of cancerous, or other serious mischief being present. It has been impouted to cold or astrigent injections for the cure of leucorrhoea, to sitting on cold or damp seats, and on stones or on the ground; to excesses in coition, and to other causes of neuralgia; but certain of these are matters rather of inference than of ascertained occurrence.

45. VII. NEURALGIA OF NERVES OF ASSOCIATION. — a. It is extremely probable that several anomalous cases sometimes occur of severe pain, or other paroxysms of extreme agony, which cannot be referred with precision to a single part or organ, but which affect the diaphragm, stomach, heart, and their vienity, or either of them more
or less prominently, are actually instances of neuralgia of these nerves, and the ramifications of them, particularly of the pneumogastric and phrenic nerves. Several of these affections have been considered as instances of angina pectoris; but, although nearly allied to that affection, they are more correctly instances of neuralgia of these nerves, than angina pectoris. In the individual cases, varying with the ramifications especially affected, and with the associated affection of ganglial nerves frequently accompanying them. Many of the cases of these neuralgic affections occur in persons who have experienced either regular or irregular attacks of gout, and have hence been viewed as occurrences of retrocedent or misplaced gout, both from this circumstance and from the immediate relief consequent upon the development of that disease in the extremities. Still, some of these cases occur either without any previous manifestation of gout, or without any attempts subsequent to their appearance to develop the gouty attack. In a case long attended by Dr. Roots and myself, in which the attacks of extreme agony were referable to the diaphragm, heart, and stomach, but sometimes to one of those situations more than to the others, there has been no regular manifestation of gout; and in another occasionally seen by me in the course of thirteen years, there has been no attempt to develop a paroxysm of that disease since the first occurrence of the visceral neuralgia, although treatment was often prescribed with this intention. In this case the violent attacks of pain in the praecordia, and sometimes also in the stomach, with marked disorder of the heart’s action, were often alternated with the most acute pain of the head, generally of some hours’ duration, or even longer. Notwithstanding the extreme suffering these two patients have endured for many years—in one case about 10 or 12, in the other for 14 or 15—the general health has not suffered, and no farther change beyond that depending upon advancing age can be observed.

46. b. Many of the more severe sufferings are often complained of by hypochondriacal and hysterical patients, and which are very generally viewed as either imagined or remarkably exaggerated, owing to the general health being but little impaired, and to the little disturbance evinced by the organs of circulation and locomotion, may be considered as forms of neuralgia affecting chiefly the nerves of organic life or of association. In many cases of hypochondriasis and hysteria, the most distressing pains are referred to the stomach or to the bowels, to the heart, and to various other viscera; and in some these pains are said either to change their seats from time to time, or to affect several organs, or even to assume different features. In these nerves, the phenomena characterizing the entire attention of the patient, and the apprehensions and despondency often attending them, being usually viewed in connexion with very slight appearance and evidences of aiment, often lead to a belief in their want of reality; while they should be viewed as evidence of greatly impaired energy of the ganglial system of nerves, or even of more serious disordered of these nerves; of asthenaemia of this part of the nervous system, associated with a morbid exaltation of its sensibility, and not infrequently with either functional or structural lesion of one or more important organs, particularly of the organs subservient to the perpetuation of organic life. I have had already frequent occasion to remark upon the efforts made by nosologists and systematic writers to point out differences, and to manufacture facts, in order to support the character of the attacks with the distinct objects of natural history, while they ought, at the same time that they mark differences and modifications of morbid action, to show obvious connexions and intimate alliances—such as are so frequently exhibited by hypochondriasis, hysteria, and neuralgia, and more especially visceral neuralgia.

47. III. Diagnosis of Neuralgia.—A fully-developed case of neuralgia is characterized by the remarkable severity and frequent recurrence of darting or plunging pains, and by the intermittent or remittent forms of the attack. The situation of the pain in the course of a nerve serves to indicate the nature of it, in the less violent cases, while the ease caused by pressure, and the absence of fever, of tendingness on firm pressure, of hardness or swelling, and of heat in the seat of the nerve, distinguish these cases from neuritis. This distinction, however, does not always hold, for I shall hereafter have to show that some cases of neuralgia depend upon a congested or slightly inflamed state of the origin or some portion of the nerve. In all cases both of internal and external neuralgia, the effect produced by firm and continued pressure aids the diagnosis; for where pressure gives case or is well borne, the neuralgic character is thereby indicated; and where the neuralgia is associated with congestion or inflammatory action, pressure will indicate their existence.

48. a. When the nerves of the face are affected in the extreme manner characteristic of tic, the disorder cannot be mistaken for any other. Even when it is attended by spasm or twitchings, &c., of the muscles of the face, it cannot, owing to the seat and violence of the suffering, be confounded with trismus; and in even the less severe cases, the recurring nature of the pain sufficiently marks it from the continued pain, increased on the action of the muscles, constituting rheumatism of the face, which also is sometimes attended by swelling. 49. b. In neuralgia of the nerves of the trunk, the chief object of the diagnosis is to determine the existence or non-existence of inflammatory action or congestion in the spinal chord, or in its membranes. This can be ascertained only by attention to the history of the case, and by a careful examination of the spine. It is of importance also to ascertain whether or not the pain is dependant upon disease of a viscus near or related to the nerves affected, or to the seat of pain; and this object is to be attained only by careful examination, and by the aids of percussion and auscultation, with due attention to the constitutional and symptomatic phenomena.

50. c. The same intentions as the above should guide our inquiries in forming a diagnosis of visceral neuralgia from inflammation or congestion, or even from organic disease of the viscus, to which the patient’s sufferings are referred; and in these, as well as in others, the continued and persistent character of the
CAUSES.

Neuralgic Affections—Causes.

the intellect, prolonged watchings, and other circumstances which affect nervous power and the state of the cerebral circulation, particularly when aided by other exciting causes, will be more or less influential in producing certain of the varieties of neuralgia, more particularly those seated in the nerves of the head or face. Bellingerii met with two cases of tic which were caused by fright.

54. b. Of all the causes whose operation is well ascertained, there are none more efficient in producing these complaints, particularly when seated in the extremities, than exposure to malaria, and to damp and cold in any form; to any of these, or to a combination of them, and more especially when they are conjoined. One of the most important services rendered to medical science in modern times is to be found in the exposition of the causes and morbid relations of neuralgic affections by Dr. Macculloch. Until that work appeared, the influences of malaria in causing the several forms of neuralgia, especially when aided by damp and cold states of the atmosphere, were hardly acknowledged, and the important connexions of neuralgic affections with other diseases were entirely overlooked. But, even without any probable operation of malaria, cold and damp, particularly when the exposure to them has been prolonged or frequent; vicissitudes of season and weather, especially in respect of humidity and electrical conditions; the partial abstraction of animal heat by currents of air, by wet clothes or shoes, or by sitting on cold or damp seats, standing or sitting on cold floors, and exposure of the face to cold and wet, or to a snow-storm, especially when outside a carriage, have been in allusion in producing neuralgic complaints. Residing in low and damp cellars or houses; sleeping on the ground or on the ground floor, or in the open air; low, damp, and misanthropic localities and a clayey soil, are often so productive of these complaints as to impart to them an endemic character; and when to these are superadded wet and cold seasons, the prevalence of rains and stormy weather, and electrical vicissitudes of the atmosphere, they may even assume an epidemic appearance.

55. Of the influence of local injury: of foreign substances lodged near to or between the fibrils of a nerve; of bruises, wounds, &c.; of overstretching a nerve by great efforts; and of undue or prolonged pressure of a nerve, in the production of both neuralgia and chronic inflammation, notice has been taken in the article Nerve (§ 20). These produce or perpetuate irritation and inflammatory action or congestion in the portion of nerve thus injured. Indeed, some of the pathological causes about to be noticed have a similar effect. But

56. c. The pathological causes and associations of neuralgia are of much importance as respects the obvious indications of cure which they suggest. Certain of these causes act directly upon the nerves affected, and some even upon the part which is the source and centre of pain, while others exert a more distant or sympathetic, and not infrequently a doubtful influence. The same causes as were stated to occasion inflammation of a nerve (§ 33) may produce neuralgia, and any of the organic lesions of nerves (§ 2, et seq., 34, 26) may have a similar effect. Various structural changes seated

pain and other symptoms, tenderness on pressure, heat, swelling, or distention, fecible commotion, the state of the pulse, of the secretions and excretions, and of the tongue, countenance, and skin, will indicate the presence of inflammation, or of active vascular determination; and in plethoric patients, of congestion; and will point out the treatment which should be adopted, while the intermittent, remittent, or periodic pain, the marked intervals of case, the history of the case, and the circumstances increasing or ameliorating the patient's sufferings, will demonstrate the neuralgic character.

Neuralgia of the extremities can hardly be confounded with any other disease, unless when the ischiatic nerve is affected. Sciatica may be mistaken for disease of the hip joint, or of the vertebræ in connexion with inflammation or abscess of the psoas muscles, extending to adjoining parts; or these affections may be mistaken for sciatica, the ischiatic nerve, or the nerves contributing to form it, being often inflamed or irritated, or pressed upon in the course of these maladies. In psoas abscesses, the pain is in the loins, the tenderness in the situation and anteriorly, the acute hectic fever, the continued form of the disease, the obvious tumour and the consequent fluctuation, the direction which the tumour takes, either to the groin or to the loins near the sacro-iliac juncture, &c., suffice to distinguish it from true sciatica. In hip disease, or even in spontaneous dislocation of the hip, the situation of the pain, the alteration in the direction and position of the trochanter, and the lengthening and subsequent shortening of the limb, show the nature of the disease.

52. IV.—Causes.—A. Predisposing.—Neuralgia is most frequently observed in the nervous and melancholic temperaments; in persons of a hypochondriacal, hysterical, rheumatic, and gouty diathesis; and in adult and aged subjects. Sex has no very marked influence upon its frequency, although certain of its forms are more frequent in females than in males, while other forms are more common in males than in females, about which and after the cessation of the menses than at any other period; and it is more common in the wealthy or easy classes of society than in the poor and laborious. It is more common in cold and humid, than in warm and dry climates. Chronic or prolonged debility, the exhaustion consequent upon acute diseases, and prolonged or neglected dyspepsia; the puerperal states, exhausting discharges, and prolonged or improper lactation; excessive venereal indulgences, menstruation, &c., anxiety of mind, &c., are among the most influential predisposing causes.

53. B. The exciting causes are not always clearly ascertained in practice, for while some cases are chiefly referable to physical causes acting either upon the brain or upon the nerves, others can be attributed only to some pre-existing disorder, or pathological condition, which, however, when more closely viewed, often appears as much an associated effect of some anterior morbid state as an efficient cause of the affection.—a. There can be no doubt that moral emotions of a powerful kind, prolonged excitement or anxiety, habitual exertions of
at the origin of a nerve, or in the nerve itself, or in contact with it, or so near it as indirectly to implicate it, may occasion either pain or spasm, or both, or palsy, according to the manner in which they either irritate the fibres devoted to sensation or to motion, or entirely interrupt one or both of these functions. Hence the intimate connexion existing between neuralgic, spasmodic, or convulsive, and paralytic maladies.

57. The pathological causes which occasionally give rise to neuralgic affections in some one or other of their seats are very numerous, and may be divided into, 1st, those which are hyperemial, or consist of congestion or inflammation in some portion of the nerve, or in its origin; 2d, those which are anemial, or which consist of a deficiency of blood; 3d, those which occasion irritation in some portion of the trunk or of the ramifications of a nerve, or even of or near to its origin; and, 4th, those which consist of irritation of a similar degree of a remote but related organs or parts. Several of the pathological conditions comprised under these four categories are probably, on some occasions, mere accidental morbid associations resulting from pre-existing disorder; but they are, with equal probability, in other cases, the active agents of the neuralgic affection. Others of them are concurring or aiding influences in developing the effects of more energetic causes.

58. (a) Hyperemia in any form, general or local, congestive or inflammatory, may, either at the origin or in the course of a nerve, occasion this affection. Evidence of this is to be found in the appearances observed in some cases after death; in the termination of several in apoplexy or palsy; and in the symptoms and the effects of treatment in other cases. I was consulted several years ago by a gentleman about fifty years of age, suffering neuralgia of the halves of his face. He exhibited the active determination of blood to the brain, and he was treated accordingly, and the neuralgia disappeared. Two years afterward he experienced a return of the affection; and he had just arrived in the vicinity of London from the country to consult me, when he was seized with apoplexy, and soon afterward died. I was called to a lady about fifty years of age, suffering neuralgia referred to inflammatory congestion or similar change within the cranum. Cupping in the nape of the neck, with other means appropriate to these views, were prescribed. She was relieved; but the complaint soon afterward returned. Her friends then requested a consulting surgeon to see her; and he prescribed large doses of the carbonate of iron. She immediately became maniacally delirious, afterward hemiplegic, and she soon afterward died. The family surgeon informed me that the appearances after death indicated intense vascular congestion, with signs of previous inflammation. A gentleman from the country very recently came under my care for chronic diarrhoea of seven years’ continuance. He had experienced two attacks of phlebitis of the femoral veins consequent upon having taken the extract of logwood, this medicine having restrained, but not arrested the diarrhoea. A cautious alternative and derivative treatment was therefore prescribed, and the diarrhoea was slightly abated and the stools improved; but a violent attack of neuralgia supervened, the pain being seated chiefly in the right side of the occiput and in the frontal branch of the fifth pair of nerves of the left side. The increased action of the carotids induced me to prescribe local blood-letting, a blister to the nape of the neck, a blister on the abdomen, &c, and the attack entirely ceased in a short time; but a few days afterward the phlebitis returned for the third time, but in a less severe form, recovery from it taking place after some days, but the diarrhoea was only moderated.

59. That cerebro-spinal neuralgia is some times owing to venous congestion or inflammatory action in a limited portion of the spinal chord or its membranes, or even of the theca vertebrae and the vicinity of the inter-vertebral foramina, cannot be doubted, inasmuch as it is sometimes observed in connexion with, and manifestly depending upon, these lesions. In two cases, both of them males between fifty and sixty years of age, the neuralgic pains, sometimes associated with spasm of the abdominal and femoral nerves and muscles, of which they complained for several years, and which ultimately terminated in paraplegia, were ascertained by post-mortem examinations to have arisen from these changes. These cases were frequently seen by the author and other physicians, and the nature of the malady recognized from the first. It is not unusual to observe, associated with, or in connexion with, lesions of the spinal chord and its membranes, to which the term spinal irrigation has been recently applied, or with inflammation of the constituent structures of the spine, or with cases of the vertebrae, intense neuralgia, or marked pain, generally of a remittent or intermittent kind, in one or more of the spinal nerves more immediately related to the seat of these lesions. When the vertebrae and their connecting structures are unaffected in the cases in which the spinal chord proportion of cases of this complaint; and in most, even of these, the attendant pain is more permanent, the intervals of case shorter and less complete, than in those cases of neuralgia where these changes are not discovered.

61. (b) Anemia is much less frequently a cause than a complication of neuralgia; and its influence is more predisposing than exciting.
The same remark equally applies to plethora. But it is not unlikely that great deficiency of blood may so affect a portion of the cerebro-spinal axis as to occasion acute pain in some one of its nervous ramifications. But whether a cause or a complication, it is not unusual to meet with evidence of anaemia in some instances, or of general plethora in others, in connexion with neuralgic affections. In hysterical females, or in those subject to menorrhagia, more or less deficiency of blood is sometimes associated with these affections, particularly with visceral neuralgia.

32. (c) The dependance of neuralgia upon irritation of a portion of the trunk or ramifications of the affected nerve may be admitted as having been proved in some instances. Sir H. Halford, in his Classical Essays, has adduced several instances of the dependance of the complaint upon a preternatural deposit of bone, or upon diseased bone. Among the most frequent of the former are exostosis in some part or throughout the frontal sinuses; thickening or hony deposits in this situation, or in the frontal and sphenoid bones; ossiflc deposits in the falce process or other parts of the dura mater; and exostosis from a fang of a tooth. Thickening or exostosis of the frontal bone, or ossiferous deposits in the dura mater, may occasion the complaint by affecting extreme ramifications of the nerve affected, or of some other nerve intimately related to it; but in these cases the connexion between the presumed cause and the disorder is not so obvious as in some cases of exostosis or other disease of the bony part. Therefore, exostosis, excretion, or of the alveolar processes, or disease of the jaw, antrum, &c. Various kinds of tumours have been found in the close vicinity of the trunks as well as the terminations of neuralgic nerves; and ossiferous deposits in the adjoining vessels, membranes, &c., have likewise been found. That the former may affect the sentinet functions of a nerve is very probable; and that the latter may be a consequence as much as a cause of neuralgia, in some instances, is also likely. We cannot with any great precision assign all, or even the majority of lesions found after death as the immediate causes of suffering. Some of them are effects of that suffering, and others are either associated results, or merely coincidences, in the varied course it has taken, or effects merely of the intercurrent disorders by which that course has been modified.

63. The irritation or similar affection of the cutaneous extremities of the affected nerve, or of the skin of the face or upper lip as in rhus, zoster, &c., by superficial injuries, punctures, leech-bites, and cicatrices, has individually occasioned neuralgia. In these cases, as well as those caused by diseased teeth, caries, and exfoliation of bone, &c., the connexion of cause and effect has been fully proved by the disappearance of the effect upon the removal of the cause. Thus, the removal of diseased bone or teeth has often cured the neuralgic complaint; and suitable applications to a cicatrix, to which a cure of neuralgia was attributed, removed the pain (Bright). In many of the cases which evidently depend upon irritation in these precise situations, the affection may be seated at a considerable distance from its local cause, or it may commence in the very seat of irritation, and suddenly dart to a remote point. Thus, as in the cases adduced by Mr. Bell, and Mr. Pirie, the pain may commence in a tooth, and suddenly pass to the arm, or even to the neck and trunk; and upon the removal of the tooth all disorder may cease.

64. (d) The cause of neuralgia may consist of irritation of an organ or part at a distance, from, but more or less related to, the seat of suffering. In several articles in this work, and more fully, and with reference to other articles, in that on Intermittents, I have shown, that disorders of various internal organs or parts may so affect not only other distant internal organs, but also remote external parts, or those supplied by cerebro-spinal nerves, as to occasion convulsions, spasms, and morbid exaltations of sensibility. It has been supposed by many that disorders of the digestive organs may give rise to neuralgic affections in various situations; and I believe that such disorders, whether consisting of irritation caused by hurtful ingesta or by a venereal irritation, or of any other visceral secretions, may have this effect, not only in these organs themselves, as in gastralgia or gastrodynia, enteralgia or colic, but also in remote but related organs, as the heart, diaphragm, &c., and even in one or more of the nerves proceeding from the cerebro-spinal axis. The disorders of the digestive organs act, in some of these cases, as a predisposing cause, and in others as an exciting or, at least, as a concurring cause, or in aiding to develop the operation of other causes, some of which may have escaped detection, and hence it may itself appear as the sole efficient agent in producing the neuralgic affection. In estimating the influence of disorders of the alimentary canal in producing this affection, too much has been imputed to it by some, and too little by others. Montfalcon and Elliotson believe that they have no influence in causing the complaint. This is, however, too extreme an opinion. Doubtless some of the cases in which these disorders are very prominent, and in which the neuralgic suffering subsides upon their removal, may be viewed as associated effects of a pre-existing morbid condition, probably of the ganglial nervous system. But, that disorders of the digestive organs are without any influence in causing or developing neuralgia is not consistent with the evidence furnished by Swan, Brodie, Andr&al, and others, and by my own experience. That paroxysms of the complaint are cured by cathartics, is an admittance without dissent. And this circumstance proves nothing as to the influence of these disorders upon the complaint, for cathartics may produce a beneficial effect upon it by deriving the blood from the brain and spinal cord. Yet, admitting this effect of cathartics, still these disorders are not without some influence, and the fact is much too important to be disregarded in practice, however it may be attempted to account for it. I have, both in the article Intermittents and in other articles and works, attempted to show that disorders of the digestive organs, and even of other organs, as of the urinary, &c., may be directly extended by means of the ramifications of the ganglial system to distant internal organs in some cases, and be there expressed by spas-
modic action or morbidly-excited sensibility; or to the roots, or even to the ramifications, of cerebro-spinal nerves; in other cases, giving rise to similar morbid manifestations of muscular motion and sensation. I have met with several instances in which focal accumulations in the cerebrum and sigmoid flexure of the colon, and internal hemorrhoids, have been attended by severe neuralgia of the lower extremities; and as soon as these have been removed, this affection has ceased. (See Notes and Appendix to M. Richerand's "Elements of Pathology," by the author (p. 546, 562, et passim), and article Irritation, passion.)

65. (c) Diseases of the urinary organs sometimes give rise to severe neuralgic pains, generally in the extremities. Instances of this cause of the complaint have been furnished by Sir B. Brodie, Dr. Rowland, and others. Mr. Swan mentions a case where severe pain of the back of the fingers was induced by evacuating the bladder when once distended. A similar complication is observed by the author, the patient being most severe under the nails and along the backs of the fingers. I have seen stricture of the urethra apparently the cause of slight agushy attacks, and of intermittent nervous affections of a painful and spasmodic nature.

66. (f) That irritation of the extremities of the nerves will occasion neuralgia in some of the branches of the same, or of intimately-connect ed nerves, appears to be proved not only by the occurrence of this affection after superficial injuries and cutaneous eruptions (66), but also by the circumstance of severe frontal neuralgia having been caused by the larvae of insects in the frontal sinus, a case of which occurred in a member of my own family; the larva escaped after a severe fit of sneezing, and the pain immediately ceased.

67. V. Compliations.—Several of the pathological states just adduced as causes of neuralgia may be considered with equal propriety as complications, or as associated results of severe anterior disease of the ganglial nervous system, as I attempted to show many years ago. The most common of these associations are irritation, congestion, or other disease of the spinal chord or of its membranes; caries or inflammation of the interverbral substance or vertebra; hysteria, and uterine disorders; epilepsy and other convulsive affections; disorders of the digestive organs; focal accumulations in the cerebrum or sigmoid flexure of the colon or disease of the rectum; ague, rheumatism, and catarrh; paralytic affections; internal abdominal and pelvic tumours; disease of the hip joint, and psoas abscess. There are occasionally other complications of neuralgia met with in practice, but these are chiefly accidental, or at least less intimately connected than the above with this affection.

68. A. The connexion subsisting between neuralgia and many of the disorders now enumerated is very obvious; certain of them, although frequently the primary affection, are sometimes consecutive, and more of them are merely consequences of pre-existing morbid conditions, one or other appearing earlier or in a more prominent manner in some instances than in others. Diseases of the spine, or of the hip joint, psoas abscess, and focal accumulations, &c., in the large bowels, are generally a pathological cause of neuralgia, although often also associated results of previous disorder. The same remark applies also to other derangements of the digestive organs, to hysteria, and to spinal irritation or congestion, although they are more frequently pure complications than the foregoing. The occasional complication of ague, rheumatism, or catarrh, with neuralgia—complications not infrequently observed—are merely the associated effects produced by malaria, cold, and wet, and currents of air. I have seen neuralgia conjoined with obscure or irregular attacks of ague, and as the former became less violent the true character of ague was more distinctly and regularly developed. In cases of sciatica, the rheumatic character is often very prominent, or rheumatism of other parts sometimes alternates or is associated with the sciatic affection. The same is occasionally also remarked in respect of toothache and rheumatism or facial tic.

69. B. Epilepsy and convulsions or spasmodic affections are often the external manifestations of the same lesion which occasions neuralgia, the one alternating with, or to a certain extent accompanying the other. Indeed, the same local lesion which produces intense pain may, in a different grade, or as it extends to the nerves of motion, occasion spasm or convulsion; and, in a still more advanced grade, loss of sensation, or of motion, or of both functions. Of this, I have met with several instances, when the primary lesion was seated within the cranium or spinal canal. In some cases, severe pain has been experienced in different parts of the lower extremities; afterward the pain has been attended by cramps in the muscles of these extremities, or of the abdomen; these have recurred at intervals, and have been followed by weak, imperfect, and irregular action of these muscles, giving the patient an unsteady and partially paralyzed gait, in some cases resembling paralysis agitans, in others chorea, or an intermediate state.

70. That neuralgia and epilepsy may be associated effects of the same lesion, the latter appearing consecutively on the former as the primary lesion increased, was demonstrated to me many years ago in the case of a compositor in a printing office, who complained of most severe neuralgic pains in the left hand, which generally originated in the situation where the metal composing-stick pressed most during his work. As the intensity of the pain increased, regular cramps of quite severe degree appeared with the removal of the local affection and its cause. Painters' colic may be considered as a form of visceral neuralgia, and this affection I have seen associated with epilepsy on two or three occasions.

71. VI. Terminations and Prognosis.—Neuralgic affections terminate, 1st. In health; 2d. In some other disease; 3d. In death. A. A return to health is a most frequent termination of neuralgia of the nerves of the lower extremities, while neuralgia of the face and head is most liable to prove obstinate, to return, or to terminate unfavourably. The result, in all cases and seats of the affection, depends upon the exciting cause of it. When it proceeds from malaria, or from cold and wet, or from any of the more passing and external physical
causes, it is generally soon removed by decided
means early prescribed. Yet, even in these
cases, a first attack leaves behind it a predispo-
sition to return upon exposure to the exciting
causes, although those causes may be less en-
ergetic than those which first occasioned it.

72. B. When neuralgia cannot be imputed to
these causes; when it is occasioned by less
manifest causes; when there is reason to sup-
pose that some organic lesion exists within ei-
ther the cranium or spine, a protracted disease
may be expected, and the supervision of anoth-
er malady, generally resulting from the progress-
ive increase of the primary lesion, and of a
still more fatal tendency, may be anticipated,
although at a more or less remote period. In
a very large majority of these cases, neuralgia
terminates in some related malady—in a convul-
sive, epileptic, apoplectic, or paralytic seizure.
From either of these the patient may recover
partially, rarely completely, and be again at-
tacked, but he seldom experiences the neural-
gic affection, or at least in the same form or
degree of severity. Of the several maladies
into which neuralgia passes, palsy, generally in
the form of hemiplegia, sometimes in that of
paraplegia, when the lower extremities have
been the seat of the affection, has been that
most frequently brought under my own obser-
vation. Next to this, apoplectic, or apoplectic
conjoined with convulsive seizures, have been
noticed.

73. C. It is chiefly, if not entirely by passing
into the apoplectic, epileptic, or convulsive, or
the universally paralytic states, that this affecti-
tion terminates in death, such termination some-
times taking place more or less suddenly, upon the
occurrence of the first seizure, or not until after
two or more recurrences or exacerbations of
the seizure. A gentleman from the country con-
sulted me for facial neuralgia. He continued
tolerably free from the affection during near-
ly two years, when a severe attack occurred,
followed by convulsions, which rapidly passed
into apoplexy and death. Another experienced
an attack of apoplexy attended by convulsions,
that superseded upon neuralgia. I found him
partially recovered from this attack. He had
been very largely bled, and the pulse indi-
cated an excessive loss of blood; yet another
attack took place nevertheless, within 48 hours,
and speedily terminated life. Whether or not
he could have recovered from the first attack
without the large depletion is difficult to deter-
mine. Still, as I have remarked in the articles
Apoplexy and Convulsions, I have rarely seen
large blood-lettings beneficial, more frequently
I have observed them prejudicial, in seizures
attended by convulsions. In these cases, it is
better to wait, or to employ other measures less
likely to be prejudicial, than to bleed largely with
the view of recovering the patient from the seiz-
ure, which cannot always be arrested at once, or
recover from under its strain, after having
been developed. Time, I may here remark,
is a necessary element in the process of recov-
ery; and if due time be not allowed for the pro-
cession of phenomena terminating in a return
to health, but disturbing, officious, or exhaust-
ing measures be adopted to hasten what admits
not of being accelerated, serious mischief may
accrue.

74. VII. The appearances observed in fa-
tal cases, particularly of neuralgia of the face,
have been the majority of those found in the
membranes and substance of the brain, and
bones of the cranium (see Art. Brain and Crani-
unm), more especially tumours, and ossific de-
posits in the dura mater, and near the base of
the brain or cranium; exostosis, great thick-
ening, and even caries of some parts of the cra-
nial bones in the vicinity of the afflicted nerves,
and many of the structural lesions already men-
tioned as pathological causes of the affection
(§ 62, 63). Various changes of structure found
both in the brain and membranes, and in re-
move viscera, may be only coincidences or
the effects of protracted suffering upon the
circulation in the brain. Softening of parts of
the brain, effusions of blood, and even ossific
deposits in the membranes, or in the coats of
the arteries, sometimes observed in cases ter-
m terrating in apoplectic or palsy, may be al-
gether or partly consequences of the repeated
returns of the neuralgic affection; morbid sen-
sation exciting or otherwise changing capillary
action in related portions of the brain and its
membranes. Still, such cases as have been re-
corded by Sir H. Halford, Tyrrell, Mont-
ault, and others, where bony deposits, fungous
tumours of the dura mater, &c., implicating the
fifth pair of nerves, compel our belief that these
lesions have been concerned in causing the af-
faction. In some cases of neuralgia of the lower
extremities, signs of chronic inflammation of the
trunk of the nerve, or the more usual conse-
quences of this state of vascular action,
particularly injection and enlargement of the
capillaries of the nerve, thickening, discolora-
tion, &c., of the connecting cellular tissue, have
been remarked by Cotugno, Cielio, Stiebol,
Bichat, Rouset, and Swan; while, in other
cases, no change could be detected in the
nerves themselves by Dessault, Wardrop, Bi-
chat, Andral, and others; nor even in the
nervous centres, when the patient did not die
of any of the diseases of these parts just men-
tioned as frequent terminations of neuralgia.
In cases of visceral neuralgia, inflammatory
changes have been remarked in the ganglia by
Lohstein, Swan, and others; but it is difficult
to estimate the morbid amount of vascularity
of these parts of the nervous system, as it va-
ries very much in this respect even in health.

75. VIII. The nature of neuralgia must
necessarily be estimated, 1. Partly from the
general character of the local and constitution-
al symptoms attending it; 2. Partly from the
appearances observed in fatal cases; 3. Partly
from its relation to other maladies, into which
it often passes; and, 4. Partly from the influ-
ence exerted upon it by medicinal agents.—(a)
That the local and constitutional symptoms ac-
companying neuralgia are different from those
of acute neuritis have been shown both in the
article Nerves (§ 23, 27), and above (§ 5). Still
there may exist, in some of the more persistent
and chronic cases, in the different states of neuralgia, chronic inflammation at the
origin, or in some part of the trunk, of the nerve
affected. The absence of fever and of tender-
ness on firm pressure, although indicating the
absence of inflammation in the majority of ca-
es, still should not be estimated as precluding
the existence of chronic inflammatory action
in all of them. The absence of fever, &c., is no
proof of the absence of the slighter states or more chronic forms of inflammation of the affected nerve or parts intimately related to it. In those cases where there is most reason to suppose that the complaint is independent of inflammation, the pulse even falls in frequency during the severity of the paroxysm. The absence, however, of all appearances and consequences of inflammation in some of the fatal cases proves strongly that neuralgia is at least occasionally independent of this state of vascular action. The nature of the exciting causes, and the characters of the other diseases with which it is often allied, or into which it occasionally passes, indicate that neuralgia varies in its nature in different cases; that it may proceed from inflammatory action in portions of the nervous centres related to the paralyzed part; from disorganization or organic lesion: from inflammatory softening, sanguineous effusion, &c., than from deficient or interrupted circulation of blood, although this state of the circulation in parts of the nervous centres probably causes palsy in some instances.

76. Those cases of neuralgia which are unequivocally caused by malaria, which are completely intermittent, and which are devoid of febrile commotion, or of tenderness of the nerve upon firm pressure, may be viewed as non-inflammatory; but it may be asked, what, then, is the nature of the affection? Does the disorder, in these cases, proceed from slight pressure of the nerve at its origin or in its course, or from a supposititious state of irritation, of which irritation we know as little as of the nature of the pain of which it is assigned as the cause? Is it merely a disturbance of function? For no actor of treatment furnishes so very conclusive evidence of the nature of the affection, not even of its inflammatory or non-inflammatory character. For even in those cases where evidence of the existence of inflammatory action is the strongest, even there an energetic exhibition of tonics, as of camphor, quinine, iron, &c., will often effect a cure. We know, at least I have fully satisfied myself, and I have shown in this work, that these remedies will often cure inflammations of the circulating vessels; and we may, therefore, infer that they may prove equally serviceable in its insistency, although we may find them still more beneficial in neuralgia of a purely non-inflammatory character.

77. Concluding, therefore, that those affections, to which the name neuralgic has been applied, may be viewed as more or less inflammatory in some instances, and non-inflammatory or functional in others, and that great advantages will accrue in practice from the scientific delineation which facilitates the physician to distinguish between these, or to estimate how much of either character may be present, it will next be inquired, having found a certain palpable condition to which the disease is to be imputed only in some cases, to what is it to be attributed in those other instances where that condition is supposed not to exist? Now those other instances have been said to proceed from irritation, altering the sensibility of the nerve, which either is the seat of this irritation, or manifests it from an intimate relation to the irritated part. In these cases, the violent pain is often the chief, if not the only cognizable disorder. Its dependence upon inflammation is not entertained for the reasons above assigned, in connexion with its sudden occurrence, and as sudden cessation—phenomena hardly to be explained by any inflammatory irritation of the cause. The affection has been viewed as functional in such circumstances as morbid exaltations of sensation, as the result of irritation of the nerve or of parts related to it. This, however, is merely a play upon words, a confession of our ignorance; for, to say that intense pain is a morbid exaltation of sensation, is a consequence of irritation, is merely a nervous disorder or affection, and so on, is explaining nothing, is merely substituting terms for the concealment of our ignorance, or with the vain hope that we are evincing our knowledge.

78. Considerable practical knowledge of neuralgic affections has suggested the following inferences: 1. That these affections often proceed from chronic inflammatory action in some part of a nerve, or of a part intimately related to it. 2. That the exciting causes of the affection should be kept in view when we estimate the inflammatory or non-inflammatory character of it. 3. That, even in those cases which present no inflammatory character, some pre-existing affection or disorder of related parts, especially of the nervous centres and internal viscera, should be suspected and searched after. 4. That, in the non-inflammatory cases especially, the neuralgic disorder should be generally viewed as an external manifestation of some latent internal disorder, which a patient investigation of the case, with due acumen, will frequently detect, and which, when once detected, will suggest the only permanently successful treatment. 5. That the connexion of these affections with gout, rheumatism, hysteria, &c., should not be overlooked; nor the tendency they often evince to terminate in palsy, epilepsy, or apoplexy be neglected, in estimating the morbid relations and nature of individual cases, and in determining the indications of cure most appropriate to each. 6. That the one-sided views published of the subject, the vaunted success of certain remedies for the cure of the affection, the publication of successful cases, to the neglect of the unsuccessful; and the silence as to the ultimate result of many cases, or as to the diseases which appeared at some period after a supposed cure, which has been preserved, have all tended to mislead the inexperienced as to these affections. 7. That the suppression of the neuralgic affection by powerful tonics and stimulants, or by the more energetic narcotics, without due reference to, or an accurate estimate of, the states of the most important visceral parts, has sometimes proved injurious; and yet, although the neuralgic affection has apparently
neuralgic affections—treatment of.

1021

ceased altogether, and for a considerable time, still some severe visceral disease, or an apoplectic, epileptic, or paralytic seizure not infrequently supervenes, and endangers, or carries off, the supposed case of cured neuralgia.

ix. treatment of neuralgic affections.

79. a. from what has been advanced above as to the physical and pathological causes and associations of neuralgia, it is obvious that our first and most strenuous endeavors should be directed to ascertain and to remove these. when the symptoms are such as indicate, or even to render very probable, the existence of an inflammatory state of the nerve, more especially in young, robust, or plethoric subjects, or when the disease has appeared after suppressed discharges, or the disappearance of eruptions, &c.; the treatment in the first instance should be that advised for necrotis, more especially local blood-lettings, dermata, and counter-irritants. i have seen recent attacks of neuralgia, with the characteristic characters, remove by these means alone, in a very short time. when any evidence is furnished of disorder in the nervous centres, or in any important viscera, the treatment suited to such disorder should be decided and promptly prescribed before the more common neuralgic remedies are had recourse to; and in all complications, as well as in all instances caused by pre-existing disorder or lesion, the associated affection should receive immediate attention, and the means afterward directed for the removal of the neuralgic affection ought to be such as may either not endanger a return of the complication, or may tend to its permanent removal. in such circumstances blood-letting, cautiously employed, is often extremely beneficial, and renders the means subsequently prescribed much more efficacious. the same remark applies to chologogue and alternative purgatives when thus early and appropriately prescribed.

80. b. having removed the causes, as far as this intention can be accomplished, and had recourse to such antiphlogistic means as the state of the case and of the patient permitted, the morbid associations of the affection having received due attention, in the use of these and other remedies, the treatment may be directed more especially to the neuralgia, according to the characters it may present, and to the diathesis of the patient. in the distinctly intermittent form of the affection, and if there be no determination of blood to the head, or no active visceral disease, the preparations of iron, oxalate of iron, camphor, arsenic, &c., are especially appropriate. in the more strictly nervous or hysterical, and in cases connected with a deficiency of blood, the preparations of iron, of opium, of belladonna, &c., are most suitable. in the rheumatic and gouty diatheses, the fixed alkalies and alkaline earths with colchicum and ammonia, aconite with camphor, &c., are most successful, especially after biliary and other secretions have been evaucated by an active exhibition of chologogue purgatives.

81. c. when neuralgia appears to proceed from disease within the cranium, or near the origins of the affected nerves, as in the cases observed by myself and others, and already referred to, a secon or issue should be established in a situation selected with reference to the inferred lesion, and an alternative course of treatment, aided by narcotics, ought to be preferred, such as the iodide of potassium with liquor potassae, plummer's pill with soap and opium, the iodide of mercury with stramonium or belladonna. in some of these cases, the application of a few leeches behind the ears, or to the spine, when the latter is the seat of irritation, or a small cupping in the same situations, and the repetition of these according to circumstances, will prove of service.

82. d. cases will occur of the failure of means directed according to the principles now stated; the utmost care in ascertaining the physical and pathological causes and morbid associations of neuralgia, and our best endeavours to remove them, being altogether unsuccessful. in these, we must have recourse to more empirical measures, yet even these measures must not be blindly, but rationally prescribed. this brings me to the consideration of the principal remedies which have been employed against this complaint, according either to rational views and principles of treatment, or to a vague empiricism. in noticing, therefore, these remedies, i shall mention the states of the disorder in which i believe each of them to be most appropriate, and the combinations in which my experience has shown them to be most efficacious.

83. a. evacuants are more frequently required in neuralgic affections than has been generally inculcated; but not so much on account of any general fullness of the vascular system, or an irregular distribution of the blood, owing to impaired tone of the vital energies generally, and to deficient or impaired secretion and excretion. —a. the propriety of having recourse to blood-letting, and particularly to local blood-letting, and even the repetition of it in some instances, and the circumstances requiring this treatment, have been already noticed (§ 79).—b. emetics have very rarely been advised in neuralgic disorders, and yet cases occasionally are met with in which an attempt to knock out some morbid mineral, or other remedial measures as the peculiarities of the case will suggest, may be given, or other remedies, about to be noticed, may be tried. at the same time that tonic, anti-spasmody, anti-periodic, and narcotic medicines are being administered internally, various external means may be applied, according to the seat, character, and duration of the affection. in the cases caused by malaria or cold and humidity, quinine, eucalyptus, camphor, arsenic, &c., are especially appropriate. in the more strictly nervous or hysterical, and in cases connected with a deficiency of blood, the preparations of iron, of opium, of belladonna, &c., are most suitable. in the rheumatic and gouty diatheses, the fixed alkalies and alkaline earths with colchicum and ammonia, aconite with camphor, &c., are...
an alternative effect similar to that produced by colchicum upon the urinary functions. I gave it many years ago in a case of neuralgia of the right pillars of the fauces and side of the tongue, and the patient continued free from the disease for more than a year, when an attack occurred and proved much more obstinate than the former, the means which were formerly successful failing on this occasion. Chologogue purgatives are often preferable to any other when prescribed with decision, and lead to good results. In 1820 I treated a case of infra-orbital neuralgia, and in 1821 a sciatica, as follows:—

No. 290. R Colchcin, gr. xii.; Pulv. ipecacuanhae, Poult. Opii, &c., gr. i.; Maculag, q.s. M. Fant Pulsiaio i. m., hork samui sundem.

85. In these cases the complaint was removed in four days, alleviation of suffering being apparent in both within twenty-four hours after the first dose of pills. Rahn, Wilson, and many others have recommended cathartics, and when there is little or no visceral obstruction or congestion, any of the more active and certain purgatives may be prescribed, particularly when a derivative operation merely is desired to be produced. In neuralgia, however, of the lower extremities, I have preferred equal parts of spirits of turpentine and castor oil (fss. of each) taken on the surface of mint water or milk, containing some calcined magnesia, to other purgatives, colocynth with colchicum and ginger, or colocynth with ipecacuanha and opium, being given occasionally at night when visceral obstruction or congestion was present. Purgatives are more particularly indicated in neuralgia of the lower extremities, which is not infrequently induced by febrile accumulations in the colon and sigmoid flexure of the colon. Their good effects are often pronounced by those occasioned by the occasional colicemia with o. terebinthina and castor oil.

86. Alteratives and deobstruents are especially indicated when neuralgia appears to depend upon visceral obstruction or structural change near the origin or in the course of the affected nerve, and in cases of visceral neuralgia. Under this head may be comprised various substances, whose beneficial operation may be differently explained. The alteratives most frequently employed are the preparations of sialium, of salicin, of moracin, variously combined.—a. Dr. Corkindale prescribed colomel with opium, and Loebenstein-Loebel, colomel with the golden sulphuret of antimony and opium, until the gums became affected. Hildenbrand and Herrmann often pushed mercurials to the production of salivation. Schlesier preferred the bichloride of mercury, two grains of it being dissolved with three grains of the extract of stramonium in an ounce and a half of diluted water, and from thirty to fifty drops being taken every second hour.

87. I have given the preparations of salicin, particularly the iodide of potassium, with liquor potassa and narcotics, the iodide of mercury, and the iodide of iron. The first and second of these preparations are most appropriate when the complaint appears to depend upon organic change within the cranium or spine; the last where it is more strictly nervous, and where it is connected with uterine obstruction. In some neuralgic affections referable to the diaphragm, heart, and stomach, or passing from the one to the other, and presenting a gouty character, the iodide of potassium, with liquor potassa and opium, was extremely beneficial.

88. e. The preparations of arsenic are more strictly alteratives and antiperiods than tonics. They have been very generally prescribed for neuralgic complaints. They have been much confused in by Nesse-Hill, Bassedow, Bedingfield, Hallyday, and Rowland. They are most successful in the more functional states of the complaint, particularly when they are caused by malaria and exposure to cold. They are also serviceable in those forms of it which are intimately allied to hysteria, and are associated with congestion of the uterus or with disordered menstruation. They may be conjointed with any of the narcotics hereafter noticed (65, et sqq.).

89. d. Spirits of turpentine, as usually given for the cure of neuralgia, acts more as an alterative than as a stimulant, diuretic, and aperient, in all which ways it exerts considerable influence. Dr. Home (Clin. Experim. and Hist., p. 247) remarks, that having found, in one of Dr. Cheyne's philosophico-medical works, a receipt composed of oleum terebinthinae and honey for the cure of sciatica, he tried it and found it to succeed; and that he has used it for many years, and found it "an efficacious and valuable medicine." Dr. Darwin (Zoonomia, vol. ii., s. iii., c. 2) also had recourse to oil of turpentine, both in this form of neuralgia and in humpy. It was afterward prescribed by myself, and the results of my experience of it in neuralgia and many other diseases, published in the London Medical and Physical Journal for August, 1821. M. Martinet also about the same time recommended it for sciatica. Pirckney, Cheyne, and Home, who first employed this substance for their sciatica, usually gave it in doses of about fifteen or twenty drops in the form of liniment with honey. At first I prescribed it as follows in neuralgic affections, but I subsequently varied the dose and the modes of exhibiting it, with the circumstances of the case, seldom giving less than half a drachm for a dose.

No. 298. R Olei Terebinthinae; Tinct. Guaiaci Ammoni, &c., &c.; Meliss. Opium, &c.; Olei Calomel, &c.; Olei Luminis, &c. Ueber die is. 3. 247; Mich. Ueber die is. 3. 247. This medicine, although recommended chiefly for sciatica, is frequently of great service, if not equally beneficial, in other forms of neuralgia; for all which it may be employed in various forms, as with calcined magnesia, on the surface of milk, or of an aromatic water, &c. When the crampings, &c., after taking it are unpleasant, magnesia is often of service, and it is serviceable against sciatica, usually gave it in doses of about fifteen or twenty drops in the form of liniment with honey. At first I prescribed it as follows in neuralgic affections, but I subsequently varied the dose and the modes of exhibiting it, with the circumstances of the case, seldom giving less than half a drachm for a dose.
cases where quinine has failed. The sulphate of quinine has, on the other hand, been said to succeed when cinchona in decoction or powder has been unsuccessful. When, however, the bark has been given as just advised, or with serpentina, capsicum, canthor, or ammonium, or with chlorate of potassa, much more dependence may be placed on its efficacy. I have rarely trusted to quinine alone in this affection, but have prescribed it with the sulphate of iron, calcium, and extract of conium or henbane, after the bowels have been freely evacuated by suitable purgatives. In a most severe case of septicemia, of which a surgeon retired from service in India was the subject, this latter combination proved very quickly and permanently efficacious. Both bark and quinine are most useful in cases caused by malaria, or by wet or cold, and when the affection is intermittent is chiefly functional. They often fail when the complaint presents remissions only, when it appears to depend upon chronic inflammatory action or upon a permanent source of irritation. If employed at all in these cases, local blood-lettings and active purgatives should precede them, the latter being given from time to time during their use.

92. b. The preparations of iron have obtained great reputation for the cure of neuralgia, especially since the sesqui-oxide was recommended for it by Dr. Hutchinson, and given in large doses by Elliotson and others. The full efficacy of this substance may be obtained in doses of iron half a drachm to a drachm, three or four times a day, conjoined with an aperient, or a smart purgative being given occasionally. This and the other preparations of iron are indicated chiefly in the same circumstances of the complaint as have just been stated to require cinchona or quinine, and when there is a deficiency of blood, or at least no general plethora or inflammatory action. The sulphate of iron is not only beneficial but carbonate, and it may be prescribed with other medicines as above stated (§ 91). The hydrocyanate of iron has been used by MM. Dupuy and Jolly in the following form:

93. c. The preparations of zinc have been prescribed for neuralgia, but chiefly in combination with sulphate of the narcotics about to be noticed. The sulphate was preferred by Mugglin, and the chloruret or chloride by Hanke, who directs one grain of it to be dissolved in two drachms of chloric ether, and from five to ten drops of the solution to be given every fourth hour in sugared water. The chlorate of potash has been praised by Helmbrandt and Meier, who gave it in doses of from three to five grains every fourth or fifth hour. I have prescribed it in somewhat larger doses in the treatment of neuralgia. The following combination is not devoid of efficacy in the rheumatic and hysterical states of the disease.

94. d. Nux vomica and strychnia have lately been suggested in the treatment of neuralgia. Linnaeus gave the former in gastralgia; and I have prescribed the alcoholic extract of it in a few instances—in one or two with decided service, but in others with doubtful advantage.

1023

NEURALGIC AFFECTIONS—TREATMENT OF.

of this compound to be taken daily. He supposed that in this manner the turpentine was deprived of many of the inconveniences attending it in other forms. Turpentine has lately been much employed, particularly in septicemia, in France and Germany, where it has received the praises of Eugenstierna, Cloquet, Larroque, Dufaux, Porrey, Thousseau, Most, Ducros, and others. A strong recommendation of this medicine is to be found in its being equally appropriate to the inflammatory and non-inflammatory states of the affection; and in the fact of relapses or a return of the complaint being less frequent after the use of it than after any other remedy.

90. c. The use of cod-liver oil may be noticed at this place. It has been long recommended for rheumatism and sciatica, and more recently for the several forms of neuralgia. As usually prepared and kept, it is a nauseous medicine; and I doubt much its efficacy over the oil procured from the livers of several other kinds of fish. The latter, however, obtained from the skate is equally beneficial; and that yielded by the liver of the ling superior to both. But the oil from the liver of the torsk, or the gadus brosma, a remarkably fine fish caught only on the coasts of Shetland, Faroe, and of some parts of Norway, is esteemed much above all others by the inhabitants of these parts, and is much employed by them as a domestic medicine, the fresh liver and oil being considered an article of great delicacy when cooked in some dishes. It does not prevent, as far as possible, the separation of the oil from the liver.* The quantity of these oils which may be taken for neuralgic and rheumatic complaints is as much as the stomach will tolerate.

91. y. Stimulants, Tonics, and Antispasmodics.—There is scarcely a substance which may be ranked under this head that has not been tried against neuralgia.—a. The preparations of cinchona and the sulphate of quinine have been very generally used; the latter, however, has recently superseded the former, although not always with justice. The more energetic preparations of cinchona, conjoined with very full doses of the alkalies or alkaline carbonates, or with opium, as advised by Schenk and Kerrison, or with the sulphuric acid, as prescribed by Lassere, have succeeded in some

* Of the oil from the livers of the torsk, ling, and cod, I can speak from experience. When obtained from the fresh livers, and used before it becomes rancid, it is not palatable, and does not offend the stomach. The fishermen in the parts above mentioned usually employ it as the only sauce to the fish they catch; these fish, and particularly the torsk, will partake of it in this manner, and are esteemed above any other sauce. But the livers of these fish (that of the torsk more especially) being preserved and smoked by the skippers when prepared in the following way, are admirable articles of diet for the sufferers under consideration, as well as for rheumatics in general. The livers of the cod are smoked to the greatest advantage. When the fish is well washed, two parts filled with the fresh liver, and firmly tied at each end, so as not to allow any of the oil to escape while being boiled. When quite warm, with a large saucepan, the brown sugar, the liver and containing the greater part of its oil, this is very palatable. The fresh livers of these fish, and also of the young cool fish and haddock, are prepared in various other ways as articles of diet, or they enter into the composition of several dishes much relished in the countries I have mentioned. I may add, that they often serve me as articles of diet very many years ago, and that I now would as soon partake of them as of turtle or venison, although no lukewarm admirer of these admirable articles of diet, which, when excellent of their kind, gratify the palate, humour the stomach, and harmonize all the organic functions.
NEURALGIC AFFECTIONS—TREATMENT OF.

This preparation is in many respects preferable to strychnine, both in this and in paralytic affections; but it is not suited to the more continued and inflammatory stages of this disorder. The same remark applies to phosphorus, which has been employed by Loebenstein-Lobell, dissolved in oil, of which, however, I have found no effect.

95. c Of camphor, given in tolerably large doses, with opium or some other narcotic, or with quinine, or sulphate of iron, I entertain a favourable opinion, as well as of valerian and guaiacum, the amoniated tincture of these being the preparations I have preferred. Schenker employed the oil of valerian both internally and externally by friction. The preparations of guaiacum with colchicum, or with aconite, and the alkaline carbonates, are most useful in the rheumatic forms of neuralgia. Musk has been prescribed by Beaumes, and by J. Frank conjoined with calomel and antimony.

96. b Narcotics and Sedatives.—a. The several preparations of opium, and more recently the salts of morphine, have been prescribed in this class of affections, in various combinations, and with different effects. I have found them of service in full doses with calomel, camphor, and ipecacuanha, particularly in sciatica, after the bowels have been freely evacuated, and in toothache with camphor, creasote, and capsiicum, applied to the gums, or to a carious tooth, often affords relief. Recamier advises the following pills in neuralgia:

97. b Aconite was first prescribed in neuralgia by Murray; but it was previously used in rheumatism. More recently it has been much employed in neuralgic affections by Jahn, Teale, Hupeland, Turnbull, and others. Spie mann advises it to be given with the golden sulphur of antimony; Roderacher with the decoctions of guaiacum and sassafras; Wildberg with the succined spirit of ammonia, the galbanum plaster with opium being employed externally; and Fritze with the boric acid. I have prescribed it with the hiburate of soda. The preparations of aconite that are chiefly to be depended upon are, the alcoholic extract and the tincture, both for internal and for external use (§ 110); but they are most quickly efficacious when applied externally. Aconite has succeeded in several cases in my practice, but it failed very recently in a case of femoral neuralgia. It is, however, a very valuable remedy, particularly in the rheumatic forms of the complaint, and in neuralgic affections of the heart and diaphragm, as well as of the nerves of the trunk and extremities. It is not indicated in the inflammatory states of the disease; and it should be prescribed only in these uncomplicated depositions being resorted to. The modes of exhibiting it advised by Hupeland and Jahn deserve notice:

[Dr. Fleming, in his recent work on aconite (An Inquiry into the Physiological and Medicinal Properties of the Aconitum napellus, Lond., 1845, 8vo, p. 160), has given a table of 40 cases treated by this remedy, of which 27 were permanently cured, and 13 only temporarily relieved. In some of them the medicine was used internally, and in others externally; occasionally both. Dr. Fleming suggests, that if the neuralgia depends on inflammation either in the painful part of the nerve or farther up in its course, or in sympathetic irritation, the internal use is more likely to be beneficial; if from local functional irritation, the topical application. We should prefer to depend chiefly on its external use, as we do not regard its internal use as free from danger. Dr. F. states that he has met with several cases of neuralgia in which the individuals had, for weeks or months, been in the habit of procuring sleep, and a temporary cessation of pain, by opiate draughts, and who, on using the aconite, obtained permanent relief of the disease. Dr. F. has tried it in 40 cases of toothache, by rubbing the gums with a few drops of the tincture, or by introducing a piece of cotton, soaked with a drop or two, into the carious tooth. In 7 of these cases it failed; in 6 it succeeded only for a short time; in the rest the relief was complete.]

98. c Belladonna has been very generally prescribed in neuralgia. I have given it with camphor and sulphate of quinine, and at the same time applied it externally, as about to be noticed (§ 111). In some instances I have found it occasion stupor and malaise, without materially relieving the pain. M. Trouseau has advised the extract of it, in doses of a quarter of a grain, to be given every hour until it causes vertigo, and then it is to be taken at longer intervals. He also has given with sulphate of quinine, or with preparations of iron; or he has exhibited these after the narcotic effects of the belladonna had become manifest. Sterbon, Thomp son, and De lau have recommended it to be employed both internally and externally. Per kira considers it inferior to aconite in this disorder.

[We regard belladonna as one of the most successful remedies for the relief and cure of this obstinate class of diseases. In a very aggravated case of neuralgia at Geneva, New York, which had resisted a great variety of treatment for twelve months, during which the patient suffered the most excruciating agony, a perfect cure was accomplished by the use of a pill composed of three grains of pil. hydrag., and one grain of extract of stramonium. One of these was ordered to be taken every night at bedtime, until the gums were a little affected; then to leave off for a few days, and resume. In two weeks a cure was effected. Whenever threatened with a return of the complaint, the same remedy always prevented it (Boyd, Med., and Surg. Journ., vol. xviii., p. 178). In the same journal, vol. xix., p. 77, is contained an account of a very severe case of neuralgia cured by the repeated use of emetics.

The following formula will prove exceedingly efficacious in many cases of obstinate neuralgia: R. Extr. Belladonnae, 3ss.; Opii Pulv., 5ij.; Adip ox. Sativ, 5ss.; Olei Thymi, 8v. M. A portion of this ointment as large as a hazelnut is to be well rubbed upon the affected part two
or three times a day, or whenever the paroxysms of pain are severe. The rubbing can be continued for eight or ten minutes at a time, until the ointment is quite absorbed by the skin; a little saliva may be added now and then, to promote the absorption. If the sight becomes affected, or any unpleasant symptoms supervene, it should be suspended for a while. This application is peculiarly well adapted to cases of facial neuralgia.

the tincture of capsicum, after the bowels had been completely evacuated by means of chologogue purgatives. The removal of the attack was rapid, and the patient did not experience a return of it for some years. Some years afterward I had recourse to the same combination for neuralgia of the muscles of the arm, in a young gentleman who had experienced a very severe epileptic seizure, for which he had been largely bled and much reduced. It was continued during a few days, and was aided by active purgatives. The neuralgic affection ceased; but some months afterward he was again seized with epilepsy; a physician saw him in my absence, and directed blood-letting, which was followed immediately afterward by another attack of epilepsy and paralysis of the arm, formerly the seat of neuralgia.

Neuralgic and, 8th. 3d. and those 5th. 3d. and those.

[Image 0x0 to 384x633]

106. 7. Externai modes of medication havete been resorted to in neuralgic affections, in nearly endless variety.—A. Of local blood-litting notice has already been taken, and the propriety of it vindicated in many instances, and wherever its application may be inadmissible, and beneficial if it be not prescribed with discrimination, and if they be not immediately followed by frictions and other means to secure reaction.

107. 2. The strictly local applications to neuralgic parts are numerous. They may be arranged into, 1st. Those which are intended to alter the sensibility of the affected nerve, without causing vesication or suppuration; 2d. Those which, by causing vesication or suppuration, in addition to the local excitement, may thereby more permanently impress and change the morbid affection; 3d. Those which may still more powerfully affect the seat of disorder, by being applied more immediately to the nerves and capillaries in the vicinity, and after the cuticle has been removed; or those which admit of being endermically prescribed; and, 4th. Those which interrupt the communication between the seat of the affection and the sensorium, and which may remove the cause of irritation in the part affected.

108. a. Those applications which are intended to alter the sensibility of the affected nerve without causing vesication or suppuration consist chiefly of compresses, epimetheus, cataplasms, pomades, and ointments, frictions with ointments, or liniments, embrocations, and plasters.—(a) Compresses and ointments of various kinds have been prescribed by Ricotti, Morel, and others; and the chief of these are compresses moistened with cold water, or with a solution of prussic acid, or of red lead with water, or a solution of corrosive sublimate (4 grs. to 5½ of distilled water) have been even resorted to by Wecking and Fleischmann. Hufeland advises compresses moistened with equal parts of laurel water, Goulard's lotion, and rose water, or with this last somewhat in excess. Trouseau recommends an ointment of a decoction of stramonium (3 vol. to 10 vol. of water).

The hydrocyanate of potash is one of our most efficient local remedies in this disease. We have known numerous cases of tic douloureux relieved by it. It should be dissolved in distilled water, in the proportion of from 10 to 30 grains to 5½, or, in bad cases, even stronger, and applied by friction over the affected part. (See H. M. and Surg. Journ., vol. v.)

109. (b) Cataplasms, or poultices, containing various active substances have sometimes proved beneficial. The powdered leaves of hyo-cyanum, of conium, of tobacco, and of the solanum nigra, have been made into poultices with linseed meal and decoction of poppies, and applied to the affected part. Poultices containing one or more of these, and some stimulating or irritating substance, as capsicum, mustard, &c., so as to conjure a narcotic with an irritant or rubefacient effect, have likewise been advantageously applied.

110. (c) Various pomades and ointments, with or without friction, have been recommended: those containing the extract of belladonna, or the acetate of morphia, by Lamberts, Bartels, Lesieur, &c.; those containing the jodides of mercury, by Thompson and Scott, or the iodide of potassium; those containing the sub-carbonate of lead, by Ouvrard; and those with veratrum, aconite, &c., by Ternbull, Rowland, and others. Several of these are more serviceable when applied by friction, so as to occasion the employment of this therapeutic agent; they have never, in any case, been aggravated by its use. 3. The paralysis which supervenes in the progress of aplaith (essentially) neuralgias yields to the same treatment. (Valjeau.)
considerable rubefacient effect, as those with the iodides of mercury or of potassium, or with veratrina or aconite.

[Veratrina and aconitine are two of our most important topical remedies in the treatment of neuralgia. An ointment composed of twenty grains of veratrina to one ounce of lard may be rubbed over the part affected, from time to time, with the best effects. The usual strength in which we have employed it is from ten to twenty grains to the ounce of lard, or simple cerate; or the alcoholic tincture, which is a neater preparation, may be used. When used internally, which we do not recommend, the veratrina may be given in doses of one sixth of a grain, with half a grain of extract of hyoscyamus, three times a day, obviating costiveness by the use of rhubarb and blue mass. (See Dr. Turnbull's Essay on the Medical Properties of the Natural Order Ranunculaceae.) We prefer the internal use of extract of belladonna to that of veratrina, delphinia, or aconitine, which are too powerful to be employed without caution.

Veratrina may be applied very successfully in these cases by dipping the point of a lancet in a saturated solution of the alkaloid, and making a number of punctures over the part affected. Each puncture will become at once the seat of a sharp pain, similar to that caused by the prick of a fine needle. This lasts but for a few minutes; ten or twelve punctures should be made night and morning, and continued till the discharge yields.]

111. (d) Frictions with stimulating liniments or with strong solutions of narcotic substances, or with both conjoined, have been employed. Colville found frictions with tar of service; and Tomé derived advantage from friction with a strong solution of extract of belladonna (3ij. of extr. in 3j. of water). I have had recourse to friction of the affected parts with narcotic and rubefacient substances conjointed, and frequently prescribed the following with marked benefit: No. 204. R Liniment Camphor Co.; Linum. Terebor thromos, &c. 3ij.; Olei Olives, 3j.; Olei Camphor, 3j.; Extract Belladonna (vel Tinct. Alcohol. Aconiti), 3ij. Mix 2 j, at flat Linimentum.

112. (e) Embrocations with various substances have been equally serviceable with any of the foregoing applications. Warm flannels, or several folds of cotton made warm, and thoroughly imbued with any of the liniments referred to in the Appendix (F. 295-314), or with the liniment just prescribed, and then closely applied to the affected part, and covered by a warm napkin, or by oiled silk to prevent evaporation, are often of essential service in most of the varieties of neuralgia, particularly when renewed from time to time, or according to the effect produced.

113. (f) Plasters of various kinds have likewise been placed on the part, and some of them have been intended to produce a rubefacient, in addition to their other effects. Those plasters which contain belladonna, or both this narcotic and camphor, have usually been preferred. M. Trouseau has employed the extract of stramonium in this manner. The following plaster has been frequently applied in sciatica:

114. b. Various mean of producing vesication, postulation, or suppuration have been resorted to for this complaint.—(a) Blisters applied, and even repeated, in the course of the nerve, have been praised by Cotugno, Magnen, and others. Moxas have likewise been recommended by Bontius, Cotugno, Larken, Barres, and Walther. Compresses moistened with a strong solution of tartarized ointment, and applied until redness or postulation is produced, has been prescribed by Maeter, but an ointment containing the tartar-emetic, or mere阜ial ointment with it (3j. of ant. tart., and 3j. of the oint) as used by Scott, is more immediate and certain in its effects than the solution. Issues and setons have been employed in the more obstinate or chronic cases. For sciatica they may be placed near the trochanter major, and, in cases of facial or occipital neuralgia, particularly when there is reason to dread organic lesion near the base of the cerebrum or cranium, they may be inserted in the shape of a noose, or somewhat higher, or even in the occipital scalp.

115. e. Applications to the affected part after the cuticle has been removed from the surface—or endermic medication, as it has been termed—have been frequently tried in neuralgia, and recommended by Trouseau, Ricotti, Bonnet, Anisaux, Ralics, and others. Various narcotic substances have been thus employed; but the acetate of morphia, sprinkled over the surface thus denuded of its cuticle, or ten grains of the acetate intimately mixed in from one to two drachms of an ointment, a portion of this being applied to it, and an ointment with a small portion of the extract of belladonna, are the means most frequently selected, although various other substances may be similarly applied.

116. d. The affected nerve in some instances has been divided above the seat of pain, in order to interrupt the communication between the seat and the sursuman; but this is rare. A measure which has succeeded beyond a short period, or given permanent relief. When there is reason to infer the existence of any irritating substance in the nerve or part affected, the removal of it, if this be at all possible, should be attempted; and, when the affection seems to proceed from the exposure of a fibril of nerve in a cicatrix, or from the irritation of an erosion, the application of a caustic to the former, suppuration being afterward promoted, and of appropriate means to the latter, according to its nature, is chiefly indicated.

(M. BERARD has seen (Malgarde's Manuel de Med. Operat., 4th edit., Paris, 1843, p. 130) an infra orbital neuralgia return after having excised three inches (nine millimetres) of the nerve; and SWAN has seen the two ends of a nerve in a horse reunite (ib.) after having excised a segment near nine inches long! M. Malgarde suggests (ib) whether it might not be advisable, after dividing the nerve, to again touch both ends by dissection, and fold them back on the trunk so as to form a noose, or to interpose between the ends a small fleshly flap from the immediate neighbourhood, the better to intercept, when the cicatrization is completed over this, the continuity of nervous influence. M. Bonnet, of Lyons, proposes in the frontal nerve to divide it freely down to the
bone by a sub-cutaneous incision. (ib. 151, 152.) M. MALGAGNE, for the infra-orbital nerve, prefers also the sub-cutaneous section on the groove of the nerve in the floor of the orbit; after which he tears out the divided fragments from its groove by means of a forceps applied to the portion of the nerve laid bare, and divided a little below the orbit (ib., p. 155). M. Boivier makes only a sub-cutaneous division of the nerve. (ib.—TOWNSEND's Vulpian, vol. ii., p. 435.)

Dr. Morr was one of the first surgeons in this country who treated neuralgia by excision of a portion of the nerve; but after extensive trials he laid the operation aside, as he found the disease very certain to return as severe as ever. In that form of neuralgia which results from an injury or wound of the nerve, Dr. Morr has in several instances effected a cure by excising the ecinitiax, in which will generally be found a nervous fibrilla. (See Lecture on Neuralgia, in the N. Y. Lancet, Feb. 13, 1842, No. 7, vol. i.)

Dr. J. C. Warren, of Boston, has reported several cases of tic douloureux cured by the division and removal of a portion of some of the facial nerves. (Boston Med. and Surg. Journ., vol i. p. 1.) In one very aggravated case of a man aged 70, who had been affected for 14 years with severe pain in the side of the face, beginning near the ear, and hence down into the lower and upper jaw, lips, eye, forehead, and scalp, and who had previously undergone three operations, with only temporary relief, viz., two on the sub-orbital nerve and its branches, and a third on the nerve of the lower jaw, where it comes out on the chin, Dr. Warren proceeded to divide the facial nerve, between the parotid gland and the mastoid process, with the effect of removing the pain in the upper part of the face, while that in the lower was as acute as ever. A portion of the submaxillary nerve was then excised by trephining the lower jaw beneath the masseter muscle, and near its angle, when the pain entirely ceased, and the disease did not return. (Loc. cit.)

In another case, neuralgia of a branch of the plantar nerve, which caused convulsions in a female, and which was occasioned by including a nerve in the ligation of a small vessel, was perfectly cured by making an incision in the sole of the foot, behind the interstices of the fourth and fifth toe, and dividing the internal plantar nerve going to the fourth and fifth toe, of which a portion, one inch in length, was removed. But one spasmodic attack occurred after the operation, and the patient speedily recovered her usual health.

The observations of Dr. Warren on the various forms of neuralgia, with numerous illustrative cases, as contained in several numbers of the Boston Med. and Surg. Journal, are highly interesting and worth the attention of the practitioner. Amputation has been had recourse to, but without any benefit, however, in cases, for example, where the hirte finger, from a mere blow, has, without any external lesion, been followed by severe neuralgic pain, and finally wasted away. Dr. Wigan, in a case of this kind in a lady who struck her little finger against a garden roller, amputated it; but holding the distress continue in two others, amputated them also, with a like unsuccessful result. Neuralgic pain in every part of the body came on, and the patient died a martyr. (Proceedings of the Med. Society of London, March, 1845; London Lancet, May 3, 1845, p. 505.) Mr. Cuspi proposes, in such cases (ib., loc. cit.), the possible advantage of removing a portion of the nerve, from the remarkable effect known from this kind of operation on the same for horses. According to Mr. Pilcher (ib., loc. cit.), the nerves of the organ of sense, as of the eye, may become paralytic by pure concussion, i.e., by a blow, without any ecchymosis or change of structure. M. Dendy, however (ib., loc. cit.), has known a family, the members of which were so delicate that slight pressure on the surface produced a kind of thrombus. It is difficult, however, to determine how far neuralgic and paralytic diseases of the nerves are dependent on the influence of the nervous centres, or on local causes. Surgery, in most such cases, seems to have less resources than internal constitutional treatment and external applications. (Dr. Townsend's Vulpian, vol. ii., p. 435.)

The cold dash is a powerful remedy in many cases of neuralgia. We lately succeeded in curing two severe cases of sciatice, which had resisted blue pill, belladonna, and the whole routine of ordinary treatment, by turning cold water upon the hip and leg from a pitcher elevated some feet above the patient. The greater the shock the more advantageous did the remedy prove, and the speedier relief it did bring. Dr. La Roche, of Philadelphia, has also succeeded in allaying and completely removing the pain of acute and protracted sciatice, which had resisted various remedies, by the application of ice over the affected part. Dr. Bell also speaks favourably of the same application. Numerous cases of neuralgia of the face have been cured by extracting decayed or wisdom teeth, a remarkable instance of which is recorded by Dr. Post, of New-York, in the 6th vol. of the New-York Journal of Med. and Coll. Sciences.

117. C. The diet and regimen for neuralgic patients must necessarily depend upon the peculiarities, causes, and complications of individual cases. In most instances, however, regular and abstemious living; due exercise in the open air; the avoidance of all depressing physical and mental causes; and a pure, dry, and moderately warm air, avoiding all injurious exposures, night air, dews, and crowded assemblies, are most conducive to recovery, and to the prevention of those recurrences of the complaint to which all are subject who have once been tormented by it. Above all, the predisposing and exciting causes (§52, et seq.) should be guarded against; the stomach preserved in good humour; and all the secretions and excretions healthily promoted, without being inordinate or excessive, or injurious to the new occasion debility. In some instances, a course of chalybeate or alkaline mineral waters proves of service, after appropriate medical treatment has ceased; and when the complaint has been caused by malaria, cold, and other physical influences, these are often extremely beneficial when the state of the digestive organs receives due attention.

NIGHT-BLINDNESS and DAY-BLINDNESS—PHENOMENA—CAUSES.

CLASS.—I. Class (Cullen). IV. Class, II. Order (Good).—I. Class, III. Order (Author).

1. Defin.—Observation or loss of vision by night only (Nyctalopia); or by day only (Hemeralopia).

2. It has been justly remarked by Dr. Forbes, that the two terms, nyctalopia and hemeralopia, have been inextricably confused, by being taken respectively by different authors to mean the same thing; one terming night blindness nyctalopia and another hemeralopia, while day-blindness has been equally designated by both terms. He has, therefore, assigned the meaning which he would attach to each of them, and conformably with what appears to him, and not unreasonably, as their derivation, he defines nyctalopia to be vision obscured by day but good at night, and hemeralopia to be vision obscured by night and distinct by day. These meanings are opposed to those which I have assigned to the terms in question, and which are those most generally received; the "a" in the middle of each of the words being manifestly viewed as privative.

3. Of the two disorders of vision about to be noticed, night-blindness is the most frequently observed, and the most generally functional. Day-blindness, when at all marked, is symptomatic of vascular irritation, or inflammatory action in the more interior or posterior textures of the eye. Still, in its milder states, it may depend upon similar pathological causes to those which occasion night-blindness, but cases of this kind are extremely rare.

4. i. Phenomena.—In persons suffering under this complaint, vision becomes gradually indistinct as the light of day disappears, until it is entirely suspended. The blindness continues during the night, and ceases with the return of daylight; but its degree varies in different cases, and in the same case with the duration of the disorder. At first, or in slight cases, the blindness is partial, and objects may be seen with a strong artificial light; but, as the complaint advances, vision becomes so impaired that the moon or stars cannot be discerned, nor even the light of a candle placed at a short distance: more frequently, however, an artificial light may be discerned, but not the bodies in its vicinity. In the more prolonged cases, blindness is sometimes so complete, that an object cannot be seen after sunset in the brightest artificial light. Generally the sight is restored as daylight returns, and it again becomes perfect when the sun has risen above the horizon: blindness and vision continue in this to correspond with the setting and rising of the sun. The approach and remission of the paroxysms at sunset and sunrise are generally gradual, but, in some cases, more or less sudden. If the disease be allowed to continue, the eyes may ultimately become so weak during daylight, that the direct or reflected rays of the sun cannot be endur'd without much uneasiness and indistinctness of vision; a certain degree of hemeralopia thus following obstinate or prolonged nyctalopia. In some, also, of these severe cases, and even when this irritable state of the eye has not been induced, the patient is incapable, when placed in an obscure situation, of distinguishing objects by day as by night.

5. Usually no uneasy sensations or visible alteration of the eye is present. The state of the pupil is variously described by authors. Some say that it is innamobile and contracted, others that it is dilated. This discordance probably arises from the pupil having been observed at different stages of the complaint or at different periods, at night or during day only. Mr. Bampfield is not always consistent with himself, when noticing this symptom. He states that, after the disorder is far advanced, the pupil is often contracted, and the patient evinces a painful irritation of the eyes when exposed to a vivid light or when looking upward; and that it is considerably dilated both by day and night, in the proportion of about one case in twelve; and at night it is often dilated, and neither contracts nor dilates when exposed to the moon or to artificial light. My own recollections of the few cases which I had an opportunity of seeing many years ago admit not of my offering any remark on this point; but they are sufficient to confirm my belief that, although the complaint is in some respects local—is dependent upon the state of the nerval apparatus of the eye in part—yet this local disorder itself depends upon more general or constitutional derangement; and this must especially be the case when the nervous systems and digestive organs are particularly affected, as observed in many cases of this affection. Indeed, very few cases will be found, in which the functions of these systems and organs are not more or less impaired. That the brain is somewhat affected in some instances, is evinced by the headache, or vertigo, which may, however, equally with the nyctalopia, be symptomatic of impaired organic nervous energy and disorder of the digestive organs. The complaint continues for a very various period. It sometimes disappears without the aid of medicine. In temperate climates, it generally assumes a milder form than in hot countries. In the former it usually continues from one month to six or seven weeks. In the latter it is often prolonged to four, six, or nine months, and even much above that period in some instances.

6. ii. Causes.—Nyctalopia is very rarely seen in this country; but in the most southern parts of Europe, and in countries within the tropics, it is not infrequently met with. It is said to be endemic in some places within the tropics; and even in some parts of the south of Europe, and of China: it has occasionally, also, assumed an epidemic form even in temperate climates, and in northern countries, where the horizon in summer is long above the horizon. Thus, Dr.

1030
Guthrie observed it very prevalent in the Russian troops in Finland, during the spring, owing to the short absence of the sun, and the strong reflection from the snow. M. Riches and states that nyctalopia is both endemic and epidemic in northern regions from the same causes, and that artisans who exert their sight in an intense artificial light are occasionally affected with it. Within the tropics, the influence of season in producing this complaint is not so evident as in very cold climates. Dr. J. Grant remarks that nyctalopia in the tropic regions is more prevalent in soldiers and sailors than in the East and West Indies; and that on the eastern shores of the Mediterranean, and in the islands of the Adriatic, it is at times very prevalent. It has also sometimes become epidemic in parts of France, Germany, Poland, and Europe. Wherever it occurs, it preserves the same characters, varying only in the severity of its attack and length of its duration, in individual cases, according to the constitution of the patient and the intensity and combination of the causes. Nyctalopia seems to have been congenital in rare instances, according to Haller and others, or at least to have appeared at a very early age, and to have continued subsequently. It has occurred in three persons in one family; and it has been said to be hereditary in some cases. Europeans residing within the tropics are more liable to it than the native inhabitants; and those who have been attacked are prone to a return of it, if they remain in the same climate. It is very rarely observed in children; and it is more frequent in males than in females. The colour or appearance of the eyes has no influence in favouring its occurrence. It rarely affects the upper classes, but is most frequent in those exposed to fatigue, watching, and debilitating influences, and whose diet is poor or unwholesome. Venereal excesses and manustipratio are also influential causes of it. Nyctalopia has been ascribed also to sleeping in the sun, to poisonous vegetables, and to the use of bread in which darning is present. The ancients believed it to be a forceful to the sight; and the observations and experiments of modern physicians have proved this opinion to be correct. It is not improbable that the Cannabis Indica, or Indian hemp, which is so much used in the East for the purposes of excitement and intoxication, has also considerable influence in producing this disease. Its probable dependence in some degree upon exhaustion of nervous power and weakness of the digestive functions, has already been noticed (9, 5).

8. VIII. PATHOLOGICAL STATES.—In most instances, this affection depends upon the over-excitement, and consequent exhaustion, of the nerves of the eye by the brilliant sunshine and light, in warm and arid countries, and in snowy regions, when the light of day is of long continuance, the retina and nerves being thereby reduced to a state incapable of being excited by the feeble light remaining after sunset, and of perceiving objects in that light. In the more extreme cases, the tector of the retina, and nerves seems to be so great as not to be overcome by even a bright artificial light. It is possible, also, that the rays of the sun combine with them so much of electro-motive agency as to favour distinct vision, and an artificial light, not possessing this property, is accordingly less influential than they in exciting vision. The same causes which exhaust the sensibility of the nervous apparatus of the eye, at the same time tend, particularly when energetic and prolonged, to occasion a congested, or a sub-inflammatory state of the retina and posterior parts of the organ, and the attendant contraction of the pupil. It is manifest, also, that all the circumstances which produce exhaustion of nervous energy, particularly many of the results above enumerated, or congestion of the venous circulation, or both nervous exhaustion and vascular congestion, will also favour the development of nyctalopia when its more efficient exciting causes are in operation. The connexion between impairment of the digestive functions and this affection, so very generally observed, is a necessary result of exhaustion of nervous power; for, when the organic nervous energy is much reduced, the functions of sense are readily exhausted, and are soon proportionately weakened.

9. iv. THE PROGNOSIS OF NYCTALOPA IS GENERALLY FAVOURABLE. As it occurs in temperate or northern climates, it very frequently undergoes a spontaneous cure with change of the season and circumstances in which it originated. Dr. 1. Grant states that it has occasionally been removed by the occurrence of diarrhoea, of haemorrhage from the nose, and of abscesses and eruptions about the head and face. I met with a case many years ago which was removed almost immediately by copious discharges of morbid bile consequent upon the exhibition of stomachic purgatives, the inordinate accumulation of bile in the gall-bladder and biliary ducts having been intimately connected with the development of this affection. Bontius, Senner- tus, Etmüller, Borhale, and some others, however, have formed a much more unfavourable opinion of the complaint than that just now expressed; and as it appears in warm climates, particularly when affecting persons addicted to intoxicating liquors, to the use of opium, or of the cannabin; nyctalopia is much more difficult to remove than in other circumstances, and sometimes long resists treatment. Much, however, depends upon the existing states of the nervous system generally, and of the digestive organs, upon the habits of the patient, and upon the continuance or interruption of the exciting causes. In these more unfavourable circumstances, total loss of sight may ensue, as remarked by Dampfield and others; but this result rarely occurs unless some internal inspissation of the eye supervenes, or is neglected.

10. v. TREATMENT.—The humoral pathologists, believing that nyctalopia depended upon inspissation and congestion of the humourous, had recourse to bleeding, attention, and deobstruents, with purgatives, stimulatives, and dialogues, and as these often removed facial accumulations and morbid secretions from the prima via and collatituous viscera, advantage frequently resulted from this treatment. In some instances an emetic was premised with benefit. The exciting substances, by which the senses of smell and taste were thus roused, sometimes tended, by nervous connexions, to remove the torpor of the nerves of the eye. Both the ancients and the moderns, in places the most remote from each other, have had recourse to
the livers of various animals, of bullocks, 

but the second demands most careful observa-

nights of various animals, of bullocks, he-

of night-blindness; these being eaten as an article of diet, or the vapour from them being used as a fumigation for the eyes.

in the case, are requisite. If, 

on the other hand, the vascular system indicate insufficiency of blood, and the state of the head a diminished flow of blood to the brain, a no-

It was then the time of the Greek fast, when the inhabitants use no animal food, but live chiefly on bread and grits prepared with oil. He was assured that, at the same period every year, a great many people are seized with nyctalopia; but that when Easter came they ate the liver of a black cock, or black swine, and were cured in a few days. He examined, by day and by night, several of those affected by the disorder, but could perceive nothing particular in their eyes, except great immobility of the pupils. In other respects, they were in perfect health, and would submit to no other treatment, assuring him that they should be free from their malady within fourteen days without any medicines. On Easter day they began to eat liver and animal food, and two of those he had examined saw as well as ever on the third day, and on the following Sunday all with extreme clarity. 

application of heated vapour; the aroma and vapour from various stimulating substances added to the liver; the use of a much more exciting diet, after a protracted fast, which had been more or less influential in producing the affection; the influence of the imagination, and still more probably, the fact of the chief causes of the complaint having ceased to be in operation, serve to explain the effect, without impugning any peculiar virtue to the particular viscous in question.

It is very obvious that this complaint should be treated upon rational principles, and if the application of these to each case fail in any one, these empirical means may be resorted to, according to the weight of evidence which may exist in its favour. The first intention of the physician should be to ascertain the predisposing and exciting causes, and to remove them; the second, to observe the exact state of the eye, and of the head, particularly with reference to the presence of congestion, or of an increased or diminished determination of blood to the brain, eyes, &c., and to prescribe means appropriate to whichever of these states may be present; and the third should be to determine the modes in which the several digestive, assimilating, and excreting functions are being performed.

12. The first of these requires no remark;
NOSTALGIA.—Etiology.

1033

flammatory states of the brain, or of its membranes, or to the more temporary excitement consequent upon an excessive use of spirituous or other intoxicating liquors, then more or less of hemeralopia is often complained of, especially in the light of the sun, or in any other strong light. Hemeralopia, like nyctalopia, may be symtomatic also of intestinal worms, and even of hysteria. In these circumstances, it may be viewed as a consequence chiefly of a morbid sensibility of the retina and nerves of the eye, and generally independent of inflammatory action.

15. The treatment of day-blindness must necessarily depend upon the state of disease of which it is symptomatic. If it proceed from inflammatory action, vascular depletions, and the antiphlogistic treatment, cold shower baths, purgatives, diaphoretics, and sedatives, are generally required, aided by cooling and anodyne coarylia. If it proceed from morbidly increased sensibility unconnected with inflammatory irritation, the treatment is more indirectly to sti-

ate, and restoratives, with anti-spasmodics, anodynes, and anheurials, is required, with change of air and attention to diet and regimen.

NOLI ME TANGERE. See Lupus.

Classification.—General Pathology; Etymology; Special Pathology.

1. Nostalgia is rather a cause of disease than a disease in itself. It has, however, been described by several writers as a form of melancholia, from which, however, it is quite distinct. I shall briefly consider it first, as a cause of disease; and, secondly, as a disease supervenu-

ing still more serious disease.

2. I. Etymology.—If we associate the suggestions or memory of our native home or place with those of many of the attendant occurrences, and the moral emotions and affections of which home has been the scene, what numerous sources of misery or happiness are often thereby called into existence, more especially if they be made subjects of contemplation or of mental rumination in different, opposite, or less happy circumstances than when they made their first impression on the mind. How frequently is the early happiness of life made the means of heightening present wretchedness, especially by the uncelebrated and ill-regulated mind, or by the mind that is unable to repose upon other and more fortifying resources. And the suggestions of memory, in continually haunting the mind of him who has removed, for the first time, from the scenes of varied enjoyments and strong excitements, to places remote, not only from these, but from all other attachments, particularly if he be doomed to different avocations from those to which he had become accustomed, are among the most distressing of the nu-

merous ills that imitate the destiny of man. They are less, or perhaps but little, felt by him who has engaged in a voluntary exile in pursuit of gain; but even he has his melancholy reminis-

ences, "when he would not, if he could, be gay!" especially after the exciting delusions of hope have lost a portion of their witching influ-

ence; and he, at times, with the compelled exi-

dile, experiences those emotions which the scenes of early life and of early attachments suggest. The person who leaves his native abode, particularly if it be endeared to him by simple joys and warm affections—if it posses sceney of wild sublimity, or seas of stormy grandeur; if he has been accustomed to gaze upon the one, while borne furiously along upon the other; if he have repeatedly escaped from the imminent dangers of either, in order again to experience the exciting pleasures they afford; however far, or in whatever manner removed from such scenes and such enjoyments, he constantly reverts to them, not only in his waking, but also in his sleeping hours. Vision of former bliss or of former dangers haunt him by night and by day. His sleep is broken; his appetite fails him; his healthy looks vanish; and a gradual bight overtakes him.

In this manner persons have been known to wither gradually, sometimes without any or-

gan evincing a disease of a prominent kind; while more frequently some particular part, owing to various concurring causes, experiences dangerous disease, to which this maladie du pays has predisposed, and rendered almost or altogether irremediable. Numerous examples of the effects of continuing to engage in pursuits of the kind occur to the medical practitioner; but they are most common among the natives of the highlands, as those of Switzerland and of Scotland, when they migrate to the low countries, where this feeling is heightened by the influence of a more depressing air upon constitutions formed in the pure and cold atmosphere of more elevated regions. Nor are the natives of richer and more fertile countries, and those abounding in peaceful occupations, without an inward pining after the scenes of early enjoyments and ten-

der associations when removed at a distance from them. Indeed, suggestions of these haunt the minds of the expatriated, whether the will-

ing or the compelled, and, with an attraction of indescribable sweetness, will not allow us to forget our native soil.

II. 130
3. Nostalgia is most frequent among those who have removed at an early age from the endearments of near and affectionate relatives, and from the simple pleasures of a country life, more especially when disappointment, fatigue, privations, and sickness overtake them soon after their removal. It is common among young soldiers and sailors who are subjected to privations and fatigue in foreign climates, particularly if these climates be unwholesome. The endemic influence of these climates, by depressing the vital energies, both favours and increases this desire of return to the place of native. Campbell has beautifully illustrated this feeling in the "Soldier's Dream," while sleeping on the field of battle, in which the joys and endearments of home appear to him, and sorrow returns to him with waking consciousness. Home-sickness is also frequent among young persons of both sexes, who have been unaccustomed to painful impressions, when they remove to large cities, and are subjected to the confinement or rigorous duties of servitude. It is rare among persons advanced in years, and particularly among those who have experienced the frowns or vicissitudes of fortune. Nostalgia, although more correctly a cause of disease than a disorder of itself, still may be viewed in the latter sense; as a disorder consisting at first of a morbid exaltation of these instinctive and moral feelings, in which recollections of home and of tender attachments are associated with sentiments of regret at the loss of the endearments which those attachments afforded. These feelings, when inordinately exerted or long indulged, depress, or even further disorder the digestive, assimilating, and circulating functions, through the medium of the organic nervous system, until ultimately disease of the organs performing these functions, or of the brain itself, according to their individual predisposition, is produced.

II. NOSTALGIA.—Nostomania; Nostrassia; Home-sickness.

Class. I. Class, IV. Order (Author).

4. Defin.—The desire of returning to one's native country immediocrately or morbidly indulged, or recollections of home and its endearments made the subject of unceasing regret, to the neglect of other considerations and objects, and to the injury of health.

5. A. Symptoms.—The earliest signs of nostalgia are unusual reserve, sadness, distaste of amusement and of occupation, a continual recurrence to the various circumstances connected with home, and expression of regret at removal, with a desire of returning, and of enjoying those pleasures which the imagination is constantly presenting in more glowing colours than are real. After some time the complexion becomes pale and anxious, the appetite is impaired; the strength sinks, and the body emaciates. The usual enjoyments of life and the society of friends or acquaintances afford no distraction from the constant and painful remembrance in which the patient is engaged. As the bodily functions become impaired by the continual indulgence of regret, and of the depressing feelings associated with it, the mind is more and more unable to resist a recurrence to the subject of distress, or to break off the train of painful ideas. The patient nurses his misery, augments it until it destroys his nightly repose and his daily peace, and ultimately devours, with more or less rapidity, his vital organs.

6. In some cases, nostalgia assumes a more acute form and rapid progress—nostomania—with cerebral irritation or excitement, presenting inflammatory characters. The ideas connected with home present an unwholesome state of exaltation amounting almost to delusion. The head becomes hot; sleep entirely departs; the pulse is accelerated; and headache is complained of; and ultimately somnambulism, or more complete mental derangement, may supervene. After this state has continued for some time, or in various grades of excitement or modification of phenomena, more or less complete collapse of the functions of the brain and of the powers of life may take place, and the patient die in the course of a few weeks, as in cases described by M. Larrey. In some instances the patient sinks into a state of marasmus, with symptoms of low nervous or of hectic fever; and in others the complaint passes into phthisis, disease of the lungs being developed during the continuance of the nostalgia.

7. When nostalgia occurs during the progress of other diseases, the complication renders the state of the patient often very critical, heightening the severity of the primary complaint, and either opposing or entirely preventing convalescence. In these circumstances, indulgence of the hopes of return to the scenes of early happiness becomes necessary to the prevention of fatal results.

8. B. The diagnosis of real from feigned nostalgia is sometimes required. The former is attended not only by sadness, moroseness, vacuity, or absence of mind and love of solitude, but also by remarkable pallor; by a rapidly progressive can of melancholy and depression; and increased heat of the forehead. If accidental mention is made of the place or persons of the patient's attachment, his countenance becomes suddenly animated; his cheeks assume a temporary flush, and his eyes are brilliant.

9. C. The appearances after death from nostalgia are stated by M. Brunn to consist of signs of vascular irritation in the superior and anterior parts of the brain, and more particularly in the pia mater and arachnoid covering them. These signs generally consist of injection of the capillaries of these parts; the effusion of an opaline serum in the meshes of the membranes; slight induration or softening of the cerebral substance, and effusion of serum in the ventricles. These changes are constant; but other viscera also often betray disease, especially the lungs, the digestive canal, and the heart; and, in some cases, one or other of these organs present the elicit alterations.

10. D. Treatment.—Nostalgia requires more of moral than of medicinal treatment. Kindness, encouragement, and exciting hopes of soon revisiting the scenes for which the patient longs, are generally of the greatest service. Varied amusement, pleasant occupations, and every means which may distract the mind from the indulgence of feelings of regret, should be resorted to. Music, dancing, gymnastic exercises, theatrical amusement, exercise in the
open air, hunting, coursing, &c., may be employed according to circumstances. All allurements which may suggest the subject of the patient's misery should be avoided, but the society of persons from the same place may be encouraged, as the griefs of the patient may be allayed by the encouragements and the happiness of his associates.

11. If indications of cerebral excitement appear, the tepid douche, and subsequently the cold affusion on the head, or the shower bath, and the promotion of the several secretions and excretions, should be recommended. If the above means fail, and when a return to home care is considered, and this most certain of all remedies should not be neglected. It will succeed even when death is apparently approaching, provided that the lungs have not undergone structural change. In the cases of young soldiers, even a temporary return to their homes, or leave of absence from their corps, has been productive of a salutary influence.

Classif.—III. Class, II. Order (Cullen). VI. Class, I. Order (Good). I. Class, IV. Order (Author).

1. Definition.—An accumulation of fat under the integuments, or in the abdomen, or in both situations, to such an extent as to embarrass the several voluntary functions.

2. Characters.—A certain degree of fatness is quite compatible with health, especially in some persons of the sanguine temperament. Other persons, also, as well as these, may be lean or fat, at different epochs of life, without any marked difference in their states of health. As long, however, as their general health is not impaired, and the fatness does not amount to a morbid pitch—to absolute obesity—nor impedes the functions of life and volition, it cannot be viewed as a morbid condition. Obesity may occur at any period of life; it may even, in a slight degree, be congenital. Infants often are remarkably fat while they are at the breast, the fat being deposited chiefly under the integuments; but after two or three years of age they become gradually thinner, owing to the exercise they are then enabled to take. Obesity in childhood is often the result of overfeeding and of hereditary predisposition; and in rare instances it continues to increase from infancy through the several periods of childhood. It is unnecessary to adduce remarkable instances of obesity in childhood and early life. Several such cases are noticed by Mr. Wadd, M. R. Age DeLorme, and Dr. Williams. They present no

very remarkable phenomena, excepting an unusual degree of muscular strength for that age, the obesity of youth differing in this from the obesity of advanced life, around and underlying.

3. With the progress of age, and as the genital organs are developed, the youthful plumpness of the body is diminished, the activity of these organs increasing all the nutrient and excreting functions, more particularly in males. The absence of the testes in eunuchs, and, indeed, castration of any of the lower animals, has a remarkable influence in favouring obesity. As age advances, especially after the fortieth or fiftieth year, when the genital organs lose much of their activity, the general inordinate accumulation of fat in the economy is most remarkably evinced; although various circumstances, as impairment of general tone and vigour, confinement, and want of exercise, the states of the locality and climate, may hasten it, and opposite circumstances delay or prevent it. After the fortieth year, the indulgences of the appetite for food are more frequent, and active physical exertion is either diminished or in a great measure laid aside. Many of the active pleasures of early life are then, or soon after, a matter of memory or regret, or by the sedentary occupations of life; while in females, the peculiar functions they have to discharge, the changes to which they are liable with the advance of age, and the various changes contingent on child-bearing and suckling, tend remarkably to produce obesity.

4. The situations in which fat is most liable to accumulate to an inordinate amount are in the subcutaneous tissue, in the interstices between the muscles, in the omentum and mesentery, under the skin of the abdomen, the hips, the kidneys, in the mediastinum, and around the mammary glands. In cases of the more sthenic forms of obesity (§ 9), the deposition of fat is general, or presents a certain relative proportion in these and other places where it usually accumulates; and, unless the accumulation is excessive, the functions of the body, excepting those of volition, are not materially impeded. But when obesity becomes truly great even in these, and still more remarkably in the asthenic forms, the accumulation of fat is more especially in the subcutaneous tissue, the skin, and the kidneys. In a very remarkable case of fatness in a female between fifty and sixty years of age, and in which death occurred from internal strangulation of the intestines, under the care of Mr. Jones and the author, remarkable collections of fat into bag-like masses or tumours were observed to be attached to, or rather to hang down from each axilla; the fat under the abdominal pareties being about six inches deep. Instances of partial fatness of a strictly morbid kind are met with also in other situations. The most remarkable, and at the same time
the most dangerous of these, is the accumulation of fat in the parietes of the heart, where it occasions atrophy, softening, pellagra, and weakness of the muscular fibres, favouring passive dilatation and even rupture of the cavities. (See art. Heart, § 227, et seq.)

6. The amount of obesity varies remarkably; and it is often difficult to draw a line between the fatness consistent with health, and that which may be viewed as morbid. The transition from the one to the other is gradual, and the progress to the latter, as well as its more unequivocal existence, is characterized by impaired vital energy and tone, as manifested particularly by the digestive and assimilating functions. The fat usually found in the healthy body has been estimated at various amounts, from one tenth to one fiftieth of the weight of the body. In extreme cases of obesity, the fat may constitute two thirds or four fifths of the entire weight. Mr. Lambert weighed 62 stone 1 lbs. 6 oz. in his prime. The increase of proportion of fat to the other parts of the body was even greater than that just assigned.

7. In the medical consideration of obesity it is requisite to view the accumulation of fat as merely a part—a part more or less prominent—of functional disorder, and even sometimes of more serious and extensive disease. The external and physical characters which the obesity presents, and the various phenomena and functional aberrations with which it is associated, will generally indicate not only its pathological sources, but also its probable consequences; and point out the kind and extent of professional interference, and of personal management it may require, as either an incipient, an advanced, or even an almost irredeemable constitutional mischief.

8. There are several points to which attention should be directed in estimating the character, tendencies, and probable consequences of obesity, as furnishing the basis of a rational treatment of it. These are: first, the fatnesses or dispositions furnished of the states of vital power as manifested chiefly in the digestive, assimilating, and excreting functions; of the conditions of the respiratory and circulating organs, and of the blood; of the muscular structures and actions, and of the general surface and appearance. The pathological conditions and tendencies of a case are indicated by them; and in proportion as these are impaired, so is the health deteriorated, whatever may be the amount of obesity. According to the state of these functions and organs, obesity has been divided into asthenic and asthenic, the transition from the extreme of the former to the extreme of the latter being gradual, and presenting no break.

9. a. When the organic or strictly vital functions are not materially impaired; when the respiratory and circulating actions proceed without material disorder, unless upon physical exertions which obesity may embarrass or impede; when the blood is not apparently deficient in quality or quantity; when the muscles are not emaciated nor deficient in firmness or power; and when the countenance and general surface retain their usual appearances or a healthy hue, the asthenic character is present; and in proportion as these evidences are furnished, in like proportion this state of vital manifestation exists. It is of the utmost importance, as respects not only obesity itself, but also the treatment of diseases which occur in fat persons, that the states of vital power, and of the circulation, particularly as regards the quantity of the blood, should be correctly estimated.

10. b. In proportion to the departure from these states of healthy function, as the vital powers become impaired; the respiration short, putrefying, or asthmatic; the circulation embarrased; the blood deficient, watery, or dark; as the muscles are weak, flabby, or emaciated, and the fatty accumulations soft or leucoplegmatic; and as the countenance becomes bloated, the surface sallow, or of an unhealthy hue, so obesity, however great it may be, should be viewed as being asthenic, and more especially morbid as regards its existence and its consecutive states. In this form of obesity, intercurrent visceral or internal disease often pursues a rapid and unfavourable course; and the inexperienced practitioner, misled by the fatness of the body, and by the incipient appearance, is often induced to take away a part of the already deficient blood. I have on several occasions met with such occurrences, the remarkable deficiency of blood being evinced, on dissection after death, by the blanched state of the viscera and structures. In all cases of asthenic obesity, lowering or depleatory measures are not well endured, even in the treatment of acute diseases affecting subjects thus circumstanced; or, if at all adopted, they should be aided by derivative and restorative means.

11. II. Causes.—The causes of obesity are chiefly predisposing, for, unless the predisposition be strong, the exciting causes are generally inoperative. —a. The predisposing causes are, chiefly, a peculiar diathesis, temperament, or habit of body hereditarily transmitted; inactivity, indolence, and quietude of body and mind; a lively, happy, and sanguine disposition; sedentary occupations, and a heavy or insufficiently pure or renewed air. Where the hereditary predisposing cause is strong, even food and drink will not prevent obesity, unless very active exercise be taken, or even great or continued exertions may be made in the open air; and where no such predisposition exists, large quantities of food and drink may be taken without any change from a state of leaness. The constitutional predisposition to obesity varies much in its character, with the state of the powers of life, and with the formation of the frame. Persons of strong constitution, of the sanguine temperament, and of good health, if fully and richly fed—if they partake of much oily and carnosous food, and of malt or vinous liquors—often become fat, although they take much exercise, especially when they advance in age, or live in the close air of towns; and if these persons, after having had the advantage of active exercise in the open air in early life, are obliged to forego this advantage, and are devoted to sedentary occupations, obesity soon overtakes them—sometimes with great rapidity, if they live thus fully and richly. But in them obesity generally presents more or less of the sthenic character, unless their general health has been previously injured, or their confinement to an insufficiency renewed air has been close or prolonged. Others, who take considerable exercise, enjoy good health, and eat heartily of nu-
A mixture of food, become fat, although not in remarkable excess; and in them obesity always presents the sthenic character.

12. In persons of a weak or lax fibre, of a leukoephegmatic temperament, and weak vital or constitutional powers, obesity is frequently hereditary; and is apt to occur, even without this predisposition, if they enjoy in abundance the necessaries and luxuries of life; but it always assumes an asthenic or atonic form. In these, the appetite is generally much greater than the powers of complete digestion and assimilation; the pulse is slow, languid, and weak, and the excursions of the bowels are feeble. Obesity often occurs in those who have been weakened by excesses, by long confinement in a close atmosphere, or by disease, and is frequent in the advanced periods of life, and in those of a cachectic habit of body. It occasionally is consequent upon torpor and chronic disease of the liver, and upon protracted dyspepsia; and in some instances it is attendant upon scanty menstruation, partial anaemia, and slight chlorosis in young females. In these cases more particularly, the muscles are pale, flabby, and wasted, in proportion to the accumulation of fat, which is soft, flabby, or semifluid.

13. b. The more immediate or exciting causes of obesity are sufficiently obvious; is generally a full and rich diet, and a life of ease; the partaking of food and liquors beyond what is requisite for the waste and wants of the economy, for the amount of exercise which is taken. Soldiers and sailors do not become obese during a campaign; but change their duties, give themselves plenty of rest, in the dress and draperies, and no one half of them would soon be corpulent. It is the quantity more probably than the quality of the food which fattens; still, many substances, particularly such as are oily and saccharine, promote obesity more remarkably than others. Fat meats, butter, oily vegetable substances, milk, saccharine, and farinaaceous substances are the most fattening articles of food; while malt liquors, particularly rich and sweet ale, are of all beverages the most conducive to the same end. The fattening effect of figs and grapes, and of the sugar cane, upon the natives of the countries where these are abundant, are well known. In various countries in Africa and the East, where obesity is much admired in females, warm baths, indulgence, and living upon saccharine and farinaaceous articles, upon dates, the nuts from which palm oil is obtained, and upon various oily seeds, are the means usually employed to produce this effect. Almost all the animals of the world, that have been kept in the old houses, and have been kept only on the food that by exercise and labour the waste of the body is increased, and the supply of oxygen augmented in the same proportion. The production of fat is always a consequence of a deficient supply of oxygen, for oxygen is absolutely indispensable for the dissipation of the excess of carbon in the food. Liebig farther argues that, since in all fatty bodies there are contained, on an average, only 10 equivalents of oxygen for 120 equiv. of carbon, and since the carbon of the fatty constituents of the animal body is derived from the food, seeing that there is no other source whence it can be derived, it is obvious, if we suppose fat to be formed from albumen, fibrin, and casein, that, for every 120 equivalents of carbon deposited as fat, 26 equivalents of oxygen must be separated from the elements of these substances. And farther, if we conceive fat to be formed from starch, sugar, or sugar of milk, that for the same amount of carbon there must be separated 30 equivalents of oxygen from these compounds respectively. Therefore, therefore, can only one way in which the formation of fat in the animal body is possible, and that is, a separation of oxygen from the elements of the food. Thus he infers that the surplus of oxygen, or the oxygen disengaged during the conversion of food into fat, goes to the support of respiration, and to supply, in part, the oxygen which is too sparingly furnished by respiration.

17. There may be much truth in these views; they are probably true in part; but Liebig does not sufficiently estimate the influence of the vital power in producing and controlling the combinations of the animal elements, while which she had taken a great liking. The cause was now obvious, as was the cure. The influence of malt liquors, particularly such as abound most in saccharine matter, is very manifest. Instances in proof of this influence, calculated more to amuse than to instruct, have been adduced by Wadd and others.

15. Rest, indolence, case of mind and body, too much sleep, sleeping after a full meal, too much food, and indulgence in any kind of vi- nous, spiritual, or malt liquor, are the chief causes of obesity, the predisposing and constitutional causes (§ 11) imparting to it the distinctive characters of sthenic and asthenic above assigned to it.

16. III. Pathology.—I have briefly stated the nature of obesity in the article on the pathology of the Adipose Tissue (§ 3); and my views, there exhibited, are in accordance with those since published by Liebig, in some respects, but different from them in others, as he imputes too much to chemical affinities or actions, and keeps out of view the controlling influence of vitality. The abnormal condition, according to Liebig, which occasions the deposit of fat in the animal body depends upon a disproportion between the quantity of carbon in the food, and that of oxygen absorbed by the skin and lungs. In the normal condition, the quantity of carbon given out is exactly equal to that which is taken in with the food, and the body acquires no increase of weight from the accumulation of substances containing much carbon and no nitrogen. If we increase the supply of highly carbonized food, then the normal state is preserved only on condition that by exercise and labour the waste of the body is increased, and the supply of oxygen augmented in the same proportion. The production of fat is always a consequence of a deficient supply of oxygen, for oxygen is absolutely indispensable for the dissipation of the excess of carbon in the food. Liebig farther argues that, since in all fatty bodies there are contained, on an average, only 10 equivalents of oxygen for 120 equiv. of carbon, and since the carbon of the fatty constituents of the animal body is derived from the food, seeing that there is no other source whence it can be derived, it is obvious, if we suppose fat to be formed from albumen, fibrin, and casein, that, for every 120 equivalents of carbon deposited as fat, 26 equivalents of oxygen must be separated from the elements of these substances. And farther, if we conceive fat to be formed from starch, sugar, or sugar of milk, that for the same amount of carbon there must be separated 30 equivalents of oxygen from these compounds respectively. Therefore, therefore, can only one way in which the formation of fat in the animal body is possible, and that is, a separation of oxygen from the elements of the food. Thus he infers that the surplus of oxygen, or the oxygen disengaged during the conversion of food into fat, goes to the support of respiration, and to supply, in part, the oxygen which is too sparingly furnished by respiration.
these elements and their combinations are within the sphere of this influence. The various changes which the food undergoes from the moment of its mastication are produced by this influence, aided by the secretions poured into the alimentary canal, in the first instances, and by the oxygen of the atmosphere subsequently, when the product of digestion is conveyed into the circulating system.

18. But Liebig states, that "the most decisive experiments of physiologists have shown that the process of chymification is independent of the vital force; that it takes place as result of a purely chemical action, exactly similar to those processes of decomposition or transformation which are known as putrefaction, fermentation, or decay." Now we have here to take M. Liebig's word for the decisiveness of the experiments to which he refers; for he has neither adduced nor referred to any of them. The fact is, that these experiments prove the converse of his proposition; and common sense and observation prove it still more strongly. And if the resources, every reason to infer that the quantity, and probably also the quality of the gastric juice, are influenced by the states of vital and organic nervous power. That the action of the gastric juice upon the masticated food is identical, neither with fermentation, nor with putrefaction, nor with decay, is most probable; that it is somewhat similar to each, or to all, may be admitted; but that it is purely chemical, as inferred by Liebig, requires further proof. That the gastric juice exerts a certain degree of action when it is removed from the system, is no proof that this action is either purely chemical, or entirely independent of vital influence; for it is sufficiently shown that all the recemencitious secretions possess a certain emanation or endowment of vitality, which is soon dissipated; and as soon as it is dissipated, decomposition supervenes. That a transformation takes place in consequence of the admixture of the gastric juice with the food is all that we know; that this transformation may be fermentative, or putrefactive, or chemical, as respects certain of its aspects, may be admitted; but that it is neither the one nor the other altogether, that it is peculiar in many respects, and that it is influenced by the states of vital and organic nervous power, are sufficiently manifest on a comprehensive view of the subject. That the gastric juice acts to a certain extent upon food enclosed in perforated balls, or even when entirely removed from the alimentary canal, and that the appearance of chyme, may even be concealed; but that the change is complete, or altogether such as it would have been if it had been subjected to the vital influence of the stomach and duodenum, in the natural process of digestion, is not proved. *

19. IV. Treatment.—The indications and means of cure are, in many cases, very obvious and easily prescribed; but they are rarely even partially adopted, and still more rarely adopted in all their parts by the patient. Temperance in eating and drinking, and active exercise in the open air, the avoidance of the chief causes of obesity, are easily insisted on; and proofs of the efficacy of the recommendation are sufficiently strong. But the patient, however well he may be convinced of the propriety of this advice, has seldom strength of resolution to adopt it, particularly when it respects the curtailment of those pleasures furnished by the palate, the indulgence of which become only the more inveterate as we advance in age, and which are the last of the sensual gratifications which are relinquished.

20. A. In the more sthenic forms of obesity, all articles abounding in fat or oil should be relinquished, and lean and white meats, the lighter kinds of fish, brown or rye bread, turnips, greens, and others of the less nutritious vegetables, are to be used; but these, it is supposed, even these should be taken in moderation. Active exercise, particularly on foot, or on a rough trotting horse, gymnastic amusements and exercises, and the shower or cold bath, followed by active friction of the limbs and trunk by the patient himself, are also most important parts of the treatment. Early rising and exercise before breakfast, and a moderate indulgence in sleep, avoiding it after dinner or during the day, ought also to be enforced. The last condemnation is one of a more general nature, the régime regimetal, little or no medicine being requisite beyond what may be necessary to preserve the secretions and excretions free, or to control injurious local determination of blood as it may occur. It has, however, been recommended to impair the appetite by giving the patient nauseating doses of antimony, of squills, or of ipecacuanha. The last of these is the safest, and it only should be employed if a recourse to this indication be determined upon. But it is such a trust to authorize temperance and exercise than to other means, of fat in animal bodies is that which is richest in starch, sugar, and other substances of a similar nature; rice, Indian corn, peas, inseed, potatoes, beans, &c., are used in husbandry in large quantities, with great effect, for fattening. Rice, potatoes, and peas, which are described as E. Bey, which is known to have a fattening effect, according to Liebig, contains no oil. Rice consists from 913 to 909 per cent. of oil; peas, about 1 per cent.; potatoes, 2% per cent. of fatty matter; hay, nearly 2 per cent. of fatty matter. Liebig has undertaken to show that hay ought to contain 7 per cent. of fat, to account for the amount of butter which it can yield; the experiment did not succeed. He undertakes to show that the ox, which is fattened, and the milch cow, furnish a smaller quantity of fatty material than the fodder contains.—See Perreira, On Food and Diet, Am. ed., p. 472. "In regard to the principle of M. Dumas," says Liebig (Ed. and Lond. Phil. Mag., July, 1813, p. 25-6), "that the organism of an animal is not able to produce fat, or to form fat from sugar or starch, but must consume the latter in order to produce fat; it is equivalent to saying that the organism produces nothing, but transforms it; that no combination takes place in its body, when the material is transformed by means of the animal's amorphous orifices. Thus, the formation of sugar of milk in the bodies of carnivorous animals cannot take place, for dog's milk, according to Simon, contains no sugar of milk. Thus, fat cannot be produced in their organism, because, besides fat, they do not consume any non-nitrogenous food. But starch, sugar, and salt contain, even with the larger amount of air, as much indigestible fat bodies; and the formation of butter in the body of the cow, and of wax in that of the bee, leave hardly any doubt that sugar, starch, amin, or pectin furnish the "carnation for the formation of the butter of or the wax."—(Loc. cit.)

* It is well known that M. Liebig and Dumas differ in opinion on this subject; for while the former believes that grammogenous animals produce fat out of sugar and starch, the latter considers it a fixed role that animals, of whatever kind, produce neither fat nor any other alimentary substance; that they receive from the vegetable kingdom only the aid of the aliment, whether it be sugar, starch, or fat. The French commission on galton, he states, have proved, beyond all doubt, that the animals which eat fat are the only ones in which fat is found to accumulate in the tissues. There can be no dispute, however, that, as Liebig maintains, the food which has a decided influence in the formation
which may be productive of disorder. If the appetite be painfully craving in the intervals between meals, the patient may take a camphor lozenge or chew a small piece of camphor with advantage; but smoking cigars or tobacco of any kind, although often efficacious, is ultimately injurious to the digestive functions and nervous system. It is preferable to endure hunger for a time: after some days this sensation will become less urgent, and abstinence be more easily tolerated.

21. A cause to recalls, whether mineral or vegetable, in order to reduce or to prevent obesity, is generally injurious, especially if persisted in for a period sufficiently long to produce this effect, and is apt not only to injure the digestive organs, but also to favour the occurrence of disorders of the urinary organs, and of rheumatic and gouty affections. The employment of soap and alkalis, as advised by Dr. Flemming, is, upon the whole, safer than the use of acids, particularly in the gouty and rheumatic. It is especially injurious, as a long-continued use of these is liable to induce chronic disorders of the kidneys and bladder.

22. B. The treatment of asthenic obesity should depend mainly upon the disorders of the digestive and assimilating organs, with which it is often associated and as often the result. In females this form of obesity is frequently complicated with disorder of the uterine organs, and hence attention ought to be paid to this circumstance. In this state of the complaint, also, temperance and exercise in the open air are the most important parts of the treatment. When the liver is torpid, the nitro-muriatic acids may be prescribed, or Flemming's pill with soap, the bowels being duly regulated by means of stomachic aperients or purgatives. The same means may be employed if the liver should be inclined to be enlarged or obstructed, or the iodide of potassium may be taken with liquor potassae, and the compound decocction of sarja. In some cases the preparations of vegetable order, and exercise in the open air, particularly the mixture of the sesquichloride, or the alkaline prepara-
tions of iron. In most instances of asthenic obesity, change of air, travelling, and a course of mineral waters suited to the peculiarities of the case, as the alkaline, the chalybeate, or the saline, as circumstances may require, should be recommended, and aided by suitable diet and regimen.

**EDEMA**—Definition—Passive.

1. Defin.—A swelling occasioned by the effusion or infiltration of water or serum in cellular structures.

2. Although the sub-cutaneous cellular tissue is most frequent, it is not the only seat of edema. Slight effusion of serum is also occasionally observed in the sub mucous and sub-serous cellular tissue, and in the cellular parenchyma of the viscera. Edema of the sub-mucous or sub-serous cellular tissue seldom gives rise to symptoms of sufficient importance to point out the nature of the lesion. Edema, however, of certain of the most important organs, may be recognised during the life of the patient, especially edema of the glottis (see art. Larynx, § 67) and edema of the lungs (see art. Lungs, § 166). Edema of the brain is not so readily recognised, and is of much rarer occurrence than that of the lungs, and is chiefly observed in the insane, particularly in the subjects of general insanity, in its more chronic and apathetic states. In whichever situation edema may occur, it presents either a passive or an active character.

3. A Passive Edema—the cold edema of some authors—proceeds from the retardation or suspension of the circulation either of the veins or of the absorbing, or from impaired or impeded action of the heart, and consequent interruption of the venous circulation.—a. It may arise from obstruction or obliteraton of one or more veins; from a varicose state of the veins; from preserving for too long a period the same position, the physical overcoming the vital influence, as in standing for a long period; from a weak action of the heart; from want of action of the muscles, whereby the venous circulation is unaided; as observed in cases of palsy, which is often attended by edema; from a thin, watery, or morbid state of the blood, often connected with deficient tone of the organic nervous system, as in chlorosis, scurvy, &c.; or from the superabundance of water in the blood, as in granular and other diseases of the kidneys, and in suppression of the cutaneous perspiration.

b. On examination after death, the volume of the part is found increased by the exhalation of serum in the meshes of the cellular tissue. The surface of the swollen part is generally pale; and, upon incising the part, the serum escapes in a fluid state; but sometimes, particularly when the serum is albuminous, it is retained in the cellular meshes, and presents a gelatinous appearance. The same characters are observed in all cases of passive edema of the cellular, sub-cutaneous, sub-mucous, and sub-serous cellular tissues. Passive edema of parenchymatous organs increases the bulk of these organs, but in other respects presents the same appearances as those just mentioned. The structure of the edematous organ is sometimes a little discoloured, and when firmly pressed by the finger it retains the impression, as observed in edema of the sub-cutaneous
cellular tissue. When incised, the divided surface permits the escape of the effused serum in drops; but when the serum is pressed out, the parenchyma of the organ presents no farther lesion than rarefaction by the evacuated fluid.

5. c. The synonym of passive or cold edema readily distinguish it from acute or warm edema (§ 6). The pallor and coldness of the surface, the depression following the pressure of the finger, the state of the pulse, and the absence of febrile action, are sufficient to point out the passive form of this lesion. The nature of the obstruction causing the edema is sometimes indicated by the appearances presented by the edematous part: thus, when the obstruction is in the veins in the vicinity of the part, the superficial veins are distended. When the obstruction is remote or central, or when the edema is produced by the state of organic nervous power, or of the blood, this condition of the superficial veins is not observed, and the surface is generally pale. The seat of the edema, also, often points out the obstruction occasioning it: thus, edema of the face, commencing generally in the eyelids, is commonly caused by obstruction to the circulation through the heart, particularly its left side, and is frequently consequent upon hydrothorax, caused by this lesion, and upon congestive inflammation of both lungs. Edema of the lower extremities most commonly follows obstruction in the right side of the heart. Edema of the upper extremities generally precedes that of the lower, in cases of hydrothorax; and sometimes edema occurs in the side of the face, and in the hand corresponding with the side of the chest in which the effusion exists, when one cavity only is the seat of effusion. Edema of the face and of the extremities may occur equally, or about the same time, in disease of the kidneys, with superabundance of serum in the blood, or with other alterations of this fluid. Edema of the lower extremities may proceed from the pressure of the gravid uterus, or of pelvic tumours, or of accumulated feces in the eecum or colon, or of enlargement of an undescended testes (Author), or of enlarged glands, and from disease of the veins or absorbents, as well as from obstruction in the right side of the heart. Edema of the male genitals proceeds from the same lesions as occasion edema of the lower extremities; but it may also arise from stranulation by the prepuce, or from urinous infiltration. Edema of the female genitals is usually caused by pregnancy.

6. c. Acute, or warm edema, is not so frequent as the former variety.—a. It is sometimes connected with inflammatory action in the part, or in the vicinity, especially with asthenic inflammation, or that weak state of inflammatory action which occurs in weak, enfeebled, of leukoplagmatic persons, or lymphatic constitutions, and which has been termed by some hydrophlegmatis. It attends, in a more or less remarkable form, certain states of erysipelas—the edematous especially—and diffusive inflammation of the cellular tissue.

It is in every respect a state or form of inflammation of the cellular tissue. The surface is not only swollen, but is also warm, and generally coloured, sometimes with various shades of deepness. It is often somewhat firmer to the touch, and does not pit from pressure so readily as in the passive form.

7. b. Upon dividing the edematous part, the effused fluid is frequently different from that found in the passive variety. It is often serous or puriform; occasionally the serum is sanguineous, sanious, or sanguineo-puriform. It is also sometimes purely serous, of a yellowish tinct. The predominance of either serous or puriform characters differs much in different cases.

The same appearances are often observed in the vicinity of inflammation of parenchymatous organs, as in edema of the lungs occurring in the vicinity of inflamed parts of the organ.

8. b. The diagnosis of active edema is easy. The increased temperature of the part, the orientation to the pathological condition or tenderness from pressure, the state of the circulation, and the general febrile commotion suf- ficiently distinguish active from passive edema. The former usually appears more suddenly, and proceeds more rapidly, than the latter; and is often consequent upon deep-seated suppuration, or upon the presence of irritating matters in the circulation. In this latter case, the fluid effused is generally of an irritating and con- taminating nature, inducing unhealthy suppuration in the vicinity of the point in which it is effused, or through which it extends.

9. c. The prognosis is important in respect both of the constitutional and of the local relations of edema. In the passive form, the edema indicates a most serious, and even dangerous, condition of the circulating system, or of the kidneys. In the active state, the danger may not be so great, particularly when the edema is associated with inflammation in its vicinity; but even then it should suggest the presence of inflammation of either the veins or absorbents, or even of both, or, at least, pressure upon, or interrupted circulation through, the trunks of veins. When edema is connected with a morbid state of the circulation, with irritative fever, or is symptomatic of deep-seated suppuration, &c. (§ 8), it should be always viewed as indicating great danger, if not increasing it.

10. d. Treatment.—It is unnecessary to enter more fully into the treatment of edema than to remark, that the means of cure should be directed to the pathological condition or cause of which edema is merely a symptom, and that the principles and means of cure which have been advised for amanaara (see art. Drophy, § 132, et seq.) should be employed for it. When the edema is consequent upon deep-seated suppuration, or is erysipelas, then the constitutional and local means prescribed for the edematous and gangrenous states of erysipelas (see that art.), or for diffusive inflammation of the Cellular Tissue (§ 35), for Asthenic Inflammation (§ 230), are in the most appropriate, the various physical or mechanical causes which may operate in particular cases being removed.

CESOPHAGUS—DISEASES OF THE.—

CESOPHAGUS, DISEASES OF THE.—

(Sesophagus from οὐς, ουτ., ὄντα, I carry, and φαγε, φαγός, I eat, &c.) (Esophage, Fr Die Speisewrhe, der Speiseitrager, Germ. —
There are two portions of the alimentary canal the diseases of which have been very generally overlooked by systematic and practical writers in this country, and which have received but an imperfect notice from foreign authors. I allude to the esophagus and cæcum. The former is, perhaps, less frequently diseased than any part of the canal; the latter is, as I have shown in the article Cæcum, one of the most liable of the organs of the body to functional disorder and organic change. Through the one, the passage of the ingesta is rapid, and on it their effects are slight or transient, unless when they are of a most irritating and noxious kind. Through the other, the passage of alimentary and fecal matters is remarkably slow, and liable to interruptions, and hence injuries interruptive of an injurious state when made on the containing parts by morbid or irritating states of the contained substances; and hence, probably, is partly owing the less frequency of diseases of the esophagus compared with those of the cæcum. Still, the diseases of the esophagus are much more common than have been supposed, the little attention which has been paid to them having been the cause of their being overlooked in many cases in which they were actually present. And when we consider the frequency of diseases of the pharynx and throat on the one hand, and of diseases of the stomach on the other, we can hardly infer that the esophagus should escape participating in them so generally as has been supposed.

2. In discussing the diseases of the esophagus I shall, first, give a rapid sketch of the structural changes which this canal occasionally undergoes in the course of diseases in which it is implicated; and I shall next consider in succession the most important of the maladies which occur with those changes, with the consequence which they usually produce in the symptoms by which they are indicated, and the treatment they require.

3. The esophagus presents organic lesions less frequently than the mouth and pharynx, and still less so than the lower parts of the digestive canal.—a. The epithelium covering its mucous surface is sometimes crooked, softened, or even destroyed, at its inferior part. This is on account of the longer periods of weaning, and in those who have been imperfectly or improperly nourished. M. Andral has found the epithelium remarkably thickened.

4. b. The mucous membrane of the esophagus is but seldom inflated or congested with blood compared with other parts of the digestive canal, unless consequent upon eruptive diseases, particularly scurfatina. It is generally injected or congested with black blood in rabies, especially its upper portion. It is sometimes thickened either generally or in parts. Its follicles are occasionally enlarged and apparently congested and obstructed, particularly in young subjects and in mucous or gastric fevers. Vegetations or excrescences, of various sizes and forms, have been found to shoot from it, narrowing the passage and most seriously obstructing deglutition. Cases of this description are mentioned by Schneider (in Haller’s Collect. Dissert., viii., No. 258), Dallas and Mono (Edin. Essays and Observ., v. iii.), and BAILIE. Ulcers are, perhaps, less frequently observed in this part of the digestive tube than in any other. I have, however, met with several cases of this lesion, which is not infrequent in children. Ulcers in this situation have been described and delineated by Sandfort (Museum Anatomicum, tab. civ., fig. 3) and BAILIE (Series of Engravings, &c., fasc. iii., pl. 3 and 4); but notwithstanding that Brunner had described ulceration of the esophagus as commencing in its mucous follicles, this form of ulceration has been overlooked by those pathologists. I shall, therefore, notice this lesion more fully in the sequel. Agglutination of the opposite parietes of the esophagus, by coagulable lymph thrown out upon its mucous coat, has been said to have been found in a fatal case of smallpox (BARTHOLOMINUS, in Act Hafn., t. i., obs. 109). This is, however, an extremely rare occurrence. Exudations of the same nature, forming a false membrane upon the mucous surface of the canal, is not rare, and is found generally in the upper part of it, in cases where this exudation is thrown out over the tonsils and pharynx (see § 23).

[Dr. GROSS states (Path. Anat., 3d ed., p. 531) that he examined, in 1838, the stomach and esophagus of a boy, 13 years old, who suddenly expired in convulsions after an illness of three days. The patient complained of severe pain in the fauces, and had great difficulty of swallowing; every attempt of the kind being followed by spasm of the throat, especially when the substance was of a fluid nature. On inspecting the esophagus, it was found lined throughout with a thin layer of lymph, closely adherent to the natural mucous coat, which was itself highly injected, and of a bright red colour. The stomach was perfectly sound, the inflammatory phenomena being limited only to the cardiac orifice. The adventitious membrane was also traced around the mouth of the larynx, and over the whole of the fauces. Dr. G. states that these membranes rarely become organized. When the inflammation subsides, they gradually lose their moisture, together with their adhesive properties, and are either vomited up in small tubular fragments, or swallowed and digested, or passed by stool. Andral relates an instance where an exudation of lymph lined the esophagus of a newborn infant, and extended over a third of its extent (Loc. cit.)]

5. c. The sub-mucous cellular tissue of the canal is sometimes inflamed or congested, in the same circumstances as those just mentioned: infiltrations of scorns, sero-puriform, or serous fluids are also observed in it as consequences of inflammation. It may also become thickened and indurated, particularly after protracted inflammatory irritation. It may be transformed into a fibro-cartilaginous substance, or into serous structure, thereby narrowing, even nearly to complete obliteration of the tube. Instances of stricture degeneration of the tube passing into the ulcerative or carcinomatous state are not rare, especially in the extremities of it; but simple thickening and induration caused by chronic inflammation have often been mistaken for stricture. Transformation
of a portion of the tube into a cartilaginous state has been observed by Morgagni, Halae, and others. This canal may be partially or entirely obstructed also by abscesses formed in its parietes or even exterior to them; or by the growth. Dilatation in the vicinitv is thus slowly increasing difficulty of swallowing attends upon aneurism of the aorta, or upon a mass of obstructed lymphatic glands pressing upon the esophagus. Bleul and has seen this effect produced by exostosis of the body of a vertebra.

The dysphagia, however, which proceeds from these causes is seldom so urgent or distressing as that which depends upon disease of the coats of the tube.

6. Softening and attenuation of the esophagus are occasionally met with, and these states may even go on to spontaneous perforation, presenting all the anatomical characters which this lesion evinces in the stomach. Gangrene of the tube is very rare. I agree with M. Andral in considering the majority of cases of this occurrence recorded by authors as pulpy softening of the part, which is not uncommon in infants and children. It, however, sometimes occurs, especially near the pharynx in malignant scarlet fever.

7. The transformation of the esophagus generally follows by effusion into the thorax. M. Andral states that the perforation in all the recorded cases has taken place in the thoracic portion of the canal near the cardiac orifice; and the surrounding part of the parietes has sometimes been found altered and softened, and at other times without any appreciable alteration. There are, however, cases on record in which the perforation had taken place about the middle and upper part of the tube. The perforation in a case attended by me was above the middle of it; and similar instances are published by Kade (De Motus Ventriculi, &c., Halae, 1798), and by Reil (Memorab. Clin., fasc. i., p. 13), who met with it in cases of typhus fever.

8. Perforation of the esophagus occurs at all ages. M. Veron met with it in an infant just born. M. Guersent observed it in a child of seven years of age. M. Bouillaud found it in an adult, in whose stomach four perforations also existed. I have seen it in a child. It occurs more frequently at the periods of infancy and childhood than at any other. In some cases, the perforation is stopped by the aorta or trachea, so that no effusion takes place. In other cases, a double perforation occurs, and the canal of the esophagus communicates with that of the trachea or even of the aorta. Instances of the communication of the esophagus with the trachea in this manner have occurred to Zeviani (Memoire de l'Academie de Verona, t. vii.), Menko (Mort. Anat. of the Gulf, &c., 1830, p. 372), and to myself. In the majority of cases of perforation, the ulceration appears to commence in one of the follicles (see § 37).

9. Sarcomata and tubercular matters have sometimes been found underneath the mucous membrane of the esophagus. Albomumous exudations also form, either in patches, or to such an extent as to form false membranes, as already noticed (§ 4, 26). M. Guri found a layer of firm matter adhering closely to the mucous surface in a new-born infant; and Hr. Denbrand states that its formation is not infrequent, but that it generally separates and passes into the stomach, being rarely exerted upward. This agrees with what I have observed in some cases of epidemic group and scarlet fever.

10. g. Dilatation of the gutt seldom occurs unless, as remarked by Portal (Anat. Med., t. v., p. 201), from stricture of the cardia and of parts of the tube below the dilatation. In some cases the dilated part forms a large sac, a portion of which falls lower than the seat of stricture, constituting a kind of diverticulum. Cases of this description have been noticed by Isenflamm and Sandfort (Med. Anat., t. i., p. 242).

11. h. Polypous excrescences have been found shooting from the internal surface of the gutt, narrowing the passage and obstructing deglutition, but they occur less frequently in this situation than in the pharynx. They present the same appearances as in other situations, and have been noticed by Pringle, Monro (Edin. Essays and Observ., vol. iii.), Baillie, Graepe, and Schneider (see Haller's Coll. Dissert., vii., No. 257). They often grow from a pedicle sufficiently long to permit of their rising into the pharynx upon efforts to vomit.

12. i. Cartilaginous and ossous degeneration of the esophagus are observed in rare instances, and generally confined to a small portion of the tube, forming a kind of ring. Gyser (De Fane Lethali ex Calloso Esophagi Angusta, 4to, Argent., 1770) found a cartilaginous ring restricting the canal, so as to prevent the passage of a sound. Similar cases have been recorded by Becker, Bang, Baldwin, Andral (Anat. Pathol., t. i., p. 276), and others. Cartilaginous degeneration of the gutt in its whole extent has been said to have occurred to Samson (Miscell. Curios., &c., Ann. 1613), Garnia (Morgagni, De Sed. et Caus. Morb., epist. xxvii., 15), and Desgranges (Journ. de Boyer et Corvisart, &c., t. iv., p. 203). Ossuous and cartilaginous deposits are also very rarely met with in the parietes of the gutt. Instances, however, have occurred to the elder Monro, Abrahamson (in Meekel's Archiv., t. 1., et iii., p. 16), and to Walter (Mus. Anat., b. 1., No. 2, 1717).

13. Rupture of the esophagus has been very rarely observed. Instances of its occurrence after vomiting and muscular efforts have been published by Borkhauve, Zeisner (Dissert. de Raro Esophagi Motu. Region., 1732), Sedillot (Recueil Periodique, t. vii., p. 194), Meier (Baldinger's Magazin, b. iii., p. 399), Guersent (Bulletins de la Faculte de Med., Z. 1), by Bouillaud (Archives Gener. de Med., t. 1., p. 33), and by Mr. W. King (Guy's Hosp. Rep., part xv). In all these the parietes of the esophagus have been either ulcerated, rupture taking place in the seat of ulceration, or softened and attenuated in the manner already described (§ 34).

II. Inflammation of the Esophagus.—Syn. Esophagitis; Inflammatio Esophagi; Inf. Gulae, Anul. Esophagiti, Fr. Entzündung der Speiseröhre, Ger.}

Classification.—III. Class, I. Order (Author).

14. Inflammation.—Inflammation is sometimes more or less difficult to credibly judge, with symptoms fever, &c.

15. Inflammation of the esophagus occurs
more frequently in a complicated and consecutive, than as a simple and primary disease. It varies as to its intensity and form or character, and as to the particular tissues of the canal in which it may occur. It may be acute, sub-acute, or chronic; it may be limited to the mucous surface, or it may extend to the more external coats, through the medium of the connecting cellular tissue; it may even affect only the mucous follicles of the canal, the internal membrane being either entirely exempt, or affected only in the immediate vicinity of the follicles.

16. A. Causes. -a. Esophagitis is most frequent during infancy and childhood, but it is occasionally also observed during middle and advanced age. Long-continued and severe dyspepsia, constipation, the abuse of spirituous liquors, the habit of wearing too warm clothing around the neck and throat, the use of tightly-laced corsets, the strumous diathesis, and sanguine and plethoric habit of body, predispose to it.

b. The exciting causes are chiefly those physical agents which act directly upon the canal, and diseases of adjoining organs or parts which extend to it, either in their course, or upon their disappearance in their original seats. The former are draughts of cold fluids, or the ingestion of ices, while the body is overheated or perspiring; the deglutition of too large a mouthful, or of too warm fluids or substances; or of hard, irritating bodies; the abuse or incalculable use of irritating medicines, as iodine, quills, ammonium ammoniaca, &c.; exposure of the neck and chest of females; the use of highly-seasoned or spiced articles of food; the accidental or intentional ingestion of acid or corrosive poisons, as the mineral acids, the bicarbonate of mercury, preparations of arsenic, &c.; acid and septic animal poisons, particularly those developed in preserved or smoked meats, mushrooms, &c.; and the injudicious exhibition of acid emetics. Esophagitis is often caused in young children by sore nipples, and by an unhealthy state of the milk of nurses.

18. This disease may also occur upon the disappearance of cutaneous eruptions, or after the suppression of accustomed secretions and discharges. It may appear in the gouty or in the rheumatic diathesis, and thus assume a modified form; but it is very rarely a consequence of suppression or metastasis of either of these diseases. It most frequently occurs during the progress of some diseases, and as a sequel or extension of others, particularly of eruptive fevers, aphthous, erysipelas, pertussis, inflammatory affections of the fauces and pharynx, and of the internal surface of the stomach.

19. Esophagitis is, moreover, not only caused by, but also often complicated with, one or other of the foregoing diseases, particularly scarlatina, smallpox, erysipelas, aphtho, gastritis and mucous fevers, inflammation of the fauces and pharynx, or inflammation of the stomach. In nearly all these associations the inflammation of the esophagus is a consequence of the affection arising from the extension of the inflammatory action, chiefly by continuity of surface, it is not the less important as respects its consequences. Inflammation of the internal surface of the esophagus may also be complicated with spasm of some part, or of the whole of the canal. In this case, the irritability of the muscular coat of the tube is so immediately increased in consequence of the inflamed and sensible state of its mucous surface, that it becomes spasmodically and painfully contracted upon the passage of substances along it. The disease is also occasionally complicated with chronic laryngitis, this latter affection being consecutive upon the former. A case of this description lately came before me. The laryngeal affection, which, owing to the paroxysms of suffocation and cough accompanying it, was the prominent complaint, and attracted the chief attention, was removed after the treatment had been appropriately directed to the primary disease.

20. ii Symptoms. - A. Of Acute Esophagitis. —Pain in some form or other is always complained of, and is usually accompanied with a sensation of heat. It extends in general behind the neck and in the middle of the back, between the shoulders, and the ninth dorsal vertebra. This burning pain varies in degree, is sometimes chiefly felt about the bottom of the pharynx, and behind the glottis; at other times, behind the sternum and xyphoid cartilage; and is occasionally accompanied with the sensation of a foreign substance in one of the above situations. In some instances the pain is dull and slight, and in others attended by the feeling of a cord extending in the course of the canal. In all cases, the pain or uneasy sensation is greatly augmented by deglutition; so much so, on some occasions, that the patient either obstinately refuses to swallow, particularly liquids, or experiences an instant regurgitation of them. Sometimes, in the more acute cases, the matters thus thrown up are ejected forcibly through the nose, or irritate the glottis so as to occasion violent and sufficient fits of coughing. Independently of the regurgitation of matters attempted to be swallowed, there is frequently an expiratory or glairy flow expelled from the mouth and upper part of the esophagus. The patient is generally tormented with thirst and singultus. This latter symptom is seldom wanting when the lower part of the tube is inflamed. In this case, the most sensible substances which are swallowed are arrested by spasm of the inflamed part, occasioning great pain, generally referred to the space between the shoulder blades, and are afterward ejected or vomited, with a considerable quantity of mucus, sometimes with blood.

21. In children, esophagitis, in its more acute states, is not infrequent, particularly during infancy; and in them the diagnosis is difficult. The child generally refuses drink, or drinks little, cries, and regurgitates the ingesta. Hicough is almost constant, and frequently vomiting, which does not often occur in the adult from this disease. When the milk is thrown up unchanged, we should always suspect the existence of inflammation of the esophagus.

22. Besides the foregoing, there are also many of the usual signs of symptomatic fever, generally of the inflammatory type, but frequently of a remittent form. The tongue is red at its point and edges, sometimes throughout: at other times it is loaded and furled in.
23. iii. Terminations.—Acute inflammation of the esophagus may terminate (a) in resolution; (b) in suppuration; (c) in softening of the mucous of the canal, or (d) in gangrene, or (e) it may pass into a chronic state of disease.

1. Resolution takes place generally with a gradual subsidence of the acute symptoms, and a more copious discharge of mucous or mucopurulent fluid; or with critical evacuations, as hypnotic urine, copious perspiration, &c. It occurs chiefly on the fifth, seventh, ninth, or eleventh day; and occasionally with the exudation of an albuminous substance, the discharge of which disposes to a resolution of the inflammatory action. This substance is secreted on the internal surface of the tube, as in croup, forming a false membrane, sometimes extending upward to the pharynx and fauces. As the inflammation subsides, this false membrane is thrown off from the mucous surface, the secretion of the mucous follicles gradually detaching it from its adhesions to this surface, and it is passed with the ingesta into the stomach.

2. Suppuration sometimes occurs in one or other of two forms: 1st. The purulent matter may be discharged in consequence of violent inflammation, from the whole internal surface of the tube; this, however, seldom takes place unless esophagitis is occasioned by very irritating ingesta. I was called some years ago to a case of this description by a practitioner in Westminster. The patient, a robust young man, had attempted to poison himself with laudanum. In order to procure the evacuation of the poison, a considerable quantity of mustard, mixed with warm water, was exhibited. This produced full vomiting, after the other means had failed. Induration of the esophagus, however, in its most distressing form, supervened, and in the course of two or three days was followed by more copious and entirely purulent discharge regurgitated from the esophagus. The quantity discharged between each visit, and collected in the vessel, was surprising. He nevertheless recovered, and without any affection of the nervous system, as is often observed after poisoning from opium.

20. Suppuration in the form commonly occurs when the inflammation attacks a part only of the tube, and implicates all its coats. A distinct abscess usually forms in this case, most frequently in the cellular tissue connecting the mucous with the muscular coat. It occurs in neglected cases of the disease, and in scrofulous habits; and is generally indicated by the complete stop put to deglutition, by great thirst, excessive pain, and by a sense of fulness, and of pulsation in the situation of the esophagus. In most of the cases on record the abscess has burst into the canal, either spontaneously upon efforts at deglutition or vomiting, or upon introducing a bougie or probang along the passage; and the patient has obtained immediate relief. Interesting cases of this description have been published by M. Bourguet (Gazette de Santé, 1823, p. 221), and by M Barras (Archives Gen. de Med., t. x., p. 134). Recovery generally takes place rapidly after the matter is discharged; it either passes into the stomach or is ejected upward.

25. C. Gangrene occasionally terminates in inflammation of the esophagus, but not so often as is stated by some writers. It occurs chiefly after esophagitis complicating scarlata, or following that disease, in which circumspection and care should be observed several occasions, generally, however, associated with gangrenous pharyngitis. I have, likewise, seen it after esophagitis caused by poisonous ingesta, particularly the animal poison generated in preserved or spoiled meats. Although it may commence previously to dissolution, yet the morbid appearances usually described as constituting this change are somewhat increased after death. When the inflammation terminates, the sphacelus is chiefly confined to the internal surface of the tube, which presents more or less, along its whole extent, soft, tumefied patches, of an irregular form, of a dark gray or slate colour, and emitting a peculiar fetid odour.

26. The symptoms indicating this change during the life of the patient are not always manifest. Two cases of this mode of termination, occurring independently of poisoning, and of complication with scarlata, have come before me in practice, and were recognised during life, and verified by an examination after death. The one occurred in a child, the other in an aged female. In both, great tumefaction and tenderness of the lateral and anterior parts of the neck; a deeply-incrested tongue, with a dark sordes; a feeble, small, unequal, and intermittent pulse; singultus, and frequent fetid evacuations; great prostration of strength, with lepithymia, and cold clammy perspirations, were remarked. There was no vomiting; but in one of the cases a small quantity of an offensive, sanguineous mucus was occasionally regurgitated upward shortly before death.

27. D. The changes of structure most commonly observed in fatal cases of acute esophagitis are injections in patches, striae, or generally of the mucous surface, with partial destruction of its epithelium, particularly in infants. This surface is usually reddened, the tint, however, varying from a rose hue to a reddish-brown. The mucous membrane is commonly tumefied, its subjacent cellular tissue thickened, injected, infiltrated with a serous or sero-puriform or sanguineous fluid, and both the one and the other softened and more easily torn than natural. Sometimes they are reduced to a nearly pulpy state, and are of a reddish-brown or purple colour. The submucous cellular tissue sometimes presents minute collections of a puriform matter, which elevate the internal surface into puntiform eminences. The whole parietes of the canal are soften, sometimes edematous, injected with blood, and more lacerable than usual. In rare cases, purulent collections form exteriorly to the mucous coat. Ulceration seldom occurs after this state of inflammation; it is more frequently met with after that hereafter to be described. When, however, it does occur, the ulcerated part generally varies in size and in depth, the parts in its immediate vicinity being very much softened, inflamed, and somewhat thickened or tumefied.
28. E. The changes produced in the oesophagus after the ingestion of strong acids are generally of a disorganizing nature in the more rapidly fatal cases. The mucous surface is eroded, and of a brownish, or brownish-black hue, and the tube generally more or less constricted. The erosion or partial solution of the internal surface sometimes extends to the connecting cellular tissue, so that the muscular coat may be readily denuded, as by rubbing a sponge firmly along the exposed surface.

29. a. Subacute and Chronic Oesophagitis.—A. The less active forms of the disease are more frequent than the acute. They may take place primarily, or they may be the consequences of neglected, or partially subdued states of acute oesophagitis. Many of the slighter cases that have occurred primarily never come before the physician until organic changes seriously interrupting the process of deglutition have taken place.—b. The slight or chronic states of oesophagitis are characterized chiefly by the symptoms forming the acute form (§ 20), but in a milder degree; by soreness and tightness under the sternum, or between the scapula; the discharge of a rropy fluid, or acidic eructations; sometimes rumination after a full meal, by a hawking or short cough, or frequently hawking or spitting, by a weak, irritable pulse and emaciation; and sometimes by obstinate dyspepsia and costiveness.

30. b. The chronic states of the disease are generally caused by previous disorders, particularly by inflammatory or neglected dyspepsia, inflammations of the internal surface of the stomach, by eruptive fevers, and inflammation of the fauces or pharynx; by the acute states of the disease, and by the causes producing these states.

31. c. The milder or more chronic states of oesophagitis terminate in resolution, or in some one or more of the organic lesions described in another section of this article, or in thickening and induration of the parietes of the canal, generally with some degree of structure, and in ulceration.

32. B. Thickening and Induration of the parietes of the oesophagus sometimes take place after repeated attacks of inflammation, but generally after chronic inflammation, occurring either in its primary form, or consequentially on the acute state. Thickening of the parietes is usually accompanied with narrowing of the passage, forming permanent stricture or obstacle to the passage of the ingesta into the stomach. This may affect the whole of the canal in a greater or less degree, or it may be limited to any one part of it.—a. The circumstances which especially favour this termination are, inefficient modes of cure; the taking of stimulating food too soon after the acute stage of disease has been subdued; the injudicious use of astringent and tonic medicines, particularly gargles, which have been suggested by the state of the fauces and uvula that I have described as frequently accompanying the different states of the disease; and the strumous diathesis. But I believe that the most frequent cause of this lesion is the use of ardent spirits, as has been proved by the observations of Michaelis (Hufeland und Himly, Journ. der Pr. Heilkunde, 1812, p. 52). This state constitutes the permanent organic structure of Doctor Monaro, and is ablly illustrated in his work on the morbid anatomy of the digestive tube.

33. b. The symptoms of thickening of the parietes, with stricture of the esophagus, are the continuance of dysphagia after the decline of the more acute symptoms; dyspnoea, obscure pain, soreness, and a sense of tightness in the course of the oesophagus; sometimes the discharge of a very tenacious mucus; impaired digestion, despondency, costiveness; and follicle exacerabations. In some cases, a gurgling sound is heard upon attempts at swallowing fluids, and a portion of them is regurgitated, exciting a choking cough. The deglutition of more solid substances is slow, difficult, and painful. The patient often feels the substance lodged some time in the canal; and, afterward, as if forcibly thrust through a narrowed passage. When the stricture is seated low in the canal the portion above it is often much dilated, forming a sac in which the ingesta lodge, and whence they are afterward partly regurgitated and partly pass into the stomach. In thickening of the parietes of the esophagus and permanent stricture, fluid substances are more readily swallowed than those possessed of some degree of consistence; while in spasm of the oesophagus, fluids pass with greater difficulty and distress to the patient.

34. c. Permanent stricture of the oesophagus, although generally resulting from inflammatory action of the kind just described, may occasionally also proceed from a different cause. It may, although rarely, arise from scirrrous degeneration, or from tumours of a fibro-cartilaginous nature developed in the parietes of the tube. I believe, however, that a great proportion of the cases which have been said to be scirrhus of the oesophagus have been only the simple thickening and induration resulting from chronic inflammation. Permanent stricture of this passage may also result from the enlargement of, and pressure upon the tube, occasioned by a cluster of enlarged costal lymphatic glands. If this is, however, a rare occurrence, and is chiefly met with in childhood and early life, in those of a strumous diathesis, and in whom the submaxillary, and other superficial glands, are tubercled; while scirrhus degeneration occurs at an advanced age, and is attended by appearances of the scirrhus cachexia. The dysphagia arising from the pressure of tumours exterior to the tube is seldom or never so urgent as that which depends upon narrowing of the passage from change of the parietal coats. The pressure on the oesophagus produced by aneurism of the aorta, even shortly before its opening into this canal, seldom occasions very marked difficulty of deglutition. This distinction has been judiciously remarked by Mondiere, and is based on the cases recorded by MM. Bertin, Laennec, Bouillaud, Raikem, Ouvrard, and others. This canal may also be partially obliterated from increased thickening—a hypertrophy of the mucous membrane itself, which is also as if puckered or drawn together. In the majority, however, of such cases, there is permanent constriction also of the circular muscular fibres of the part affected.

35. Permanent stricture of the oesophagus, whether proceeding from inflammatory thick-
sour or other formations, or tumours developed in the parietes of, or external to the tube, may be seated in any part of the tube, either at its commencement in the pharynx, or in any intermediate portion between this and its termination at the cardia. Sir E. Home thinks that it occurs through the former cause; but, although this may perhaps be, upon the whole, the part most frequently affected, the other parts are also not unfrequently the seat of this change. It is, however, generally remarked that, even when the disease is confined to the lower portion of the tube, many of the more urgent symptoms are often referred to the lower part of the pharynx and top of the oesophagus.

38. a. The Diagnosis of permanent stricture of the oesophagus is somewhat difficult. This lesion may be confounded with spasm of the tube, with inflammation of the internal surface of the canal, with disease of the cardiac orifice of the stomach, or even with affections of the larynx and trachea; or these maladies may be mistaken for stricture of this tube. The permanence of the symptoms, generally attributed to this stricture, would serve to establish the existence of it in doubtful cases, if such permanence were always observed; but Heinke, Ladd, and others have noticed marked remissions in the symptoms of cases of this lesion. In these cases, the exacerbations have been owing to more or less of spasm attending the permanent stricture. Indeed, when difficulty of deglutition occurs in any of the diseases just mentioned as simulating permanent stricture of the gullet, it is generally owing to spasm. In some diseases of the larynx, or of the stomach, spasm may occur in the gullet as in the case recorded by Mr. Shaw (Loc. Cit. Phys. Journ., vol. xlviii., p. 185). When difficult deglutition is observed in affections of the stomach, or of adjoining parts, and even in consequence of tumours in the vicinity of the tube, it generally is either owing to, or aggravated by flatus rising into this canal from the stomach, the flatus occasioning both obstruction to the descent of the matters swallowed and spasm in parts of the tube. The chief diagnosis, therefore, between permanent stricture of the gullet and other affections is thus actually between the former and spasm of the parietes of the tube.

Permanent stricture is generally consequent upon inflammation, and is slowly and gradually progressive, until deglutition is impossible. When it is far advanced, the difficulty of swallowing is more or less permanent, although exacerbations are remarked in some cases. The difficult deglutition which is occasioned by spasm, and is sometimes caused by disease of adjoining parts, occurs chiefly in hysterical and hypochondriac persons, and in persons and delicate constitutions. When the difficulty is caused by the pressure of serofulose or enlarged lymphatic glands, this circumstance is generally rendered apparent by the state of the neck and throat, and by the appearances and sounds in percussion, near the top of the sternum and sternal ends of the clavicles.

37. C. Ulceration of the oesophagus may occur in consequence of inflammation of its internal surface, in one of two forms: namely, ulceration commencing in the mucous follicles, and ulceration of the mucous and sub-mucous cellular tissue unconnected with change of the state of those glands. It has been considered doubtful whether or no the ulceration, which is seated in, and proceeds from a particular change of the follicles, is actually a consequence of inflammation. It is very probable that obstruction in which the gullet is stricken with ulceration, and that the inflammatory irritation either preceding or accompanying the ulcerative process may be very slight—and possibly of an unhealthy description. I believe, from several instances which have occurred to me among children, that such is the case, and that neither the local appearances nor their causes, nor the attendant circumstances and phenomena, are such as mark syphilitic action, or energetic vital change. This form of ulceration was first noticed by Brunner (De Glandulis Douden, cap. x., p. 136), as occurring in the oesophagus; and I believe that it occasionally proceeds to perforation of the tube, and affects most frequently its lower part, while the next form of ulceration is more commonly found in its upper portion.

38. b. Ulceration which takes place independently of the follicles, I consider to be more decidedly a result of inflammatory action than the foregoing variety. The procession of phenomena in cases of this description appears to be the following: The inflammation of the mucous surface often implicates more or less of its subjacent cellular tissue, and a serous or sero-puriform fluid is diffused in distinct points, elevating, in the form of pustules or minute blisters, the mucous tissue, the detached portions of which lose their vitality and separate, leaving an excavated or ulcerated spot, which extends in width and depth, according to the habit and temperament of the patient, to the cause in which the disease originated, and to the treatment employed. Ulcerations of this description, as well as the preceding, are most commonly met with among infants and young subjects, and are frequently connected in them with softening of the coats of the tube. When ulceration occurs in adult subjects or in persons advanced in life, it is generally accompanied with, if not consequent upon, either thickening or narrowing of the parietes of the oesophagus, or both; and it is usually seated in the part above the constriction, excepting in scirruses of the tube, when the narrowed portion itself often becomes ulcerated, and in this case carcinomatous. But it sometimes is met with independently of either thickening or induration of the parietes of the tube. Ulceration from inflammation of the internal coats of the oesophagus is very seldom seated in several different parts of its surface in the same case, the ulcers of this description being never so numerous as those commencing in the follicles, and rarely exceeding one or two. This kind of ulcer most frequently attacks the upper portion of the canal, and extends from three to eight or nine lines in width. M. Scouetter met with a case in which the ulcer was twelve lines in diameter, and had destroyed all the coats of the posterior part of the tube, and had even laid bare the anterior part of one of the vertebrae. Generally, when the ulcer is large, one only is found. Sir Everard Home thinks that the posterior part, or that applied to the vertebrae, is more usually
the seat of ulceration; but this is not satisfactorily shown. There can be no doubt that this form of ulceration occurs more frequently in the upper part of the tube, while the ulceration which originates in the follicular glands is more usually found at its lower part, and is more frequently accompanied by the prompt upon eruptive fevers and febrile diseases, particularly those characterized by depressed energies of life. Ulceration of the esophagus may occasion ulceration effects of a very important character, previous to its usual termination in death. A case, to which I shall more particularly allude, occurred to me where it occasioned a fatal hemorrhage. And Dr. Monro mentions a case where the ulcer penetrated the trachea and occasioned death, by the escape of matter from the esophagus into the trachea. A similar dislocation of the arch, noticed as having occurred to ZevLin, and another has been seen by myself. **Rupture,** as well as perforation of this tube, may also be occasioned by ulceration.

39. c. Symptoms.—When the ulceration is seated in the anterior and superior portion of the esophagus, posterior to the larynx and trachea, many of the symptoms of laryngitis and tracheitis are observed. An interesting case of this description is recorded by **Palletta** (**Eccentric Pathology**, p. 228). Ulcers in the esophagus are generally accompanied with many of the symptoms which attend simple inflammation of this tube. The pains, however, are usually more acute, particularly upon deglutition; sometimes there is vomiting of a glairy matter, generally streaked or coloured with blood. Solid substances are swallowed with difficulty, but fluids, when taken in considerable quantity, pass with more case. Salivation often occurs during the last stage of the disease. M. *Mouyrens* mentions a case in which a large ulcer of the esophagus was seated near the cardia, and where the patient, during the four months he was under treatment, complained of a burning sensation at the superior part of the epigastric region. This patient frequently rejected rounded and purulent matter, a symptom noticed both by **Palletta** and *Leroux*. In some rare cases, the ulceration may give rise to sudden death from hemorrhage. A case of this description occurred to me a few years ago in an aged female who had been under my care for several years, and had undergone a series of digestive organs, accompanied with porosis. A few days previous to her death she was affected with esophagitis complicated with pharyngitis, and attended by a constant hacking cough, and great depression of the powers of life. I was suddenly called to her about the eighth or ninth day of the attack for sudden and profuse discharge of blood, which was described as having been ejected upward without evident effort; but before I reached her she had expired. The quantity of blood thus discharged was very considerable. Upon examination the stomach contained about a pint and a half of blood partly coagulated, and its coats, particularly the mucous coat, were considerably softened. The pharynx was of a dark colour, in patches, some of which were of a purplish tint. In the upper third of the esophagus, towards its anterior parietes, upon the left side, was a large irregular ulcer, which had destroyed, in some points, the mucosal coat, and in all, the mucous and submucous tissue. The internal surface of this part of the tube, particularly around the ulcer, was of purple hue, tinctured, soft, and easily torn. The bottom of the ulcer was of a deep red colour, and the subjacent parts red, vascular, and injected. The hemorrhage had most probably arisen from erosion, by ulceration of some of the terminal vessels.

40. Ulceration, perforation, and rupture, in consequence of ulceration of the parietes of the esophagus, are generally followed by death with more or less rapidity; and, until shortly before death, the patient may not have come under treatment, either from the slowness or neglect of the symptoms. Instances have even occurred in which sudden death has taken place, the patient not having had recourse to medical advice, and, in such ulceration, a large perforating ulcer has been found in some part of the tube. In a case of this kind which I saw, the ulcer was seated a little above the cardia.

[A case of cancer of the esophagus, opening into the right lung, has been recently reported by Dr. Jackson in the New-Eng. Quarterly Journ. of Med. and Surg., Oct., 1842, p. 253. The patient was a female, 53 years of age, and for the last 8 or 10 she laboured under difficult deglutition, with regurgitation of food, but without pain in the neck. The skin was generative, and the body quite emaciated. Latterly, she had hemorrhage from the bowels, and shortly before death was seized with acute pulmonary symptoms. The disease was found to have commenced two inches and a half above the inferior extremity of the tube, extending upward in front of an inch, and behind 21/2 inches. The cavernous surface was ulcerated, soft, ragged, and of a whitish aspect, not unlike eucaphalic. The cut edge exhibited no trace of the original structure. At the centre of the diseased mass, on its anterior surface, was a perforation through into the substance of the right lung, which was gangrenous at this part. The descending aorta adhered to the altered portion of the tube, and had upon its outer surface, near this point, an apparently malignant deposit.—(Gross.)

41. **Scurvy ulceration,** or carcinoma of the esophagus, most frequently occurs either at the upper or the lower extremity, more frequently extending from either the pharynx or the cardiac orifice of the stomach, than affecting the tube primarily. It rarely or never appears without being attended by the lancinating and burning pains, and the carcinomatosous cachexia characteristic of this disease.

42. d. The prognosis of inflammation and permanent stricture of the gullet should necessarily depend upon the causes, progress, complications, and severity of the disease. Acute and sub-acute esophagitis, in which the prognosis is generally more favourable than in the chronic state of the malady and in permanent stricture, should be viewed as a most serious disease, as respects either its more immediate results, or its contingent consequences; and it is still more so when it occurs in cachectic habits and in the course of exanthematos and continued fevers. When it is caused by powerful stimu-
lants or irritants calculated to produce a local effect merely, without directly disorganizing the parts, or remarkably depressing the vital power, it is generally removed by appropriate means; but when it is caused by agents which occasion these injurious effects, and which even extend from thence to adjoining parts, the prognosis should be very unfavourable. When the symptoms indicate the passage of the acute or sub-acute into the chronic state, a caution is due, if not an unfavourable opinion ought to be formed of it; and when they indicate the suprervision of stricture or of ulceration with or without stricture, the prognosis should be very unfavourable, although the result may be long delayed. The history of the case, the previous health and present state of the patient, and the effects of treatment, ought always to be duly estimated in the opinion which is to be formed as to the result.

43. TREATMENT.—A. Of acute Esophagitis.

43. A. General and local bleeding is indispensable in this state of the disease. Bleeding from the arm should never be neglected; and afterward local depletion may be employed, either by leeches or by cupping. In esophagitis, the local blood-letting recommended by Celsus Aurelianus, viz., the opening of the sub-lingual vein, may be practised. It has received the sanction of the greatest, even in the present day, of practical authorities, that of Hoffmann, as well as of Janson and others. Hildenbrand recommends the application of leeches in preference to cupping: in children, either or both may be employed, according to circumstances. When the local depletion is directed to the throat, leeches are certainly preferable. Next to depletion, as perfect inaction of the tube as possible should be enforced. The patient should be deprived of all ingesta, excepting cooling fluids, which may be used merely to moisten the mouth and throat, without attempting to swallow them. After the acute symptoms are removed, and the necessity of having recourse to light nourishment is urgent, the blandest and most mucilaginous substances, in a semifluid form, and of the temperature of the blood, may be taken. The patient should at the same time be kept quiet, not be allowed to talk, and have the bowels freely evacuated by cathartic enemata, which, while they procure the evacuation of accumulated and hurtful materials, may occasion a derivation of the circulating fluid to the lower part of the digestive tube. In the slighter forms of esophagitis, these means, even without any considerable depletion, will be often sufficient to remove the disease.

44. b. When it is necessary to exhibit medicines by the mouth, particularly those of a purgative nature, my experience leads me to prefer a full dose of calomel, either alone or combined with James’s powder, exhibited in a semi-consistent substance. The advantages resulting from the use of calomel are, that it diminishes the phlegm which it passes immediately after, while it occasions vascula-ry derivation to the lower part of the intestinal canal. It may be mixed in some sweet butter, which should be allowed to melt gradually and pass insensibly along the esophagus, the mouth being guarded by subsequent ablation. When it is necessary to act decidedly on the bowels, and yet prevent the increase of thirst—one of the most distressing symptoms of the disease—the superatrate of potash, with a fourth part of the sub-borate of soda, given in the form of electuary, and combined with congestion of senna and the insipid juice of elder-bibes, is one of the best means that can be employed. If the inflammation be attended with much spasm of the tube, or if an irritable state of it still continue after depletions, or if the modified condition be apparently still unsubdued, the hydrochlorate of ammonia or nitre should be prescribed in the form of linctus or mixture with mucilages, sirops, and anodynes, in frequent doses, and these, swallowed gradually and often, will generally afford marked relief. When the upper part of the tube is affected, some benefit may be procured from the use of emollient fomentations and poultices to the throat, particularly after the application of leeches to the part.

45. c. Rectuviae or derivative means are sometimes of service, especially when they follow, as they always should, vascular depletions carried as far as the state of the case may require. Revulsions ought to be prescribed in a decided manner; for, in order to be beneficial, the artificial irritation should surpass in degree that which it is intended to supersede. The irritation of blisters while inflammatory action remains unsubdued will often chiefly tend to increase febrile commotion, and thereby to augment the local excitement. As to the means of derivation and the situation of applying them, opinions are various. Bleuland recommends blisters and moxas to be applied between the shoulders. Many prefer sinapisms and irrita-tating pedulvia. The turpentine embrocation or epitaph applied to the throat and sternum, or between the shoulders, or a mustard poultice in the same situations, are the most decided and the most rapid in their effects. Either of these may be used for children; but blisters ought not to be applied to them for a longer period than three or four hours, when a warm bread and water poultice should replace them.

46. d. Esophagitis, in various degrees of activity, is not infrequent in children, but it is often complicated with inflammation of the fauces and pharynx, or with bronchitis, or with inflammation of the visous surface of the stomach, and is generally seated in the mucous membrane, seldom extending deeper than the submucous tissue. In them, also, the mucous follicles are often chiefly implicated. The local affection is, moreover, often associated with weak vital power, and sometimes with general cachexia—circumstances which require a very modified practice. After active inflammatory action has been subdued by depletion, or independently of depletion, in this latter class of cases, I have derived much advantage, particularly in the complications now alluded to, from the hydrochlorate of ammonia, or the sub-borate of soda given in honey, or in the insipid juice of elder-berries and syrup of marsh mallows, or of roses.

47. e. Esophagitis, complicated with the inflammations just mentioned, requires very nearly the same treatment and regimen as above recommended; but when it supervenes in the course of eruptive or continued fevers, very different means are necessary, and particularly when those fevers acquire an asthenic or ma-
lignant character. I have seen several cases of this description in children and young persons, and have never obtained in them any advantage from vascular depletion, except from a cautious recourse, in some cases, to local depletion. The mineral acids, particularly the muriatic, camphor, the pyroglycine acid with camphor, the boracic acid, and sub-borate of soda, small doses of the sulphate of zine, or of the sulphate of quina in confection of roses; the solution of the acetate of ammonia with camphor mixture and the decoction of marsh mallow, the hydrochloria of small ointment or the nitration of potass in the sirup of roses, &c., are severally beneficial in these associations of the disease. When esophagitis is complicated with pharyngitis, as observed in the more malignant states of sccharlatina, or in other exanthematos and continued fevers, the sulphate of quina, the preparations of echinola with camphor or the mineral acids, particularly the hydrochloria; or the decoction of bark with the chlorate of potash; or small doses of the chloride of lime in nacy or sirup, may be prescribed: the derivative means above noticed (§ 45) being also employed.

48. B. The sub-acute and chronic states of esophagitis require similar means to the above, but in a less active form. In these, local depletions are often required, and they may be repeated according to circumstances. Purgatives are generally also necessary. The frequent use of refrigerant, demulcent, and soothing liniments and mixtures, as almond emulsion or sirup of marsh mallow with hydrocynam, or lady's-lazulies with such a small quantity of ammoniac or nitre, should not be neglected. In some cases of the chronic as well as of the acute form of the disease, calomel or the gray powder may be mixed with a little fresh butter and placed upon the tongue. As this melts, and is gradually and slowly swallowed, a healing effect is produced by it upon the inflamed surface. When there is reason to infer the existence of ulceration, this is often of service. If the bowels require further aid, enemata should be administered. As a series of changes from the more permanent derivatives, as blisters frequently repeated, or kept open and freely discharging, and putulation by means of the tartarized antimonial ointment, or of croton oil, rubbed in the situations about to be mentioned. In the more obstinate cases, moxa may be applied, or an issue made near the top of the sternum, or a seton inserted in the nape of the neck.

49. For permanent structure (§ 31), as well as for ulceration (§ 37) of the esophagus, the same means as have been advised in the treatment of esophagitis and this list is employed. If these fail, after having been fully and appropriately tried, surgical aid should be obtained, and dilatation or cataractation be had recourse to. But of these and other surgical measures it is not my duty to treat.*

* (Surgical operations for the relief of organic obstructions of the esophagus are rare. For a very interesting and instructive case of this kind, by John Watson, of New-York, see Am. Jour. Med. Sci., vol. viii. N. S., p. 269. In this case, which was of several months' standing, the obstruction existed about the middle of the esophagus, which was cannulated so as to enable admittance of a small bougie. The patient subsisted entirely on fluids, was free from cough, had no pains of any sort, no soreness or tenderness about the throat, either from pressure or from attempt to swallow. He was feeble and much emaciated, had

III. HEMORRHAGE FROM THE ESOPHAGUS. — SYNON. ESOPHAGorrhagia; Blutung aus der Speiserohre, Germ. CLASS. — See art. HEMORRHAGE.

50. Hemorrhage very rarely takes place from the esophagus, unless from mechanical injury. When occurring spontaneously, the source of the hemorrhage is ascertained with great difficulty during the life of the patient. Blood effused from the internal surface of this tube is seldom excreted directly upward, but generally passes almost insensibly into the stomach, where it is partially digested, and escapes in the other way. In the case of the hemorrhage, if it be in small quantity, or is reunited, if the effusion be very considerable. In this latter case, hemorrhage from the esophagus simulates HEMORRHAGE FROM THE STOMACH (which see). The chief circumstances which lead us to suspect, when blood is discharged upward in any way, that it is effused from the internal surface of the esophagus, are the symptoms of previous disease of this part, especially pain and heat in the

a frequent and copious flow of saliva and mucous from the mouth; the thyroid bodies were larger than usual, and one or two lymphatic glandular swellings existed on either side of the throat. The appearance of the 'nodes of the anterior cervical glands, if free from inflammation, the tonsils were not enlarged. Everything about the fauces appeared perfectly healthy, and the palate was not hemorrhagic. Alcoholic and trying simple bougies and catheters, an altered bougie was passed down to the structure, and a piece of linear cartilage, as large as a pin's head, allowed to melt at the seat of obstruction. This afforded no relief, although repeated on the day following. The patient was then supported by nostril injections for ten days, which were subcutaneously administered, through a very small catheter introduced into the tube. They consisted of beef-tea, both containing boiled flour, boiled starch and arrow-root, boiled eggs, and such other articles as were thought necessary to enlist the appetite and to raise the patient's spirits. The patient was discharged with a marked effect in recruiting his strength and in assuaging the sense of hunger. They increased the volume of the pulse and the fullness of the capillary vessels; but at times they excited torpor, and occasionally purged him, especially when highly seasoned with salt. All other resources failing, the esophagus was laid open, opposite the thyroid cartilage; the patient's life was then saved. The tube was then cut away, and he sank and died, three months after the operation.

On examination after death, the pouch of the pharynx and upper part of the esophagus were lined with a membranous, the whole surface of the ulcer being irregular, and of a greenish colour; its upper and lower edges were ragged and irregular, of a pale yellowish colour. The muscular layer was composed of a pale, yellowish white colour, varying in size from that of a pea to a small nutmeg; and seated in the sub-mucous cellular tissue. Some of them had broken down in the centre, so as to admit a probe to pass through them and under the tissues, among which they were situated. The mucous membrane, over a great part of the ulcer, was wanting, or hung in shreds, or was burred and undermined. The septum between the gullet and trachea was perforated in two places on the esophageal surface, both of which were like irregular, longitudinal slits, a quarter of an inch or more in length, one just under the lower edge of the incised cartilage, the other two inches lower down. Below the ulcer, the esophagus was healthy throughout, and of its usual extent.

Permanent contractions of the esophagus are generally considered as the result of cicatrices, but the disease in the presence of ulceration is according to Dr. W. J. III. of a teresulous character. This was clearly shown by the large tubercular masses imbedded in the surrounding tissues. There had been recurring pains, with the latter appearances of sears. Dr. W. mentions another case which came under his care, which had a similar origin, and one which resulted in an attempt to swallow a piece of food. In another case, which occurred in the New-York Hospital, structure of the esophagus was produced by attempting to swallow a solution of corrosive sublimate. This was cured by repeated dilatation of the caudal by means of a 1st stomach tube. There are but four cases of esophagotomy on record in the living subject, according to Dr. W. and Steele, and on account of which I have had a failure of relief of structure. For these cases, and for some very judicious practical observations on organic obstructions of the esophagus, see the 9th vol. Am. Journ. Med. Sciences. loc. cit.)

II. 132
the course of the canal, with difficulty of, and increased pain on, deglutition; and a sense of heat and titillation behind the trachea, in the situation of the tube. Haemorrhage seldom or never occurs in this part of the digestive canal, unless from pre-existing disease of a severe character, as inflammation terminating in ulceration, a case of which I have had an opportunity of observing; or from the presence of a foreign body lodged in the canal, circumstances tending to facilitate the diagnosis; but without which it will be difficult to determine whether or no the haemorrhage proceeds from the stomach, or even from the respiratory organs. The phenomenon already alluded to is calculated to confound it with hematemesis, while the cough, which frequently accompanies disease of the esophagus, particularly when seated in its upper portion, is likely to mislead us, and to suggest its origin in pulmonary disease.

51. Treatment.—When the source of the effusion is tolerably manifest, the treatment differs but little from that which is indicated in haemorrhages from other parts. It should have reference to the states of vital power and of vascular tone. Esophageal haemorrhage very rarely occurs under circumstances requiring general or even local blood-letting. The application of cold externally—as a stream of cold water poured on the throat; the use of ice, or the lemon ice, or cordials and other astringents internally, particularly in the form of linement or electuary, or in any semiliquid vehicle, are means which should never be overlooked. The most certain remedy, however, in these cases, is the spirits of turpentine mixed with honey or the yolk of an egg, and taken in repeated doses. In addition to these, hot pediluvia, cathartic emenata, sinapisms, blister, and other derivatives, may be prescribed. As haemorrhage from this part is generally consequent upon chronic esophagitis and ulceration, the same treatment as already recommended for these diseases (§ 48, et seq.) should generally be instituted after the effusion has been arrested.

IV. SPASM OF THE ESOPHAGUS.—SYN. SPASMODIC STRUCTURE OF THE ESOPHAGUS. ESOPHAGOSPASMUS; DER SPEISERÖRENKRAMPF, GERMAN. ESOPHAGISMUS, FRI.

CLASS.:—H. CLASS, I. ORDER (Author).

52. Definition.—Difficult and painful deglutition, occurring either suddenly, and without evidence of previous disease of the esophagus, or as a symptom of such disease, and of several nervous affection.

53. This affection has attracted but little attention, although the justly celebrated Hoffmann wrote a treatise on it (De Spasmo Gulae Inferiores, Hube, 1783). It is, I suspect, in its slighter forms, more frequently brought before the physician than recognised by him. It forms a most distressing part of the series of morbid phenomena which characterise the hypochondriasis, and hypochondriasis; and it constitutes the form of dysphagia which is sometimes met with in delicate and nervous females, particularly those in whom the uterine functions are disordered, or the uterus itself in an irritable and slightly inflamed or congested state.

54. i. Causes.—The circumstances just alluded to may be viewed as predisposing causes of this affection. It may also be considered as occasionally appearing hereditarily, particularly in connexion with the nervous temperament and delicate and hysterical constitution. The most common exciting causes are swallowing cold fluids when the body is perspiring; fits of anger or passion in nervous or irritable persons; the irritation occasioned by the ingestion of acid, unwholesome, and injurious substances; and flatus rising to the canal and causing spasm of one part and dilatation of another part adjoining the former, particularly upon attempts at deglutition. Owing to this last cause, temporary spasm of the esophagus is not an infrequent occurrence during the course of dyspeptic, hysterical, asthmatic, and hypochondriacal affections. Indeed, the dysphagia often attending the slight or imperfectly developed form of hysteria, consisting chiefly of the globe, or of borborygmi, is entirely owing to esophageal spasm; or, rather, this spasm is chiefly the cause of these phenomena, especially when a portion of the tube is distended by flatus. That spasm of this tube is often symphomatic of inflammations or irritations of the stomach, and of the uterus and ovaria, is fully established. Hoffmann states that it is often attendant upon inflammation of the upper portion of the spinal marrow. It has also been caused by mania, by worms rising into the canal from the stomach, by sea-sickness, by excessive retchings or vomitings, by menstrual or uterine irregularities, and even by powerful mental emotions, particularly those of a depressing kind. It forms a most distressing symptom of rabies, and is a chief cause of the distress which attends at deglutition occasion in that malady; although spasm of the pharynx is also present in that as well as in some other diseases in which it is a prominent phenomenon. (Esophageal spasm is occasionally caused by the influence of the imagination, as shown by impossible deglutition, or the forcible regurgitation of a substance through the mouth or nose, when disgust is conceived against it, and by attempts to take disagreeable medicines by children or even grown-up persons. Gräfengäisser says that he has seen this spasm produced by electricity. It has already been stated (§ 19, 20) that it heightens the distress in cases of acute, sub-acute, and chronic esophagitis.

55. ii. The Symptoms of Esophageal Spasm are chiefly the sudden occurrence, without previous disorder referable to the esophagus, of difficult or even impossible deglutition, and pains excited by attempts to swallow that are felt in some portion of the tube. The symptoms vary with the part of it affected. When the spasm is seated at the top of the esophagus and pharynx, then deglutition is almost or altogether impossible, and substances are forcibly rejected. When it is seated in the lower portion, then the morsel swallowed is arrested at its seat, and the attempts at deglutition are rejected, or remains there for a considerable period, when it slowly passes into the stomach, or is violently ejected from the canal. If the spasm be attended, or is caused, by fluent distention of a portion or portions of the tube, attempts to swallow are often very painful, difficult, or even choking; but the distress is relieved, or entirely removed, by eructations of flatus, the dysphagia occurring only at the com-
mencement of eating, although it sometimes only occurs towards the close. In some in-
stances the most urgent distress or the induced
by the retention of the substances swallowed
in the oesophagus, attempts to pass them into
the stomach or to reject them being equally
unavailing. I have seen this occurrence con-
ected with the presence of flatus in the tube.

56. The nature, consistence, fluidity, and
influence of the substances taken often in-
fluence, or aggravate, or alleviate the symp-
toms, but in no uniform or definite manner.
In some cases, fluid or warm substances are
most easily swallowed; in others, consistent or
putrid, cold must be forced.

57. The duration of this affection varies with
its causes, and with the disorders of which it is a
symptom, or with which it is associated.
It may be, hence, of very short continuance,
and may not again recur; but where it has
once appeared it generally returns after irreg-
ular intervals, or upon the recurrence of its
causes. When symptomatice of, or associated
with, any of the disorders above alluded to, it
is very prone to recur as long as the exist,
although it may be removed for a time, or pre-
vented from recurring, by attention to diet and
by treatment. Fear of its occurrence often as-
sists in occasioning an attack, as well as in ag-
gravitating its severity.

58. iii. Treatment.—The cure of this affec-
tion, which, as above shown, is most frequent-
ly symptomatice, must necessarily depend upon
the nature of its pathological cause and rela-
tions. When it seems to arise from inflamma-
tory irritation in the oesophagus itself, the
means advised for acute and chronic oesopha-
gitis (§ 43, 48) should be employed. If it ap-
pear to proceed from irritation and debility of
the stomach, as frequently is the case, particu-
larly when it is attended by flatus, the treat-
ment recommended for the more inflammatory
states of indigestion (see that article) is ap-
propriate. When it accompanies other hys-
terical phenomena, or inflammatory irritation,
or congestion of the uterus or ovaria, or irreg-
ularities of the catamenia, the means prescrib-
ed for those affections (see Hysteria, Men-
struation, Ovaria, and Uterus) should be pre-
scribed.

59. In most instances, however, whether
idiopathic or symptomatice, means directed to
the affection itself should be employed, linctu-
ces or denucleate mixtures, containing a combi-
nation of narcotics or anodynes with antispas-
matics, as the sirup of poppies, or the com-
pound tincture of camphor with small doses of
borax, or of nitre, or of the hydrochlorate of
anodyne, the former in small doses, the latter in
large doses of belladonna in mucilage and the sirup of or-
ange pecl; or the bitter infusions with these,
or with the preparations of henbane or hemi-
lock. At the same time, a belladonna or cam-
phor platter, or a platter containing both these
substances, may be applied to the throat and
upper part of the sternum. A portion of the
following embrocation, sprinkled on warm flan-
nel and applied to these parts, is the most im-
mediately efficacious of all other applications
that I have employed.

60. Having removed the affection by these
or similar means, the return of it should be pre-
vented by the means directed to the disorder of
which it is frequently a symptom. If it pro-
ceed chiefly from chronic debility and nervous
susceptibility, tonics and antispasmodics, with
generous diet, pure air, and regular exercise,
should be enforced. If it arise from an irritable
or torpid and weakened state of the digestive
organs, stomachic aperients, tonics, antispas-
matic and purgative emuncta, &c., ought to be
given. If it be caused by functional, or con-
egestive, or inflammatory states of the female
organs, the local remedy of nasal, or other
means recommended for the removal of these
states, especially antispasmodics, emen-
ga-gues, chalybeate preparations, pure air, reg-
ular exercise, and chalybeate or alkaline min-
eral waters, should be prescribed. In cases of
frequent recurrence of oesophageal spasms, par-
ticularly when it is connected with hysteria,
much advantage will be procured from chewing
a piece of camphor, or from holding a piece of
it in the mouth, so that the salva is imbued
with it. In those cases, and in others, the various
kinds of ices, or even iced waters, will be found most useful palliatives.

V. PARALYSIS OF THE OESOPHAGUS.—Palsy of the Gullet. MONRO.

CLASS.—Sec art. Paralysis.

61. Dr. Monro remarks that there are various
degrees of palsy of the gullet, and that in many
diseases accompanied by great debility, a tea-
spoonful cannot be swallowed, while the con-
tents of a larger spoon readily pass down. The
loss of power of deglutition is so frequent in
some cases and slow in others. In many, a difficulty of
swallowing solids only is perceived at first;
and often the effort of deglutition is attended
by much agitation of the frame, amounting in
some instances to convulsion. The throat ex-
hibits nothing uncommon, excepting paleness
and flaccidity of the uvula and fauces. When
difficult or impossible deglutition depends upon
palsy, it is persistent or continued; and the
easy passage of a probang into the stomach
shows that it is not owing to any mechanical
obstruction. In many of those the oesophagus is gen-
ernally associated with palsy of some other part
or parts, palsy of it alone being extremely
rare. I have seen palsy of this tube associated
with palsy of the pharynx and of the muscles of
arteculation, no other part being paralyzed,
in three or four cases, all of which terminated
fatally. It is sometimes symptomatice of hy-
s teria, and it often attends apoplexy, hemi-
plegia, and the last stages of fever and other acute
diseases, in all which it is generally a fatal
symptom. I have seen cases, also, as well as in
cases of hysteria, with spasm of the gullet, in the course of se-
vere and anomalous forms of hysteria, the
most favourable mode or form of its occurrence.

62. A. The diagnosis of palsy of the gullet
is easy. The continued difficulty of swallowing
small quantities or volumes of any substance,
while larger quantities are taken with greater
case, distinguish this affection from spasm of
the tube, while the passage of a probang shows
that there is no permanent obstacle. In the
slightest or most irregulare those in the
phenomena of deglutition, some patients swal-
lowing more easily solid than fluid or semifu-
clid substances, while others can take the latter
with most ease. Some swallow with rapidity, or endeavour with great effort to project the morsel through the canal; others accomplish it slowly, and others, again, require the aid of fluids to perfect the act. When the palsy is complete, then deglutition is impossible. The alimentary bolus is then arrested in either the pharynx or the oesophagus, as the case may be. It may even pass into the larynx, and cause cough or suffocation. Owing to the want of power of swallowing the saliva, a discharge of this secretion from the mouth is usually observed.

63. B. The causes of palsy of the gullet are rarely such as act directly on this tube. They are to be looked for at the origins, or in the course of the nerves supplying this part and the pharynx, particularly of the pneumogastric. Baglivi, Valsalva, Depuy, and others, have shown that animal which have died after division of these nerves were incapable of swallowing, and have retained the aliments in the oesophagus; and cases have been recorded by Köehler, Wilson, Flandin, Montant, Esquel, and others, in which this form of palsy was owing to hydatides, tubercles, cysts, tumours, or other organic lesions, at the origin of these nerves, or at the base of the cranium, or in their vicinity. Palsy of the gullet is often a part, and even the most important and prominent part of the palsy, so frequently observed in the most severe and other cases of insanity.

64. C. The treatment should depend upon the cause of which this affection seems, in each case, to be the effect. If it proceeded from congestion or pressure at the origins of the nerves, local depletions and permanent derivatives are required. If it be viewed as the result of tumours of any description pressing upon the nerves of the tube, the preparations of iodide, particularly the iodides of potassium or of mercury, or a solution of the bichloride of mercury, may be employed. In a case recorded by Wilson, this affection was caused by venereal exostosis of one of the cervical vertebrae, and was cured by anti-venereal treatment. Doctor Monro adduces two cases which were cured by electricity, which agent, however, is not suitable for cases arising from organic disease at the origin, or even in the course of the nerves. Blisters, mustard poultices, stimulating liniments or embrocations, ointments, containing strychnine, &c., applied to the neck, throat, or upper part of the oesophagus, were used in these cases.

65. VI. Foreign Bodies in the Oesophagus.

—Fragnents of bones, or other hard, or solid, or sharp bodies, are not infrequently swallowed and arrested in some part of the gullet. The usual consequences, when they are allowed to remain for any time in this situation, are inflammation, suppuration, ulceration, and ultimately even perforation of the parieties of the tube.—A. The symptoms vary with the size and form of the foreign body, and with the position of it in the parieties of the tube. When it is lodged; but there is always severe pain, referred usually to the throat, upon attempts at deglutition, which is generally attended by spasms and by more or less difficulty, or complete inability to accomplish the act. If the body be large and arrested in the upper part of the tube, or near the pharynx, there are also various strangulating and almost suffocating paroxysms of cough. When angular or sharp bodies continue long in the oesophagus, they may not merely perforce the parieties, but even ulcerate or perforate adjoining parts, as an important artery (Kirby), the trachea, &c., or produce caries of a vertebra (Velpaeu), and in still rarer instances, dilatation of the gullet above the seat of mechanical obstruction.

66. B. Leeches are sometimes swallowed, when drinking water from pools incautiously, and, fastening themselves to the parieties of the gullet, sometimes occasion severe and peculiar symptoms. Accidents of this kind have been noticed by Galen, Celsus, Pliny, and Dioscorides, and in modern times by Larrey, Double, Duval, and others. M. Velpaeu states that, besides the pain, they produce a peculiar sensation of suction, with difficulty of swallowing, followed by vomiting of blood; and sometimes by very severe nervous symptoms.

67. C. The treatment of these accidents is more surgical than medical. When the foreign body can be extracted, to attempt extraction is preferable to pushing it by a probe into the stomach. The nature, size, shape, and chemical composition of the body should guide the physician in his opinion as to the propriety of attempting extraction or the other alternative. In some cases it may be advisable to try the effect of an emetic, when this can be passed into the stomach; but the propriety of having recourse to this treatment should depend upon our knowledge of the obstructing body. In the case of leeches adhering to the sides of the tube, enemas may be employed without risk.

As to the surgical means, I must refer to modern works in which this subject is treated.

BIBLIOGRAPHY AND REFERENCES:
OSSEOUS SYSTEM.—INFLAMMATION OF BONES.

Classifi. — Special Pathological, and Pathological Anatomy.

1. The bones are liable to the same diseases as other parts of the frame; to similar changes of both a constitutional and a local nature to those which affect other structures. Many of these changes are merely results of inflammation arising generally from local causes, but are always injurious, and sometimes even produced by constitutional peculiarity or diathesis, or by a vitiation of the fluids and ultimately of the solids of the body, as observed in scrofula, gout, fever, scurvy, &c. Other changes, and these the most serious and often the most dangerous, appear independently of inflammation, and are more or less the result of constitutional vice, although frequently excited or developed by local causes, as by contusions or other injuries. I shall consider, first, inflammations of bones, and their consequences; and, next, the organic lesions of bones that appear independently of inflammation, although often accompanied with it in their course.

I. INFLAMMATION OF BONES.—SYNON. Ostætitis (from ostæa, a bone). Ostæitis; Inflammation ossium. Ostæite, Inflammation des Fr. (Knockeuzenndung, Gutm.

Classifi. — III. Coass, I. Order (Author).

2. Defin. — Pain in the situation of a bone, increased upon firm pressure, or when sustaining a weight, with more or less swelling, and often with symptomatic fever, the substance of the bone being increased in vascularity, and often otherwise changed.

3. i. Seat and Anatomical Characters. — Inflammation may attack the substance of a bone and be limited to it; or may affect chiefly the periosteum, or the medullary membrane, and extend thence through the substance of the bone, or may extend from the latter to these membranes. In either case the inflammation may affect a portion only, or it may extend to the bone, or to the articular extremity. When commencing in the external or internal layers of the bone, it often is confined for a long time to them, but it frequently extends to the whole structure, especially in the spongy bones, and in young subjects.

4. Ostæitis is generally a chronic disease, or it is rarely so rapid in its course as inflammations of other organs: a circumstance manifestly owing to the nature of the osseous structure. Of the most acute or rapid forms of the disease are usually from several weeks to some months in duration, while the worst cases may endure for several years.

5. Ostæitis may occur in any bone, but it is most frequently observed in the more superficial bones, and in the more spongy and vascular in their structure. The bones of the hands and feet, the bodies of the vertebrae, and the articular ends of long bones, are the parts most frequently affected.

6. The principal changes consequent upon inflammation of the bones are, increased size of all the vessels running through the vascular orifices and canals; vascular injections in parts which usually do not contain red blood; and a somewhat reddened and swollen state of the affected bone. In the more prolonged cases,
the cells and canals increase in size, are irregular, or partially run into each other by absorption of their walls, and are filled with a sanguineous lymph, so that the fine membranes lining them are found somewhat thickened. The proportion of lime in the bone is sometimes more or less reduced, according to the duration and intensity of the inflammation; and occasionally the periostium is thickened and relaxed, particularly when the disease commenced in it, and then the surface of the bone is usually rough and porous.

7. ii. Causes.—Osteitis is more frequently met with in children than in adults—a. The predisposing causes are the rheumatic and gouty constitution, the scrofulous diathesis, and the scrobutic and syphilitic contamination of the frame. Of these, the scrofulous, syphilitic, and scrobutic vices are the most influential—b. These often also excite osteitis. Rheumatism frequently attacks the fibrous tissue covering the bones, and the inflammation, thus originating, often extends to the bone itself, and terminates in caries. Articular osteitis occurring in adults generally originate in rheumatism. Gout occasionally excites articular osteitis, chiefly in persons advanced in age, and after repeated attacks. Scrofula is a most influential predisposing and exciting cause of osteitis, in both children and adults, particularly in the short bones, and in the spiny ends of long bones. It also favours the passage of the disease into caries. Severe gradual affects the bones until it is far advanced, and then it implicates the dense structure of the bones, rendering it softer, and favouring the rapid superinfection of caries, as fully shown by M. J. L. Petit. Syphilis inflames the bones often consecutively upon periositis, and frequently gives rise to exostosis. Exhaustion of vital energy, venereal excesses, and masturbation, fevers, and visceral disease, also favour, and even directly cause osteitis; but in these cases the vertebrae are the parts most frequently affected.

8. c. The more local causes are usually exciting only, and often concur with the preceding in developing the malady. Every kind of external or local injury, as fractures, contusions, wounds, pressure, &c.; intense heat or cold applied to an extremity or part; inflammation, particularly those which are chronic, in the immediate vicinity of a bone; and suppuration, or purulent collections coming in contact with it, are the most common and active causes.

9. iii. Symptoms.—At the commencement of osteitis the patient feels a dull, sometimes an acute pain within the bone or deeply seated. The pain is increased upon firm pressure, and upon any exercise that affects the bone, as standing upon it, or supporting a weight by it. This is often the only symptom for a considerable period. After a very variable time, a short period before the swelling may be expected by passing the fingers over the seat of pain, unattended by any discoloration of the surface. The swelling is hard, and commences with the surface of the bone; and, although the substance of the bone is generally more or less trenched, still, the chief part of the swelling that is detected is owing to inflammation of the periosteum covering the affected bone.

10. The progress of osteitis is always slow, owing to the low vitality and structure of the affected part; but sometimes the pain becomes extremely acute, and the swelling increases more rapidly, the disease assuming a more acute form. This state is most common to venereal osteitis, and is not readily distinguished from periostitis, excepting that the pain is referred to the bone itself at the commencement, and that the swelling is at first very slight, and the progress of the affection slow. When the swelling is caused by periostitis, its progress is more rapid than that of osteitis, it advances farther, is less hard, and becomes at last somewhat soft and elastic. The aching nature, the persistence and the seat of pain, with the modifications of it by position, exertion, &c., are the chief guides we possess as to the existence of inflammation of deeply-seated bones.

11. When the inflammation implicates the medullary membrane lining the canals of long bones and the cells of the spongy structure, this membrane is injected, red, and, according to Losterin, more dense; and the marrow is augmented in volume, as well as the fluid contained in the cells of the spongy structure. Inflammation of this membrane is not infrequent after amputations, and is then sometimes propagated from the amputated surface along the whole medullary canal. It is attended by the same symptoms as those characterizing osteitis; but, when following amputations, it is not so painful, is more rapid in its progress, and more readily passes into suppuration, than in other circumstances, and other states of osteitis.

12. iv. The terminations or consequences of osteitis are, resolution, exostosis and induration, suppuration, gangrene or caries, and necrosis.—A. After resolution, the structure inflamed regains its former state, but the swelling generally continues for some time after pain has disappeared.—B. Exostosis and induration are sometimes associated results, while either may occur singly. The indurated portion of bone assumes an ivory or dense appearance, more especially in some exostoses. The increased deposition of bony matter—exostosis—hyperostosis—occurs as internal and external exostosis. The former, in a lesser degree, is a usual consequence of inflammation, the deposition of bony matter in the diploe necessarily increasing the weight and solidity of the bone. If the inflammation have been of very long duration, the more the weight and solidity of the deposit are increased, the part assuming an ivory state, and the medullary cavity being encroached upon by the deposition.

13. The external form of increased deposition of bone is more common than the internal, and is often injurious. In some cases, the bony deposit takes place in the loosened periosteum, which first becomes carthaginous, and afterward hard and formative, a bony tumour or granula. In others, the bony deposit occurs in the outer table of the bone, forming a localized and defined prominence—a bony tumour or external exostosis. An exostosis may form simultaneously in the internal and external surface of a bone. This takes place chiefly in the bones of the skull. These bones and the tubular bones are the most frequent seats of
exostosis, and next to them the vertebral and pelvis; but they may be produced on any bone, or even on several bones at the same time. They often form in a considerable number in the vicinity of cartilaginous bones. They may assume any form, and attain any size, from that of a split pea to that of a child’s head. The structure of exostoses varies greatly. Some are firm, dense, and ivory-like; in others, innumerable bony fibres spring up from the bony surface into the inflamed, spongy, and loosened periostea. These fibres are harder and closer at their base than at their termination in the periostea, where they are often soft and cartilaginous. In a third variety, the exostosis seems to consist of an expansion of the external table or surface of the bone, from within, by the effusion or infiltration of matter beneath it. Bony tumours of this kind are common in the lower jaw and bones of the hand. Their interiors are loose, cellular, or spongy, very vascular, and the cavities are filled with substances varying in consistence from lymph to soft cartilage. This last variety becomes much larger than the others, readily inflames, and suppurates; or increases still further in bulk, by dilatation of the internal cells composing them.

14. C. When suppuration takes place, in addition to the characteristic changes of inflammation, the periostea becomes fungous or spongy, and less adherent, when the external surface of the bone is inflamed. And this surface is rough, unequal, and eroded, and changed to a grayish or dark hue. If the disease has commenced by destruction of the articular cartilages, the affected bone presents similar appearances. If osteitis has originated in the substance of the bone, the bony structure is softened, is changed to a yellowish, greenish, or brownish tint, and the central spongy parts are infiltrated with pus, or with a dirty grayish ichor of an offensive odour. As the disease proceeds, the softening and discoloration of the bone increases, until caries and ulceration are established.

15. D. Caries consists in a greater or less destruction — ulceration — and discoloration of bone, with a secretion of a puriform or of a fetid sanguineous matter. Young and spongy bones, abundantly supplied with vessels, most readily become carious. In many instances, owing to destruction of adjoining parts, the periostea and outer surface of the bone are first destroyed; but when the disease commences in the substance of the bone, a circumscribed abscess is sometimes formed; or the softened portions of bone, infiltrated with a sanguineous fluid, are partially absorbed or partially dissolved, as they lose their vitality in the diffused fluid, thereby forming ulcerated or fistulous cavities, containing puriform or sanguineous matters. These cavities, or sinuses, make their way to the surface of the bone, and thence to more external parts.

16. E. Necrosis, or mortification of bone, is a frequent consequence of osteitis, as well as of destruction of the periostea. It may occur in any part of the skeleton, although it more frequently attacks the hard bones, and is always succeeded by the separation of the dead portions of the bone from the living. According to the state of the bone, and the causes and circumstances of the inflammation, of which necrosis is the consequence, the dead bone exhibits various differences. If the bone die in consequence of gangrene of the surrounding parts, the necrosed bone is spongy, light, fragile, and blackish brown. If the necrosis be caused by seurry or hospital gangrene, it is similarly discoloured and softened. In common necrosis, however, the dead bone is dry, rough, different in gelatinous, porous or corroded externally, generally white, but sometimes coloured blackish or brown by the offensive sanaes poured out around it. When necrosis follows osteitis, it may be either the consequence or the cause of caries. Mortification sometimes occurs only in certain layers of bone: in the external superficial or external necrosis; or in the internal layer or table — internal or central necrosis; or the whole substance or mass — total necrosis. The first usually arises from exposure or deminution of the bone, but it may also proceed from inflammation of the surface or external layer of bone, and the consequent detachment of the periostea. Internal necrosis occurs almost only in tubular and round bones; total necrosis in solid bones also. Total necrosis, especially in tubular bones, is attended by a discharge from the internal surface of the periostea, and external to the dead bone, of a jelly-like mass, which gradually hardens and is ossified, surrounding, like a sheath, the necrosed bone, or sequestrum. As this bony sheath separates from the enclosed sequestrum or dead bone, it becomes lined by a delicate medullary membrane. In the midst of the bony sheaths are one or several holes — the foramina grandia of Trolle, the cloaca of Wiedmann — which communicate with the existing sinuses of the soft parts, and form an outlet for the continually-absorbed and diminished sequestrum, as well as for the secreted pus or lymph, and when these are discharged, these holes gradually close. In the internal necrosis the process is nearly the same; but in this case the jelly-like matter forming the new bone is poured out from the internal surface of the remaining living bone — from the surface of the living bone adjoining the dead bone; the living bone often swelling at the same time, and being somewhat softened.

17. a. Causes of Necrosis. — Whatever, either in the resistance of the bone or in the periostea, interrupts the nutrition of the bone, or inflames it, may conduce to necrosis. But if the mischief in the periostea, medulla, or substance of the bone, be of trivial extent, limited suppuration, or abscesses, passing into caries and ulceration, are the more common results. The causes of necrosis are the same as those of osteitis — are external, or internal and constitutional. But either of these may be so energetic as almost immediately to destroy the life of the bone; the most commonly irritate inflammation of the bone, of which the necrosis is a termination or consequence. Mr. Stanley has shown that bone may perish from inflammation of it without our being always able to recognise inflammatory symptoms, and yet the existence of inflammation antecedent to the necrosis is undoubted. Owing to the grade, severity, and constitutional relations of the inflammation, or to other causes, the symptoms of osteitis may be so slight as to escape notice. The existence of necrosis is generally more easily detected.

18. Osteitis productive of necrosis may be
either mild, slight, or severe and active. The symptoms of osteitis are sometimes so mild as to render the diagnosis difficult. This most commonly occurs in debilitated constitutions, in which the necrosis affects only the external part of a bone and originates from some chronic and constitutional cause, as syphils, scurvy, &c. But when necrosis supervenes in the substance and the interior of a bone, and occurs in plethoric, irritable, or robust persons, it is both preceded and attended by acute symptoms, by severe pain, much fever, and restlessness; the disease proceeding more rapidly to a termination.

19. Symptoms.—The swelling accompanying necrosis forms and increases gradually, particularly when caused by osteitis. In the slower and more mild cases, the pain is insensible and dull or aching; but when the swelling increases rapidly, or when the patient is plethoric and irritable, it is more violent. The swelling, as soon as mortification takes place, is much greater than in osteitis; still it is not elevated into an apex, but is so diffused along the bone that its limits cannot be distinguished; and this diffusion of the swelling is the more remarkable the more deeply seated the inflamed and necrosed bone may even extend over the whole bone or limb. The swelling communicates with the osteitis, and increases until the matter which is formed finds its way out through the soft parts, when the tumefaction partially subsides. When necrosis is advancing, edema of the soft parts is often present. The abscess attending necrosis proceeds more rapidly than the inflammation, and the nearer the bone is to the surface; but when the necrosed bone is deeply seated, and the inflammation more chronic, the abscess is greater and advances more slowly to the surface; but when the necrosed bone is deeply seated, and the inflammation more chronic, the abscess is greater and advances more slowly to the surface, often forming sinuses, particularly if fasciae intervene. The matter discharged varies in character with the constitutional symptoms and origin of the osteitis which has thus terminated. It is sometimes pure pus, but most frequently is serous, aacid, and fetid. As the necrosis is chronic it is somewhat firm, and by the surface and outlets of the matter become fistulous, through which not only the matter, but the remains also of the dead bone make their way.

20. The swelling attending necrosis is always diffused and situated upon a bone, the bone seeming included in the swelling. Even when suppuration has commenced and advanced, it appears deeply seated and obscure. The skin long retains its color, and does not exhibit a red or livid hue until matter is advancing through the soft parts.

21. The formation of new bone is a most important part of the phenomena attending necrosis, and much discussion and experimenting have been devoted to the subject by modern surgeons, the results being nearly as follows: When the bone dies, consequently either upon osteitis, or upon destruction of the medullary membrane or of the periosteum, the phenomena vary with the part which is first destroyed. If the medullary membrane is destroyed, or the inner layer, or the whole substance of the bone becomes dead, then the periosteum acquires a high degree of vascularity, and becomes thickened, soft, spongy, and loosely adherent to the bone. The cellular tissue also surrounding the periosteum becomes more vascular and infiltrated with lymph. The periosteum thus changed, quitting its hold of the dead bone, is now the formative organ of the new bone; and a reddish fluid mass is secreted by the internal surface of this membrane, and is gradually changed into new bone, and thus the same periosteum which had covered the old bone is also the periosteum to the new. If, on the other hand, the periosteum is destroyed, together with the bone, while the medullary membrane, which performs the office of an internal periosteum, is preserved, this membrane undergoes changes similar to those ascribed to the external periosteum, and is the medium of the formation of the new bone. This latter fact, insisted upon by Wiedmann and Boyer, has been fully confirmed by the recent experiments of Mr. Stanley, who states that, "if one side of the walls of a bone be removed without much injury to the medullary texture, the lost bone will be reproduced by the vessels of the medullary membrane." Mr. Mayo also remarks, that if one aspect of the cortex of a cylindrical bone is killed by an injury, the cancellous structure granulates, and reproduces what has been lost.

22. Mr. Stanley has shown that, when necrosis is attended by destruction of the bone and medullary structure, the bone may be regenerated from three sources: 1st. From the articular ends of the original bone, which are seldom implicated; 2d. From the periosteum which invested the dead bone; 3d. From the soft parts indifferently, whatever their nature may be, which takes the place of the periosteum, in a similar manner to that previously described. If the periosteum be removed from a dog's tibia, and destroyed the medullary texture, yet reproduction ensued, evidently by the vessels of the surrounding cellular tissue, which had become exceedingly condensed and adhered to the surfaces of the new bone, thus forming its periosteum. This result agrees with the evidence furnished by the experiments of Villeme, Beynecet, and Deputyre on the formation of callus. The increased density of the new bone, self, particularly its divided surface and exposed cancellous structure, will produce granulations, or a fluid substance which will be converted into bone, even independently of the surrounding tissue. I once observed in the cranium of a man who had been trepanned many years before for injury of the head, the circular portion of bone removed being unusually large, that the aperture had been fully filled up with new bone, and that the ossific matter had evidently been produced from the divided margins of the old bone, as it proceeded from them in striae, which converged to the centre of which had been the opening, these striae being larger near the margin of the old bone, and tapering as they converged to the centre of the opening which they had closed. The new formation was dense and without diploe.

23. v. Treatment.—The treatment of osteitis and of its consequences necessarily depends chiefly upon the predisposing and exciting causes, and upon the constitution of the patient. The pain and swelling should be com-
bated by local depletions, and the antiphlogistic regimen; by warm and emollient cataplasms and fomentations; by the frequent application of a small number of leeches to the seat of pain; by alternative aperients and diaphoretics. If suppuration take place, an early vent should be given to the matter that is formed. These means should be pursued with an activity commensurate with the severity of the symptoms and the strength and youth of the patient. If pus accumulate in the medullary canal, it may be necessary to procure it an outlet by perforating the bone. Dr. MacFarlane explained the tuba in two cases with success, in order to give vent to the pent-up matter. The diagnosis, however, of such cases is the chief difficulty.

24. If the disease proceed from syphilis or scrofula, the preparations of iodine, especially the iodides of potassium or of mercury, or the bichloride of mercury, with sarsa or the compound tincture of echnoeha, or the iodide of potassium with liquor potasse and sarsaparilla, are the most efficacious constitutional remedies. I have lately prescribed Mr. Donovan's solution of the iodides of mercury and arsenic with great benefit in one case of veneral osteitis. If seury be connected with the appearance of osteitis, the means advised for that disease should be chiefly relied on (see Art. SEURY).

25. If accrescence supervene, the indications suggested by Friedmann are most appropriate, namely, to remove the original cause of the disease; to alleviate the symptoms; to support the patient's strength and improve the state of the constitution; and, lastly, to remove the dead portions of bone when they become loose. These comprise the same means as have just now been recommended. In order to improve the constitution of the patient, whether syphilitic or scrofulous cachexia be present, the preparations of iodine, or of mercury, or a combination of both; those of sarsaparilla and echnoeha; the chlorides, particularly the chlorate of potash, combined, according to circumstances, with other remedies, should be principally employed and aided by pure air, and suitable diet and regimen.

II. ORGANIC LESIONS OF BONES, OCCURRING INDEPENDENTLY OF INFLAMMATION.

CLASSIFIC.—IV. CLASS. IV. ORDER (Author).

26. There are various lesions found in bones which are independent of inflammation at their commencement, although limited or slight osteitis may be excited by them in their course, particularly around them, or in their immediate vicinity. These lesions are generally of rare occurrence compared with those which proceed from inflammation.

27. A. SOFTENING OF BONES—OSTEOMALACIA, MALACOSTEON, OSTEOSARCOEIS, MOLLITICS, ASSUM— IS sometimes caused to a slight extent by the long continued rest of a joint, but commonly by rickets and scrofula. Softening is owing to the disproportion of the phosphate of lime to the amount of animal matter or jelly; the former being generally reduced to one half its usual amount, and the latter increased about one third. Softened bones are more or less flexible, and are usually bent or mis-shapen, partly by the action of the muscles, and partly by the weight of the body. Softening of bones occurs in two forms, 1st. In connexion with rickets and general debility in childhood; 2d. In adults and aged persons, from constitutional vice or debility.

(a) Rickets bones, according to the increase of their vessels and the expansion of their cells with jelly, become of a red colour and swollen. This softening is sometimes congenital, but it usually occurs in children, and is rarely so general and so malignant as that which affects persons advanced in age. (6) The softening observed in adults and old persons is often very remarkable, and even in the slighter cases is very rarely controlled by treatment. It is either partial or general. It is met with chiefly in females, and has been observed consequent upon seury, syphilis, mercurial disease, tubercles, scrofula, diabetes, lepra, rheumatism, and gout, and the accidents connected with parturition, or the more usual consequences of childbed, as disordered lochia, &c.

28. a. Softening of bones, particularly in adults, is generally attended by pains resembling those of chronic rheumatism, or by ach- ing in the bones affected. After a bend or yield to the action of the muscles, or to the weight of the body, and the pains increase on muscular action. The height, size, and form of the body are diminished, changed, and deformed respectively; and the affection usually continues to advance, with all the indications of general debility, until it terminates fatally. In some cases, the teeth are the only bones which altogether escape change.

(b) The softening of bones in adults differs from the rickets of children. The latter is generally cured by treatment or by the payment of age; but the former is progressive, whatever may be the remedies employed. The softening accompanying rickets is not attended by pain; that of adults always is accompanied with pain, although the pain is not constant throughout the disease. The softening in the latter also is usually more general and much more remarkable. These circumstances indicate that they are distinct maladies.

30. C. THE TREATMENT consists in the employment of tonics, with lime-water, and small doses of lime-water or other preparations of lime and phosphorus. Sea-air and sea-bathing, chalybeate and refreshing mineral waters, exposure to the light and to the sun's rays, nutritious and light diet, a dry and pure air, and sleeping in a large airy apartment, are the most appropriate remedies. (See, also, Art. RICKETS.) These are generally efficacious in softening in children; but their influence upon the softening of bones in adults is very doubtful.

31. B. FRAGILITY OF BONES—BRITTLNENESS—SPONTANEOUS PERFORATION—This change is very rarely congenital, and also rarely observed in youth. It usually occurs in advanced age. In it the animal matter is comparatively less abundant than the earthy constituent. The cancellous cachexia is often the cause of this alteration, as shown by Hamilton, Strack, Lobstein, and others. Fragility of bones has been observed also consequent upon gout; and, in rare instances, upon the same maladies as have preceded softening of bones. Orto states that fragility is not infrequently the sequel at Breslau consequent upon cancer, syphilis, and scrofula. It is often preceded by pains in the bones. It is rarely amenable to treatment.

32. C. EROSION OF BONES generally arises
from the pressure of aneurisms or tumours of any kind. In these cases, the cause is mecha
nical: the portion of the bone subjected to press
ure, having its vitality thereby impaired, is re
moved by absorption; or the pressure, while it
obstructs the circulation, favours absorption in
the part pressed upon. Orto and others, how
ever, believe that the pressure excites inflam
mation in the parts subjected to it; that the
inflammation is rapidly followed by ulcerative
absorption, and that this change differs from
caries only in not being attended by suppura
tion or discoloration of the eroded part.

33. D. Sanguineous tumours are sometimes
found in bones, and numerous instances of the
occurrence have been recorded by authors.—a.
Some of these tumours are manifestly aneuris
tmal, or owing to a remarkable dilatation of the
vessels penetrating the bone. As the small
aneurismal tumour enlarges, the surrounding
ossseous tissue is absorbed, a cavity is formed,
the two tables of the bone are thinned, and ul
tilimately perforated. When the tumour be
comes considerable it presents the same char
acters as other aneurisms. The periosteum
around the tumour is generally thickened, and
the nerves and surrounding tissues pressed
upon, stretched, flattened, &c. In some cases,
related by Duysstren, Breschet, Pearson,
Lallemand, Scarpa, and others, the tumours
acquired very large dimensions. They gener
ally occur in adults, consequently upon injuries,
contusions, &c., and are attended by a pules
ting pain. When they are large, the superficial
veins are distended, and the limb swollen and
sometimes discoloured. The pulsations cease
upon firm pressure on the artery of which the
aneurismal vessel is a branch. The treatment
of these cases is principally surgical, by ligatu
re of the principal vessel or by amputation of
the limb.

34. b. Sanguineous tumours of a doubtful na
ture are sometimes found in bones. These tu
mours are described by M. Bernard as differ
ing from the aneurismal and from the fungoid,
or hama-fungoid, and as consisting of a reticula
ted structure, resembling that of the cavernous
body, containing altered blood and clots of fibrin.
These tumours resemble those usually
termed aneurism by anastomosis. M. Bres
chet considers them to arise from a peculiar
inflammation of the osseous tissue, in which
the venous canals of the bone are chiefly affect
ed. They may be also viewed as erectile vas
cular tumours. The growth is similar to that of
aneurismal tumours, but more slow. They are
not amenable to treatment, amputa
tion being the only certain cure.

35. E. Tubercular formations are occa
sionally found in bones, and have been very
minutely described by MM. Delpech, Nichet,
Nelaton, and Bernard. They present them
selves in two forms, the cæsured and the inflam
trated. The cæsured is found in two states,
the acute and the softened.—a. In the former
state, tubercle is a part of the bone, the places or
cavities they occupy being a loss of the substance of the bone, owing
to the absorption of it as they are developed and
increased. The cavities are smooth at first,
but become, as they increase, rugous and an
fractured. They ultimately, by their enlarge
ment, open, either into each other, if the tuber
cles are clustered, or ultimately in the perios
teous, or into a joint. The bone is generally
slightly injected to the extent of one or two
lines around the tubercules. As they open into
the periosseous this membrane becomes inject
ed at that part, and deposes a layer of ossicle
matter, which, for a time, resists their farther
progress. These tubercules commence in small
grayish, semitransparent granulations, each of
which is enclosed in osseous cells with solid
partitions; but as they increase the partitions
are absorbed, and the matter is contained in a
single cavity, and one cyst (Nelaton). They
thus resemble tubercules in other organs.
As the tubercular mass, thus formed, increases,
it becomes softened generally from the centre
to the circumference, but sometimes at first at
its periphery, and it ultimately assumes a pol
taceous state, in which it escapes by an open
ning, or a fistula, in the surface of the bone, and
gives rise to an abscess in the soft parts cov
cring the outlet from the bone. As it is evac
uated, the cavity in the bone is obliterated
gradually by thickening of the membrane of the
cyst, and ultimately a spontaneous cure is
thereby effected. The filling up and cicatriz
ation of the tubercular cavities is thus fully es
tablished in respect of bones.

36. b. Tubercular infiltration of bone has been
only recently described by M. Nelaton, who
particularizes two forms of it, one semi-trans
parent and firm, the other opaque and puriform.
The infiltrated matter softens gradually, and be
comes liquid and puriform. At the same time,
the osseous cells of the infiltrated part become
partly obliterated by thickening of their parti
tions, and the blood-vessels obstructed by this
interstitial hypertrophy, so that the death of the
portion of the bone thus affected often ultimat
ly follows, the necrosis not being the result of
inflammation, as supposed by M. Delpech, but of
obliteration of the vessels of the part.

37. c. Tuberculosis of the bone is much more
common in childhood than at any other
age. It may occur in adults, but is the more
rarely observed the more advanced the period
of life. It affects chiefly the spongy parts, but it
may affect any of the bones. It is most com
monly observed in the bodies of the vertebrae,
in the extremities of the long bones, in the ster
num, &c.

38. d. The duration and progress of the mal
ady varies with the parts affected by it. The
cæsured variety generally advances to the ex
ternal surface of the bone as it softens, pene
trates the periosteum, notwithstanding the de
fence offered by this membrane to its progress
(§ 35), opens into the soft parts, suppurates,
and forms a fistula, and the matter, advancing
to the surface, is discharged externally. Ulti
mately the cavity in the bone is obliterated in
the manner stated above, if the case proceed
favourably. When the tubercular mass forms
in the extremity of a long bone, it generally
makes its way to the articular surface, in pre
ference to the bone under the skin. The cæsured
variety proceeds more slowly, and generally ter
minates by caries or necrosis.

39. e. The symptoms of tubercles of the bones
are very obscure in the early stages. As long
as the disease is confined to the substance of
the bone, slight or occasional pains are only
complained of. But when the mass affects the
periosteum, and especially if it have penetrated into the soft solids, the abscess that is formed, and subsequently the tubercular character of some of the discharge, will point out the nature of the disease. The changes which afterward take place vary much; but the state of the bone may be partly ascertained by examination, by the local appearances, and the constitutional symptoms.

40. f. The treatment is necessarily the same as that suggested for scrofulous osteitis and scrofulous arthritis (q 24, 25). See, also, the article on Abscess.

41. F. Osteosarcoma, or Malignant Tumour of Bones—Bony Cancer—Osteoclastoma—Fungus ossium—Cancer ossium—Erosiosis fungosa—Erosiosis carnosus—Ev. carcinomatosa, &c.—presents various forms.—a. In some cases it approaches the fungo-hematoid or encephaloid character; in others it more nearly resembles the scirrous; in a few it is fleshy, and in many it presents cavities filled with a substance of varied density, which, however, the tumour at first consists of a somewhat homogeneous, grayish, or grayish white, unvascular mass, intermixed with bony points and fibro-cartilaginous fibres, more or less firmly consolidated with albumen. As the tumour advances, its tissue becomes rarefied or loosened, forming cells of various sizes, filled with a light-coloured, semi-transparent jelly. Inflammatory action or vascular excitement now often takes place in the tumour, and the cellular tissue lining the cells becomes thickened, and secretes an alburnous substance, which is sometimes soft and bran-like, at other times more consistent, or even hard. In other cases, cellular tissue, loaded with albumen, is formed in it. The blood-vessels gradually enlarge in the periosteum, and in the interior of the tumour, and cavities are formed in the latter filled with venous blood. Blood is sometimes also diffused in the brain-like substance, or is mixed with it. Incommensurable bony fibres or plates commonly project from the bone outward, penetrate the tumour in various directions, and, becoming softer and larger, are finally united with the fleshy and membranous parts lying upon it.

42. These tumours assume various changes and appearances in different cases. If they are formed in the centre of a bone, they distend the layers or plates, and reduce them to a thin shell. In many cases the bone almost disappears, and merely a few irregular osseous speculae or plates are formed in the tumour. These tumours may reach a very large size—may even be two feet or two feet and a half in circumference, and ten or twelve pounds in weight. They are generally knobbled or irregular on the surface, and of various degrees of hardness. The bone adjoining the tumour is altered to some extent. The cells are enlarged, red or inflamed, occasionally even carious. New formations of bone are sometimes produced in the vicinity.

43. b. Osteosarcoma may affect any bone, but it is observed most frequently in the bones of the face, at the base and arch of the cranium, in the long bones. It is most frequently observed in adults and advanced age, and very rarely in childhood. The precise tissue in which the malady originates has not been fully determined. BAYLOR supposed that the disease commences in the soft parts, and attacks the bones only secondarily. Others believed that it begins in the bone itself. M. SANSON supposed that it originates either in the medullary membrane, or in that lining the spongy cells, an opinion which seems to accord with that entertained by Sandfort, Siebold Walther, Ennemeyer, and Ossius. Lohstein, however, considered the medullary membrane not to be its original seat, as the tumour is sometimes found external to this membrane, which has remained sound. It may probably arise either from this tissue, or from the membrane lining the vascular canals and spongy cells.

44. c. Symptoms.—This malady is first announced by acute, deep-seated pains, which often are long felt before any tumour can be detected. The constitution also frequently betrays disorder before it is observed. As soon as swelling appears, its hand, knobbled, unequal surface, the manner of its involving the whole bone, and others, is observable. It is of very various and deep-seated, and red, fleshy, or fungous excreences, which bleed on the slightest contact, spring from the surface. The patient's condition becomes rapidly worse; fever, sleeplessness, and marasmus characterizing the last period of his existence.

45. d. The prognosis of this malady is most unfavourable; amputation or complete extirpation of the disease, where either can be done, so as completely to remove the affected part, being the only treatment which is of any avail.

46. G. Hydatids are rarely found in bones; but instances of the occurrence have been recorded by Van der Haar, Ucellier, Webster, Wickham, Frick, Dupuytren, Cooper, Keate, and others. The hydatid cyst contains the rounded vesicles, &c., presents the same appearance and changes as are described in the article Hydatid. It is usually found in the spongial part of the long bones, or in the diaploe of the flat bones; but it is also sometimes seen in the diaphysis of the former. In very rare instances the hydatid mass, after having perforated the bone, if seated near a joint, may penetrate into the articular cavity.

47. a. The progress of this disease is very slow, being seldom of shorter duration than several years. Having perforated the bone, the hydatid cyst invades the adjoining soft parts. Ultimately these are destroyed, and it reaches the surface. But in all the cases on record, the tumour formed by it has been opened by the surgeon before it has perforated the skin. The hydatid mass, of various bulk, being evacuated, suppuration is established in the cyst, and the debris of membranous cysts and dead hydatids, generally mixed with a fetid put and sordes, are discharged. When the cyst is inflamed it becomes the seat of an abundant suppuration, which can rarely be arrested without its destruction. When a considerable portion of a long bone is destroyed by the cyst, fracture of it may take place. Cases of this kind are recorded by some of the writers referred to; and is, upon the whole, a less evil than the next
to be noticed. If the hydatids are seated near a joint, they may penetrate into it, causing acute inflammation of it at first, that generally passes into a chronic state with structural change of the tissues composing it, and of the heads of the bones.

48. b. Hydatids of the bones are caused by the influences which produce them in other tissues. The majority of cases on record show that contusions or other injuries had been received on the part in which the hydatids were seated, or that the veneral disease had preceded their appearance.

49. c. The symptoms of hydatids in bones are extremely obscure; the first indication furnished by them being a tumour in the part affected, and this rarely appears until they have penetrated the bone. The tumour is attended with little or no pain or tenderness, and no constitutional disturbance besides that constitutional weakness or deficiency of vital power which frequently accompanies the parasitic formations. As the tumour increases, it becomes softer and more elastic, similar to lipoma or fango-hematoid tumours. Ultimately it may present more or less fluctuation. It still occasions little or no pain, although it may altogether prevent the use of the limb in which it is situated. The absence of pain, the slow progress of the disease, and the slight affection of the constitution are the chief means of diagnosis afforded by it. Still, in most of the cases on record, the malignity of the malady was not known until the hydatids were evacuated.

50. d. The prognosis of this malady is always more or less unfavourable. As long as the tumour is unopened, it occasions but little constitutional disturbance; but when it is opened, inflammation takes place, which seriously affects the general health, commonly already impaired, and a prolonged and weakening suppuration is the usual result, which often destroys the patient. The development of cancer, however, depends upon the seat of the hydatid, and the possibility of removing not only them, but the cyst containing them. When they are seated in the bones of an extremity, and are not developed in any other part, surgical interference, aided by tonic or restorative constitutional means, will often prove successful.

51. e. Treatment.—The indications of cure are, 1st. To remove or destroy the hydatid cyst, or to remove the portion of bone containing it. 2d. To support the natural constitutional powers, and to enable them to throw off or to resist the disease; and, 3d. To subdue accidental changes of an unfavourable or inflammatory nature, whether local or constitutional, as they arise. The fulfilment of these indications is to be accomplished by surgical and medical measures, of so obvious a kind as not to require particular notice.

52. H. SPINA VENTOSA.—I agree with M. Broussais in considering it to be a distinct disease of bones, as generally held; but the result of the organic maladies described above, when they are attended by tumour, swelling, or protrusion of the external plate of bone and periostium, or by that external configuration which has been described as constituting spinous ventosa. These changes and appearances are most commonly produced by the malignant, hydatid, tubercular, and sanguinous tumours, which have been as fully described as my limits will permit.

53. I. FOREIGN BODIES have been found in bones; and these have lodged in them, either from external injury, especially by leaden bullets, small shot, &c., or been conveyed to them through the medium of the circulation, as in cases where mercury, arsenic, or sulphur has been detected in them. Neither of these, however, requires more than a simple notice at this place. In the former case, the leaden balls may remain a long time in bone without producing much disease; still caries or necrosis may be occasioned by them.
OVARIA—INFLAMMATION OF THE—CAUSES—SYMPTOMS.

connected with these states. Primary and uncomplicated ovaritis is comparatively rare: but ovaritis is more likely to occur in a primary and unassociated form in females who are neither pregnant nor recently confined, than in those who are thus situated. When it occurs after parturition, it is most frequently complicated with metritis, or with inflammation of the uterine veins.

6. i. Causes.—1. The predisposing, as well as the exciting causes of ovaritis, have not been clearly defined. In some instances, a constitutional disease having been very generally overlooked by writers and practitioners, but the following may be considered as the chief; and the authority of Hildbrand and others may be adduced in proof of their influence, especially when any of the exciting causes come into operation. Excitement of the imagination by reading voluptuous or immoral works or romances, or by descriptions of circumstances which affect the desires and emotions, particularly of the opposite sex, may rise from a want of the due sublimity of mind, to resist the impulses of feeling and passion; frustrated expectations of marriage with a beloved object; venereal desires often excited without being fully gratified; frequent abortions and difficult parturition; and sudden constinence on the parts of those addicted to sexual indulgences; hence, says Hildbrand, prostitutes, when they are imprisoned, and widows, are more frequently than others affected with diseases of the ovaries. Walthers states that, in his numerous post-mortem examinations, he very rarely found the ovaria of prostitutes free from inflammatory and structural lesions.*

* I have preserved the notes of four cases of acute uncomplicated ovaritis, occurring independently of the puerperal states. Besides these, slighter and less clearly defined cases have been seen by me, which have usually been considered as cases of hysteria depending upon vascular excitement of the ovaria. Of the four cases alluded to, one was caused by the sudden suppression of the catamenia, and one from metastasis of rheumatism. The others might be referred to a concurrence of several of the causes assigned above for the disease. The case of rheumatism, was remarkable in several respects, especially for the severity of the attack. The following is abstracted from the original notes.

Mrs. P., age 36; street, Walworth, was attacked 13th of July, 1851, with most excruciating rheumatic pains in the loins and limbs, increased on the slightest motion, or on attempting to get in bed. She was totally inexpressive; and her pulse was full, strong, and about 100. She attributed the attack to sleeping in a damp bed when travelling. She was about 20 years of age, stout, strong, and of the sanguine temperament. The catamenia were usually very abundant, and seldom at longer intervals than 14 days. She had never been pregnant, and, so far as I could learn, she was never expected. She had never been pregnant. About three days after the commencement of the rheumatic attack, and while I was attending her, she suddenly experienced an attack of most acute pain in the hypogastrum, a little above each groin. Soon after ward two tumours could be distinctly felt in the regions of the ovaria. They were extremely painful and tender upon pressure. The pains in the limbs were greatly stated, but pain was still complained of in the loins.

8. Ovaritis is often observed after delivery, but it is then rarely unconnected with metritis or metro-peritonitis, or with inflammation of the uterine and ovarian veins, or of the Fallopian tubes and connecting cellular tissue; but the associations of ovaritis, in the puerperal states, vary much with the prevailing epidemic, with the predisposing and exciting causes, and with the different circumstances in which the disease presents itself. These complicated forms of ovaritis are often observed in lymphatic fevers, in chronic ventilated apertures, and in low, crowded localities; and occur most frequently after difficult parturitions, after abortions, and upon the sudden disappearance or suppression of the locchia or milk.

9. ii. Symptoms.—A. The mild and more chronic states of ovaritis, whether in the unimpregnated or puerperal states, is generally an insidious, latent, and deceptive disease, unless the nature of the case be strictly investigated. Indeed, in many instances, the complaint is not only brought on by the physical, but also by the mental infirmity, of mind, and has taken place from an insufficiency of mind, and has taken place from a want of the due sublimity of mind, to resist the impulses of feeling and passion; frustrated expectations of marriage with a beloved object; venereal desires often excited without being fully gratified; frequent abortions and difficult parturition; and sudden constinence on the parts of those addicted to sexual indulgences; hence, says Hildbrand, prostitutes, when they are imprisoned, and widows, are more frequently than others affected with diseases of the ovaries. Walthers states that, in his numerous post-mortem examinations, he very rarely found the ovaria of prostitutes free from inflammatory and structural lesions.*

* I have preserved the notes of four cases of acute uncomplicated ovaritis, occurring independently of the puerperal states. Besides these, slighter and less clearly defined cases have been seen by me, which have usually been considered as cases of hysteria depending upon vascular excitement of the ovaria. Of the four cases alluded to, one was caused by the sudden suppression of the catamenia, and one from metastasis of rheumatism. The others might be referred to a concurrence of several of the causes assigned above for the disease. The case of rheumatism, was remarkable in several respects, especially for the severity of the attack. The following is abstracted from the original notes.

Mrs. P., age 36; street, Walworth, was attacked 13th of July, 1851, with most excruciating rheumatic pains in the loins and limbs, increased on the slightest motion, or on attempting to get in bed. She was totally inexpressive; and her pulse was full, strong, and about 100. She attributed the attack to sleeping in a damp bed when travelling. She was about 20 years of age, stout, strong, and of the sanguine temperament. The catamenia were usually very abundant, and seldom at longer intervals than 14 days. Walthers states that, in his numerous post-mortem examinations, he very rarely found the ovaria of prostitutes free from inflammatory and structural lesions.*

* I have preserved the notes of four cases of acute uncomplicated ovaritis, occurring independently of the puerperal states. Besides these, slighter and less clearly defined cases have been seen by me, which have usually been considered as cases of hysteria depending upon vascular excitement of the ovaria. Of the four cases alluded to, one was caused by the sudden suppression of the catamenia, and one from metastasis of rheumatism. The others might be referred to a concurrence of several of the causes assigned above for the disease. The case of rheumatism, was remarkable in several respects, especially for the severity of the attack. The following is abstracted from the original notes.

Mrs. P., age 36; street, Walworth, was attacked 13th of July, 1851, with most excruciating rheumatic pains in the loins and limbs, increased on the slightest motion, or on attempting to get in bed. She was totally inexpressive; and her pulse was full, strong, and about 100. She attributed the attack to sleeping in a damp bed when travelling. She was about 20 years of age, stout, strong, and of the sanguine temperament. The catamenia were usually very abundant, and seldom at longer intervals than 14 days. She had never been pregnant, and, so far as I could learn, she was never expected. She had never been pregnant. About three days after the commencement of the rheumatic attack, and while I was attending her, she suddenly experienced an attack of most acute pain in the hypogastrum, a little above each groin. Soon afterward two tumours could be distinctly felt in the regions of the ovaria. They were extremely painful and tender upon pressure. The pains in the limbs were greatly stated, but pain was still complained of in the loins.

8. Ovaritis is often observed after delivery, but it is then rarely unconnected with metritis or metro-peritonitis, or with inflammation of the uterine and ovarian veins, or of the Fallopian tubes and connecting cellular tissue; but the associations of ovaritis, in the puerperal states, vary much with the prevailing epidemic, with the predisposing and exciting causes, and with the different circumstances in which the disease presents itself. These complicated forms of ovaritis are often observed in lymphatic fevers, in chronic ventilated apertures, and in low, crowded localities; and occur most frequently after difficult parturitions, after abortions, and upon the sudden disappearance or suppression of the locchia or milk.
nia, by contamination of the circulating fluids, and by depression of the vital powers. But the occurrence of the disease in these circumstances, and thus associated, is fully considered in the article on "Puerperal Diseases." 12. Inflammations and Consequences.—A. Resolution is the most frequent issue of inflammation of the ovaries when the disease occurs independently of the puerperal state; and is indicated by subsidence of the pain and swelling; by the accession of the catamenia; or by a more abundant flow of the lochia when this discharge had been diminished or suppressed in the puerperal state of the disease. (See Puerperal Diseases.)

19. B. Softening and friability are generally present to a more or less degree when ovaritis is very acute and the swelling considerable. In this state the organ is generally three or four times its natural size, or even larger. In addition to these changes, it is infiltrated with a yellowish serum, or with a violet-coloured fluid, and occasionally it presents numerous small ecchymoses or bloody points.

14. C. Suppuration may occur in the puerperal and in the non-puerperal states of the malady, but most frequently in the former.Hillary also met with a case in the latter state which opened externally and terminated favourably. Ovaritis very commonly followed by suppuration in an advanced stage, when softening of the organ is very considerable, a puriform matter or serum, infiltrating the substance of the ovarium, partially breaking down portions of it, and forming either one large or more small abscesses. This result is often observed in the puerperal states, but the disease is then usually associated with metritis, or metrorrhagia, and the case terminates fatally, from other changes in the pelvic and abdominal visera and circulating fluids, before any large abscess is formed or breaks into adjoining parts. But in cases occurring independently of parturition, a considerable abscess is sometimes formed, which may open into the peritoneal cavity, or into the rectum, or some other adjoining viscera.

[Dr. Meigs (Ann. ed. of Columb. p. 412) relates a case of ovaritis in a female after confinement, attended with very painful symptoms, and where a hard and extremely painful tumour formed in the lower part of the left iliac region, which fluctuated and pointed. It was opened with a common lancet, and discharged near a pint of pus, the discharge continuing for many days. At length, the patient completely recovered. Dr. M. also relates a second case of a similar kind in a lady affected with carcinoma of the cervix uteri; the discharge was very great, but the abscess was cured.—(Loc. cit.)]

15. D. Effusions of a puriform lymph or serum, or of a gelatinous lymph, are sometimes observed upon the peritoneal surface of the inflamed ovaria and Fallopian tubes, the latter effusion often gluing their surfaces to adjoining parts. It is not improbable that, in the slighter and more chronic cases of ovaritis, a similar effusion of coagulable lymph takes place gradually into the structure of the organ, and occasions the enlargement, with various grades of induration, which are observed in some instances. In these latter cases the enlargement of the organ is somewhat greater than that observed in acute ovaritis, amounting commonly to the size of an orange. It often remains stationary for a very considerable time, and affects but little the general health.

16. Whether or not the Graafian vesicles are ever affected by inflammation, excepting in common with the substance of the ovarium, it is difficult to determine. Purulent matter has been met with in cysts after ovaritis of a subacute or chronic character, but it has not been proved whether this arises from inflammation and suppuration of the vesicles, or is circumscribed abscess in the cellular tissue. Dr. Seymour remarks that it would be still more difficult to say what is or would be the effect of inflammation of the corpora lutea; that is, of vascular excitement greater than what is necessary for their formation; for their formation may be said to be owing to increased action of the vessels of the part. Corpora lutea form, in some cases, after rupture of the vesicle, independently of impregnation, owing to excited feelings connected with the generative system; and hence it is reasonable to expect that any morbid affection of the ovaria dependant upon such excited feelings would have their origin in the ovarium. In the case met with by the author, in which the ovaria were altered in structure, in conjunction with furor uterinus, no farther information is generally given than that puriform matter was found in the ovaria. The coats of the vesicle, Dr. Seymour remarks, undergo in advanced life remarkable thickening; and, instead of containing fluid, are filled with a thick matter of a red colour, from the presence of vessels, sometimes nearly solid, at others of a thinner consistence. This change exhibits on a small scale some of those hard tumours which are sometimes found in the parietes of an ovarian cyst. Is it not possible that these may be some of the superficial vesicles, having undergone the change alluded to, and magnified by disease?" The fluid contained in the Graafian vesicle is sometimes altered, it being red, or even black from the admixture of blood. [After death from puerperal peritonitis, we generally find the peritoneal surface of the ovaries red, and the ovaries thickened, without any visible alteration of the parenchymatous structure; or their whole volume may be much enlarged, swollen, red, and pulpy; blood is seen effused into the Graafian vesicles, or around them, and circumscribed deposits of pus will be found often dispersed throughout the substance of the enlarged ovaria. In some cases we find the structure of the ovaria reduced to a soft vascular, flocculent pulp, no traces of their original organization being left. We often meet with inflammation of the peritoneal coat of the ovaries and false membranes, by which they are firmly united to the Fallopian tubes and uteri.]

17. iv. Treatment.—The treatment of ova-
Of Ovaria and the circumstances in which the complaint occurs, and the constitution of the patient. The means most beneficial when the disease is unconnected with parturition are generally either inappropriate or unavailing when it occurs at this period. The treatment of puerperal ovaritis is, therefore, comprised in the article on Puerperal Diseases.

18. A. The slighter states of the complaint require chiefly local depletions, as the application of leeches to the thighs a little below the groins, cooling applications, and baths, with a mild, unexacting diet and regimen. In the more acute cases, general blood-letting or cupping in the loins or sacrum, antimonal diaphoretics with nitre, small doses of camphor with nitre, the tepid bath, when much tension of the hypogastrum is complained of, and low diet, with perfect quietude, and the avoidance of mental and sexual exactions.

19. B. Where the slighter states of ovaritis occur in persons of the serofulous diathesis, they generally become chronic, particularly in those who present indications of their having experienced serofulous affections of glandular parts, and are commonly attended by severe pains, and much swelling or enlargement remains after the treatment now recommended. In these cases, abscess not infrequently is formed, and all the symptoms are aggravated until it makes its way either into the rectum or vagina, the most favourable course it can take. If it burst into the peritoneal cavity, fatal peritonitis is usually the result. In this form of the disease, the usual dose of the hydroiodate of potash, with liquor potassa, conium, and sarsaparilla; and injections, per vaginam, of emollient and morose fluids, or operative suppositories, are chiefly indicated. I have prescribed suppositories consisting of the extracts of hyoscyamus and conium, and vaginal injections containing the same medicines, with very marked relief. Dr. Seymour praises the extract of colchicum, given in the dose of a grain, twice or thrice daily.

20. C. When abscess forms in consequence of either acute or chronic ovaritis, and makes its way into the rectum, or vagina, or bladder, or even externally—this latter being the most rare course it takes—the strength of the patient ought to be supported, particularly in the serofulous diathesis, by the preparations of cinchona, by suitable diet, pure air, and residence near the sea-side. Attention should be paid to the digestive functions, and moral and physical quietude should be recommended. The alkaline and chlorate mineral waters may be subsequently tried.

III. Organic Lesions of the Ovarium, apparently independent of Inflammation.

Classif.—IV. Class, I. Order (Author).

21. i. Cysts, of various sizes, having their origin in some part of the ovarium, are the most frequent lesions to which this organ is liable. When one or more of these cysts contain fluid, the term serous or ovarian cyst is commonly given to the disease, although the serous cysts are sometimes formed in the broad ligaments and Fallopian tubes. The cysts are to be distinguished from hydatids by their being nourished by vessels supplied to them from the parts in which they are found; while hydatids are parasitical formations, having an independent vitality, and are unconnected with the cyst containing them. One or both ovaria may be changed into simple cysts; and when the cysts are either numerous or large, the cellular substance and vesicles disappear the fibrous coat of the organ becoming the fibrous covering of the cyst.

22. Dr. Seymour and M. Crevelhier in considering this disease to originate in alteration or enlargement of one or more of the Graafian vesicles. When the enlargement takes place in degree, it is usually on the side nearest the proper exertion, which often becomes distended to an enormous extent, the internal membrane of the cyst secreting a great quantity of fluid. When the cyst is single, the ovarian dropy exists in its simplest state, and often in its greatest degree. When one, two, or more of the Graafian vesicles undergo the change, the disease consists of an equal number of cysts filled with fluid. The quantity of fluid furnished by this disease is sometimes very remarkable. In a case under the care of my friend Mr. Watt, of Lowestoff, the quantity of fluid taken away by him amounted nearly to as much as in the case detailed by Mr. Martinæus, in which 6631 pints were lost by tapping in 25 years.

[A case is related by Mr. Atkinson (Lancet, July 20, 1844), in which a woman aged 53 was tapped 78 times in 7 years, six gallons being drawn off at each of the first 50 operations, but only half that quantity on each subsequent occasion. The interval between the operations, which used to be five months, came at last to be only three weeks, but the patient resumed her active habits in a day or two after each puncture.]

23. The symptoms attendant on these tumours are not severe, and are occasioned chiefly by pressure on adjoining parts. When the tumour is seated low in the abdomen, pressure on the nerves and veins often occasions swelling and numbness of the leg and foot on the side where it is largest; but it may continue stationary for months, or even for the greater part of a life. In some cases the discharge of urine is more or less affected. The history of the case generally assists the diagnosis of this disease; but I must refer the reader to the article Dropy the Ovarium, for a full account of its symptoms, history, diagnosis, and treatment. (See art. Dropy, § 198-213.)

24. ii. Cysts containing fatty matter, intermixed with hair and teeth, have been met with, either in the substance of one of the ovaria, or adhering to it in a narrow neck, and generally before the period of puberty; consequently they do not arise from impregnation. Similar cysts have been found in other parts of the body, in different individuals. They may be viewed as a species of monstrosity, termed by Ollivier and Breschet, "Diplogendis par pénétration," as the result of an imperfect conception in the mother of the individuals in whom they are found. The hair found in these cysts varies in quantity and appearance. It may be isolated, or mixed with fatty matter, or short or long, with or without bulbs. Teeth have usually been found implanted in fragments of bony or cartilaginous substance, or even of a part or the whole of a jaw.
25. iii. Congestion and extravasation of blood in the ovaries have not been satisfactorily observed. The former may possibly be of not infrequent occurrence, either in connexion with inflammation, or independently of it; and the latter has very rarely been seen to any great amount, unless in connexion with ovarian distention.

26. iv. Fibrous bodies, resembling those found in the uterus, are occasionally found in the ovaries. They vary in size from a few ounces to 30 or 40 lbs. M. Cruveilhier met with a tumour of this kind which weighed 46 lbs. They can hardly be distinguished from similar tumours connected with the uterus. Indeed, they have been formed in one or both ovaria, and in the uterus also, of the same subject.

27. v. Cartilaginous, osseous, and even calcarious formations, are not infrequently found in the ovaria. Meckel considered them to originate in the Graafian vesicles. Fibro-cartilaginous and fibro-osseous formations, with or without ossifereous deposite, are often met with in aged females. I have seen this change in a chlorotic female twenty-three years of age, who died of consumption, and had never menstruated, but without any ossifereous deposite. Calcareous depositories are more rare; but have been noticed by Morgan, Saviard, Petermann, Muret, and others.

28. vi. Hydatids are very rarely seen in the ovaria. Instances, however, of the occurrence have been adduced by Cruveilhier, Roux, and Dreyer.

29. vii. Tubercles are also very rarely formed in the ovaria; but they have been found in this situation by Dugas, Boivin, Seymore, Tonnelé, and Dugas.

30. viii. Scirrus of the ovarium is not often observed. The organ is increased in size, sometimes remarkably: and the tumour is composed of a very solid substance intersected by fibrous membranes, running in various directions. Occasionally portions of the tumour contain whitish bodies, filled with secretions of various consistence. These scirrous tumours very rarely ulcerate. In a case referred to by Dr. Seymore, the scirrous mass was breaking down into a thick, brown, fetid fluid. This lesion is occasionally found in females who had scirrous or open cancer in the uterus or some other part, and is attended by weight and pain in the seat of tumour, which is hard and movable, and by signs of general cachexia.

31. ix. Fungoid and other malignant tumours are occasionally found in the ovaria. Some of these consist of a large cyst springing from the ovarium, and containing within it tumours varying from the size of a pin's head to that of an orange. Sometimes a great portion of the parietes of the cyst is formed of tumours growing between the external and internal or secreting coats, the interior of the cyst having the tumours projecting into it, being filled with fluid secreted from the scirrous lining. The tumours, when divided, present a semilunar gelatious substance, with white bands running through it, between which bands are smaller cysts, containing the same viscid, gelatious-like matter (Seymore).

32. x. Encephaloid or fungo-haematoid tumours of a very large size are formed in some cases in the ovaria. M. Velpeau supposes them to be less rare than other malignant diseases of the ovarium. The encephaloid, or fungo-haematoid formations, may exist in the same ovarium or tumour, with the scirrous structures described above (§ 30), or with cartilaginous, fibrous, or fibro-osseous formations, as noticed by Meckel, Andre, and Velpeau; but it may compose nearly the whole mass. The walls of the cysts in this disease are thick, and their cavities gradually enlarge until a tumour is formed which fills not only the hypogastrum, but the whole abdominal cavity. The outer surface of the tumour is unequal; in some points a fluctuation can be felt, while in others it has a hardness equal to bone.

33. This fatal malady occurs usually in younger subjects than those in whom the scirrous and fungoid tumours already noticed (§ 30, 31) are usually found. Dr. R. Lee remarks that it sometimes seems to be excited by impregnation. It runs its course with great rapidity, and the constitution of the patient is sooner affected by it than by other diseases of the ovarium. It generally, also, coexists with cancerous or fungo-haematoid disease in other parts, as the pylorus, uterus, mamma, &c. It may be recognised by the uneventfulness, rapid growth, and hardness of portions of the tumour; by the occurrence of acute lancinating pains in it; by the simultaneous affection of other parts; by the general cachexia and rapid emaciation; by the signs of anemia; and by the very rapid, small, and feeble pulse, hectic fever, remarks on sense of sinking, and aphthous state of the mouth.

34. xi. Melanosis is very rarely observed in the ovaria. When it has occurred, it seems to have commenced, or been seated in the Graafian vesicles.

35. xii. Encysted tumours of the ovarium, as well as malignant tumours, have been supposed by Dr. Barox to arise from vesicles formed by a change of the lymphatics of the part; the extremity of a lymphatic being closed, and thus forming a tumour distended with fluid, a pyriform vesicle. Dr. Barox has shown the important fact, that the diseases which are produced from these vesicles, as tubercles, encysted tumours, cancer, &c., may be artificially excited by bad food, impair air, insufficient nourishment, and confinement. Dr. Hégarin supposes that, in the formation of these tumours, a large cyst, which he calls the superior cyst, is first developed, from the inside of which tumours grow, of different sizes and shapes, pushing up the internal membrane of the superior cyst, which is reflected over them, as the pericardium and pleura are in the natural cavities of the body. These secondary cysts contain smaller. Sometimes the smaller cysts grow so fast as to strangle one another, and the death of some of them causes altered appearances in the secretions of the part. Occasionally they burst through the reflected membrane, and present a fungoid and fringed appearance.

36. xiii. Fautuses are occasionally developed in the ovarium, when some obstacle has occurred to the escape of the impregnated vesicle. Several cases of this occurrence are on record: one of the most interesting of these has been observed by Dr. Granville, and published in the Philosophical Transactions.

37. xiv. The Treatment of the foregoing or-
game diseases of the ovary, even when their precise nature is recognised, is frequently attended by little permanent advantage beyond alleviating urgent symptoms and supporting the vital energies, and thereby resisting, for a longer period than might otherwise elapse, the fatal progress of the malady. Various alternatives have been advised for the removal of the tumours detected in this organ, such as the preparations of iodide of mercury, liquid potassae, conium, muriate of lime, &c., and, when they are prescribed judiciously and cautiously, they are sometimes beneficial when the tumours are not malignant. Of these the most deserving of notice are the preparations of iodine and liquid potassae. Of these preparations, the iodide of potassium alone, or with the liquid potassae, conium, or sarsa, or with all of these and the iodide of iron, have appeared to me the most beneficial. I have employed them since their first introduction into practice; but always in smaller doses than were or are usually exhibited, and generally in combination with vegetable tonics or alteratives. In malignant tumours, however, of the ovary, little or no benefit will be derived even from them, beyond the support they may afford to the constitutional powers. The iodide of potassium, however, when conjoined with full doses of liquid potassae, conium, or other narcotics and anodynes, not merely accomplishes this intention to a certain extent, but also affords considerable alleviation of the more painful or urgent symptoms.

[Mr. Brown (Lancet, May 4, 1844, and April 5, 1845) Combats the generally received opinion concerning the uselessness of medicine in ovarian dropsy, and relates five cases in which the following plan proved successful. Small doses of mercury were given internally, and mercurial friction made over the abdomen, and so regulated as to keep the mouth slightly sore for some weeks; administering also duretices, aperientives, and narcotics, whilst the patient was kept quiet, and daily exercise attended to. The local treatment consisted in careful and tight bandaging the abdomen with flanne. When these means appear to have taken effect, by the non-inebriate or positive decrease of the tumour, he advises that the eyst be then tapped and emptied. After the operation, pads should be applied over the cysts, and tight bandaging continued for three weeks, and the friction and medicines for at least six weeks longer.] 38. Dr. Seymour states that the liquid potassae given in large doses as the stomach will bear, has appeared to produce in diseases of a malignant nature, more alleviation than any other remedy, particularly in those tumours that are not attended by acute pain, or any considerable symptomatic fever. Next to the liquid potassae, Dr. Seymour ranks the muriate of lime in the treatment of the non-malignant tumours of the ovary. It has received from Dr. James Hamilton much praise in the treatment of enuresis to cysts of these organs, but holds but limited efficacy in other organic lesions, unless such as are of a serotinous nature, and these are not frequently observed in the ovary.

39. Conium formerly obtained some reputation in serotinous and malignant tumours, and has been frequently employed in cases of organic disease of the ovary; but I doubt its possession of any efficacy beyond that which may be derived from its narcotic and anodyne properties. When medicines possessed of these properties are required, the preparations of opium or morphia, of belladonna, or even ofaconite, may be brought in aid of other means, or may be conjoined with the preparations of iodine, of iron, of camphor, &c., according to the circumstances of individual cases. In the malignant diseases of the organ they are often of service as palliatives, and are advantageously conjoined with these or with the liquid potassae or the bromide of potassium. This last substance, however, is more likely to be of service in the non-malignant tumours of the ovary, in which, however, it has not received sufficient trial.

40. Of extirpation of the diseased ovarium some notice has been taken when discussing the treatment of dropsy of the ovary (see art. Dropsy, § 208, et seq.). I have little to add to what I then remarked. Since that was written, however, this operation has been performed successfully by several surgeons; and in three cases by Mr. Walne; the great majority of cases being those of dropsy of this organ. While this success places the operation in a more favourable light than that in which it was formerly held, still the great dangers and complications connected with it, which I have noticed in the article referred to, should not be overlooked; nor should it be attempted without due discrimination of the nature and morbidity relations and connexions of the disease.

[The first of the following tables shows the rate of mortality from both the major and minor operations in all cases where the extirpation of the ovary has been either attempted or actually performed; and the second, the comparative mortality from the two operations in all cases in which the ovary has been removed. Four and six inches may be taken as the line of division between the major and minor operations.]

### III. DISPLACEMENT AND HERNIA OF THE OVARIA

41. i. One ovarium, very rarely both ovaria, may be displaced, either independently of, or consequent upon, organic lesions of it. The displacement may also be connected with adhesions of the ovaria to adjoining parts, or it may be without adhesion. When thus displaced, the ovarium may be useless in respect of its generative function, sterility being the result.

42. ii. Displacement of the ovarium is not infrequently met with to the extent of constituting a hernia of it. The ovarium may protrude through, 1st, The inguinal ring, the most com-
mon form of ovarian hernia; 3d The crural canal; 3d. The ischiatic foramen; 4th. The umbilical ring; 5th. Any accidental opening in the abdominal peritoneum; and, 6th. Into the vagina.

Hernia of the ovary is very rarely met with in any of these situations, excepting the first. The hernia may be reducible or irreducible, simple, or complicated with organic lesion of the organ, or with adhesion of it to adjoining parts, and it may be strangulated. But these displacements, and more particularly the treatment of them, concern the surgeon more than the physician.

OZENA (from 6ς, I smell).—SYNON. OZON. Fr. Stinking Nasengeschwür, 4toth.

CLASSIF. IV. CLASS. II. ORDER (Author). DEFIN.—A discharge of a fetid, putrid, or insidious matter from the nostrils.

1 a. This disease is generally symptomatic ulceration of the membrane lining the nostrils, the palate, maxillary, and frontal sinuses, &c., or of caries of the bones in these situations, and always attends syphilitic disease of these parts. It may accompany also scrofulous, syphillic, and pulmonary afebrile affections, either in these situations, or in the vicinity. A slighter form of it sometimes follows chronic chorea, particularly in scrofulous constitutions, in the cachectic, and in those of a lax and leucoplagmatic temperament. In some cases, the matter secreted is scanty, but it is often attended by the discharge of fetid crusts. This state, as well as other states, of ozena may follow or attend malignant scarlet fever, and erysipelas of the face.

In a case lately treated by Sir B. Brooke and myself, the ozena, with consistent crrets, was occasionally by an injury of the nose received when hunting; and was followed by erysipelas of the face and head; the ozena, however, continuing, in a slighter form, after the erysipelas was cured.

b. The progress of the disease is generally slow; and it is rarely attended by acute pain, unless when caused by cancer. Hence it is often neglected until the bones are affected, when it proceeds from chronic inflammation and ulceration of the membrane. In some cases, however, an aching is complained of.

c. The prognosis should depend upon the nature of the pathological causes of ozena, or of the disease of which it is the consequence. If there is reason to infer the existence of caries of the bones of the parts above named, the prognosis should be either unfavourable or guarded.

d. The treatment ought likewise to depend upon the origin, or cause of the discharge; but in all circumstances it ought to be both constitutional and local.—(a.) The former should consist of tonics, conjointed with alteratives, as the liquid potassie with the preparations of sarsa, and in some cases also with the iodide of potassie; or the preparations of bark, either with alkalies, or with the hydrochloric or nitric acids, or with both these acids. A dry, pure air, or residence near the seaside, and light, nutritious diet, are generally also beneficial. If the ozena proceed from syphilis or scurvy, the treatment suitable to those maladies should be prescribed.

(b) The local measures consist chiefly of weak injections of the chlorides, particularly of the chloride of lime, or of the chloride of potash, or the passage of a stream of hot-water, or of fluid containing either ercasate, or a small quantity of the sulphate of zinc, or of nitrate of silver, or of alum, through the fuses and nostrils. The local as well as the constitutional treatment, however, should be guided by a careful inspection of the parts, and by a correct estimate of the existing extent of mischief, as well as of the exciting and concurring causes. In some obstinate cases, the ozena have been cured by a seton in the nape of the neck.
